3.03 Anatomy of the Hippocampus and the Declarative Memory System

R. D. Burwell and K. L. Agster, Brown University, Providence, RI, USA

3.03.1 Introduction

3.03.1.1 A Short History of the Anatomy of Declarative Memory

A half century ago, Scoville and Milner (1957) described profound memory loss following bilateral medial temporal lobe resection in the landmark patient HM. In the following years, scientists studying memory and the brain narrowed in on the hippocampus as the critical structure for everyday memory for facts and events. In the past two decades, however, we have come full circle: It is now apparent that the cortical areas surrounding the hippocampal formation also play critical roles in memory. Today, it is generally accepted that the hippocampal formation and the nearby parahippocampal region together are necessary for human declarative memory, but many questions remain concerning the functional diversity of structures within the so-called declarative memory system. To what extent can the function of hippocampal and parahippocampal substructures be dissociated? How discrete are such functions? How do these structures interact to permit encoding, storage, consolidation, and retrieval of representations of facts and events? What additional cognitive functions might be supported? Understanding the structure and connectivity of these regions is necessary for generating and testing sound hypotheses about the neurobiology of memory.

3.03.1.2 Overview of the Hippocampal System

3.03.1.2.1 Nomenclature

The structures that are the topic of this chapter have variously been termed the medial temporal lobe memory system (Squire and Zola-Morgan, 1991), the hippocampal memory system (Eichenbaum et al., 1994), and the hippocampal region (Witter and Amaral, 2004). The terms hippocampal region or hippocampal system have the advantage that the terminology translates effectively from humans to animal models of human memory, including rodents.

These regions are thought to support a type of memory that has been variously called episodic memory, declarative memory, or autobiographical memory. For research on memory using animal models, the terms episodic or episodic-like memory may be most appropriate.

The hippocampal system comprises the hippocampal formation and the parahippocampal region (**Figure 1**). The hippocampal formation includes the dentate gyrus, the hippocampus proper (fields CA1, CA2, and CA3), and the subiculum (**Figure 2**). The primary criterion for inclusion in the hippocampal formation is the trilaminar character of the structures. In addition, the included structures are connected by largely unilateral pathways beginning with the dentate gyrus granule cell input to the CA3 (**Figure 3**). CA3 pyramidal cells, in turn, provide a unidirectional input to the CA1. Finally, CA1 projects to the subiculum. Because corticocortical connections in the brain are overwhelmingly reciprocal, such a multisynaptic, unidirectional circuit is unique. In contrast, the entorhinal cortex projects to all portions of the hippocampal formation. The connectivity and laminar structure of the entorhinal cortex differentiate it from hippocampal formation structures. The dentate gyrus, hippocampus proper, and subiculum are therefore collectively referred to as the hippocampal formation (**Figure 3**, structures shown in yellow), and the entorhinal cortex is considered part of the parahippocampal region.

The parahippocampal region, also called the retrohippocampal region, includes the perirhinal, postrhinal (or parahippocampal), entorhinal, presubicular, and parasubicular cortices (**Figure 1**). The postrhinal cortex in the rodent brain is considered the

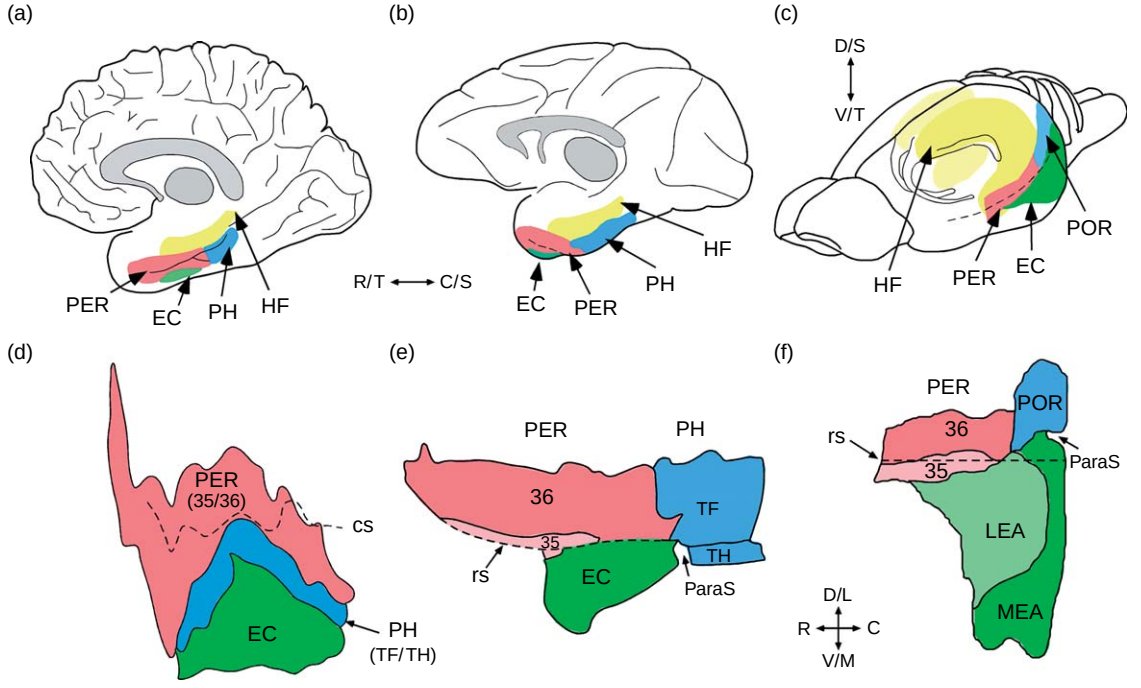

Figure 1 Comparative views of the hippocampal system for the human (left), monkey (middle), and rat (right). The upper panel shows the relevant structures in lateral views of the human brain (a), the monkey brain (b), and the rodent brain (c). The lower panel shows unfolded maps of the relevant cortical structures for the human brain (d), the monkey brain (e), and the rodent brain (f). Shown for the human and monkey brain are unfolded layer IV maps of the perirhinal (PER) areas 35 and 36, parahippocampal (PH) areas TF and TH, and entorhinal cortex (EC). Figures adapted from Burwell RD, Witter MP, and Amaral DG (1995) The perirhinal and postrhinal cortices of the rat: A review of the neuroanatomical literature and comparison with findings from the monkey brain. *Hippocampus* 5: 390–408; Insausti R, Tuñón T, Sobreviela T, Insausti AM, and Gonsalo LM (1995) The human entorhinal cortex: A cytoarchitectonic analysis. *J. Comp. Neurol.* 355: 171–198. Shown for the rodent brain are unfolded surface maps of the PER areas 35 and 36, the postrhinal cortex (POR), and the lateral and medial entorhinal areas (LEA and MEA). The rodent POR is the homolog of the primate PH (see text for details). In the monkey and the rat brain, the parasubiculum (ParaS) is interposed between the entorhinal and POR/PH (arrows). The pre- and parasubiculum, which are components of the parahippocampal region, are not shown (but see Figure 2). Abbreviations: cs, collateral sulcus; rs, rhinal sulcus; DG, dentate gyrus; D, dorsal; L, lateral; M, medial; ParaS, parasubiculum; PreS, presubiculum; S, septal; Sub, subiculum; T, temporal; V, ventral.

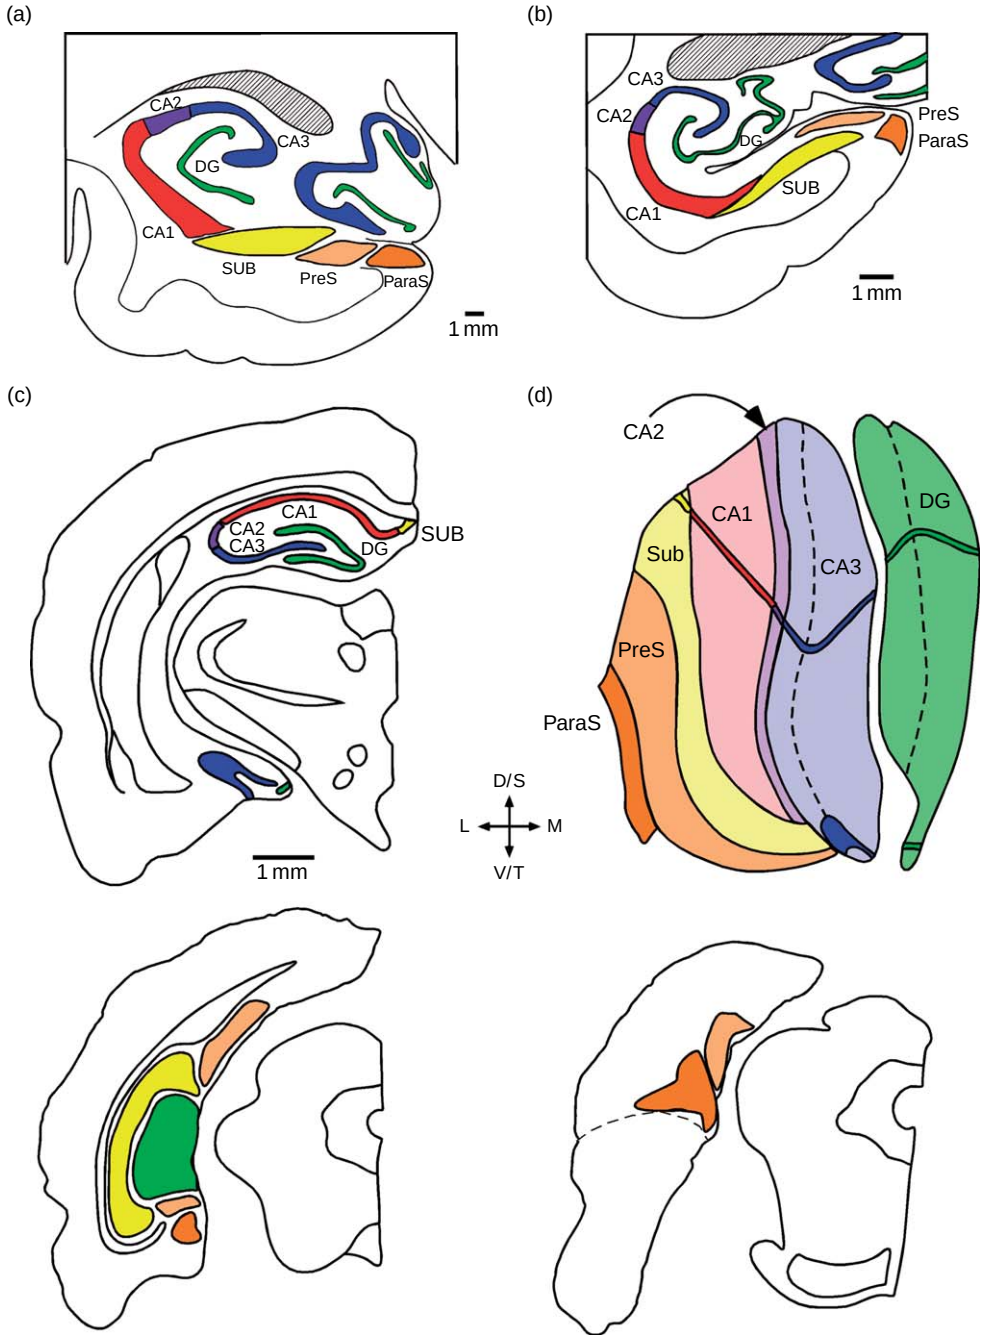

Figure 2 Comparative views of the hippocampal formation with the pre- and parasubiculum. (a) Coronal sections of the human brain (a), monkey brain (b), and rat brain (c) showing the cellular layers of the hippocampal formation structures: the dentate gyrus (green), CA3 (blue), CA2 (purple), CA1 (red), and the subiculum (yellow). (d) An unfolded map of the rodent hippocampal formation. Rodent schematics adapted from Burwell RD and Witter MP (2002) Basic anatomy of the parahippocampal region in monkeys and rats. In: Witter MP and Wouterlood FG (eds.) *The Parahippocampal Region, Organization and Role in Cognitive Functions.* London: Oxford University Press. The presubiculum (light orange) and parasubiculum (dark orange) are also shown at two rostrocaudal levels in panels (e) and (f). Also shown are perirhinal areas 36 and 35 (panels (c) and (e)), the lateral and medial entorhinal areas (LEA and MEA, panels (e) and (f)), and the postrhinal cortex (POR, panel (f)). Abbreviations: DG, dentate gyrus; D, dorsal; L, lateral; M, medial; ParaS, parasubiculum; PreS, presubiculum; S, septal; Sub, subiculum; T, temporal; V, ventral.

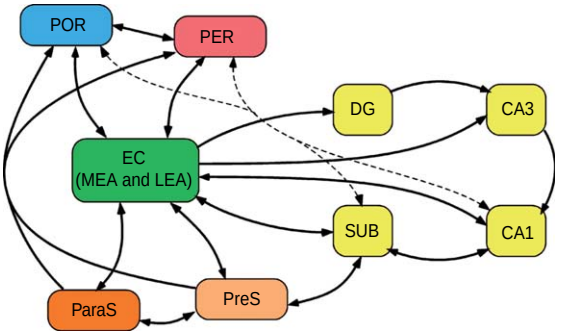

Figure 3 Simplified schematic of the hippocampal system. The schematic includes the hippocampal formation (structures in yellow) and the parahippocampal region (structures in red, blue, green, and orange). The hippocampal formation comprises three-layered structures characterized by largely unidirectional connections, whereas the parahippocampal region comprises six-layered cortices characterized by reciprocal connections. Note that the perirhinal and postrhinal cortices (PER and POR) have reciprocal connections with CA1 and the subiculum. Abbreviations: DG, dentate gyrus; EC, entorhinal cortex; LEA, lateral entorhinal area; MEA, medial entorhinal area; ParaS, parasubiculum; PER, perirhinal cortex; PH, parahippocampal cortex in the primate brain; POR, postrhinal cortex in the rodent brain; PreS, presubiculum; subiculum (SUB).

homolog of the parahippocampal cortex in the primate brain. The perirhinal and postrhinal cortices are the major recipients of cortical afferents, and they project heavily to entorhinal cortex. The entorhinal cortex and the pre- and parasubiculum also receive direct cortical inputs. The entorhinal cortex projects directly to all components of the hippocampal formation and all other components of the parahippocampal region (**Figure 3**). The entorhinal connections with CA1, the subiculum, and all other parahippocampal structures are reciprocal.

One practical problem in the comparative anatomy of these structures is the confusing use of the term parahippocampal. In the rodent brain, the term has only one use (i.e., in the phrase 'parahippocampal region'). In the human and monkey brains, the term is used in two additional ways. First is the parahippocampal cortex, a cortical region in the medial temporal lobe that is a component of the parahippocampal region (and is the homolog of the rodent postrhinal cortex). Second, the parahippocampal gyrus is the fold or gyrus that contains a large portion of the entorhinal, perirhinal, and parahippocampal cortices.

There are also discrepancies in the terminology for the perirhinal cortex. In Brodmann's (1909) nomenclature, which includes verbal and numeric terms, the verbal term for area 35 was perirhinal, and the verbal term for area 36 was ectorhinal. Although Brodmann defined area 36 as a very narrow strip of cortex that did not include the temporal pole, other classic studies, which reported more detailed cytoarchitectonic analyses of these regions, included the temporal pole in area 36 (von Economo, 1929; Von Bonin and Bailey, 1947). There was no designation in Brodmann's nomenclature for the caudally located region we now call the parahippocampal cortex (reviewed in Suzuki and Amaral, 2003b). Using a different nomenclature, von Economo and Koskinsas named the rostral perirhinal/ectorhinal region areas TG and TGa and the caudal (parahippocampal) region areas TF and TH. In modern terminology, the term perirhinal cortex was used to designate the combined areas 35 and 36 (Amaral et al., 1987) or 35a and 35b (Van Hoesen and Pandya, 1975). In the latter nomenclature, area 36 was termed TL.

Currently, the most commonly used nomenclature for memory research in the primate brain is perirhinal cortex comprising areas 35 and 36. Burwell and colleagues (Burwell et al., 1995; Burwell, 2001) adapted that nomenclature for use in the rodent brain. The term ectorhinal is no longer in use except in rodent brain atlases. Thus, within a comparative framework for experimental neuroscience, it seems reasonable to adhere to the nomenclature of perirhinal cortex as designating the combined areas 35 and 36 for both the rodent and primate brains.

3.03.1.2.2 Location of the hippocampal system structures

The focus of this chapter is the rat hippocampal system about which we have the most detailed anatomical information, but it is worth noting that there are surprising similarities and interesting differences between these structures in the rodent and the primate brains. The upper panel of **Figure 1** shows that the hippocampus is C-shaped and relatively larger in the rodent brain (**Figure 1(c)**). The dorsal or septal portion of the region is associated with the fimbria-fornix and the septal nuclei. The ventral or temporal portion of the structure is associated with the temporal cortices. The hippocampus is relatively smaller in the primate brain (**Figure 1(b)**). The structure is still shaped like a C, though shallower and rotated

about 90° clockwise, such that the opening is pointing upward. In the primate brain, the rostral hippocampus is associated with the temporal cortices, and the caudal hippocampus is associated with the septal nuclei. Accordingly, for cross-species comparisons, the best terminology for the long axis of the hippocampus is the term septotemporal.

In the human brain, the rhinal sulcus is relatively small and is associated with only the most rostral portion of the perirhinal cortex. The collateral sulcus forms the lateral border of the parahippocampal gyrus (**Figure 1(d)**). As in the monkey brain, the entorhinal, perirhinal, and parahippocampal cortices occupy the parahippocampal gyrus and the temporal pole. The perirhinal cortex occupies the temporal pole and continues caudally. The entorhinal cortex lies in the medial portion of the anterior parahippocampal gyrus and is bordered rostrally and laterally by the perirhinal cortex. The parahippocampal cortex forms the caudal border of the perirhinal cortex.

In the monkey brain, which is less gyrencephalic (smoother) than the human brain and more gyrencephalic than the rat brain, the rhinal sulcus is associated with the full extent of the perirhinal cortex. Area 35 is a narrow band of agranular cortex that occupies the fundus and the lateral bank of the rhinal sulcus. Area 36 is a larger strip of dysgranular cortex located lateral to area 35 and including the temporal pole (**Figure 1(b)** and **1(e)**). All but the most rostral part of the lateral border of area 36 is shared with area TE of inferotemporal cortex. The rostrolateral border is formed by the superior temporal gyrus. Suzuki and Amaral (2003a) extended the border of area 36 rostrally and septally to include the medial half of the temporal pole on cytoarchitectonic and connectional grounds. The monkey parahippocampal cortex, comprising areas TH and TF, is located caudal to the perirhinal and entorhinal cortices (**Figure 1(b)** and **1(e)**). Area TF is larger than area TH and is laterally adjacent to area TH. Area TH is a thin strip of largely agranular cortex medially adjacent to area TF. The parahippocampal cortex is bordered rostrally by the entorhinal and perirhinal cortices, laterally by TE, medially by the para- and presubiculum, and caudally by visual area V4.

In the rodent brain, the rhinal sulcus, or fissure as it is sometimes called, is the only prominent sulcus (**Figure 1(c)** and **1(f)**). It extends along the entire lateral surface of the brain, though it is quite shallow in its caudal extent. The region is bordered rostrally by the insular cortex. Insular cortex is classically defined as the region overlying the claustrum. The transition from insular cortex to the perirhinal cortex occurs when claustral cells underlying layer VI of the cortex are no longer visible. The perirhinal cortex comprises two cytoarchitectonically distinct strips of cortex, areas 35 and 36. Area 36 lies dorsally adjacent to area 35. The entorhinal cortex provides the ventral border of area 35. The dorsal border of area 36 is formed by secondary somatosensory cortex, rostrally, secondary auditory cortex at midrostrocaudal levels, and ventral temporal association cortex at caudal levels. The postrhinal cortex is located caudal to perirhinal cortex and provides the caudal border. It lies ventral to the ventral temporal area and dorsal to the medial entorhinal cortex (**Figure 2(f)**).

3.03.1.2.3 Cross-species comparisons: Human, monkey, and rodent

A comparative analysis of the unfolded maps of the human, monkey, and rat brains shows that the spatial relationships of the perirhinal, parahippocampal/postrhinal, and entorhinal cortices are similar (**Figure 1**). Aside from the obvious differences in scale, the relative size differences are also interesting. Studies in rats, monkeys, and humans suggest that the perirhinal cortex accounts for roughly 3% of the cortical surface area, suggesting that the region scales linearly with cortical surface area. Also, in all three species, the surface area of the perirhinal cortex is roughly twice that of the postrhinal/parahippocampal cortex. Therefore, postrhinal/parahippocampal cortex also appears to scale linearly with brain size. The relative size of the entorhinal cortex, however, differs dramatically across species. In the rat brain, its surface area is more than three times that of the perirhinal cortex, but in the primate brain, entorhinal cortex is considerably smaller than the perirhinal cortex.

The homology of the rodent postrhinal cortex with the primate parahippocampal cortex is based on the structural and connectional similarities. In rodents and primates, the region receives substantial input from visual associational, retrosplenial, and posterior parietal cortices. Subcortical connections are also similar. For example, the rat postrhinal cortex is strongly and reciprocally connected with the lateral posterior nucleus of the thalamus (LPO). Likewise, the monkey parahippocampal cortex is connected with the pulvinar, the homolog of the lateral preoptic area (LPO) in the rodent.

In human, monkey, and rat, the entorhinal cortex is a six-layered cortex characterized by a cell sparse layer (lamina dissecans) separating the deep and

superficial layers. The medial part of the entorhinal area is, structurally, more highly differentiated as compared to the lateral part, and the lamina dissecans is more evident. It should be noted that in the rat, the medial entorhinal area is more caudal and ventral, whereas the lateral entorhinal area is more rostral and dorsal (**Figure 1(c) and 1(f)**). In both rat and monkey, the intrinsic connectivity of the entorhinal cortex appears to be organized into intrinsic bands of interconnectivity that form discrete associational networks. In the rat, these bands of intrinsic connectivity project to different levels of the dentate gyrus, suggesting a functional topography. There is evidence that a similar topography exists for the monkey.

All hippocampal formation structures observed in the human brain are also present in the monkey and rat brains (**Figure 2**). The absolute size of the hippocampal formation is largest in the human brain and smallest in the rodent brain, though the structure is relatively larger in the rodent brain. As previously mentioned, the hippocampus is situated differently in different species. In the human and monkey brains, it is as if the hippocampal formation has swung down and forward, such that rostral hippocampus in the primate brain is comparable to ventral hippocampus in the rodent brain. Similarly, caudal hippocampus in the primate brain is comparable to dorsal hippocampus in the rodent brain. For ease of comparative analysis, it is most efficient to use the terms septal and temporal to describe the long axis because these terms can be applied similarly across all species. The septotemporal axis in the rodent hippocampus is equivalent to dorsoventral axis, and the septotemporal axis in the primate hippocampus is equivalent to the caudorostral axis.

3.03.2 The Parahippocampal Region

3.03.2.1 The Postrhinal Cortex

The postrhinal cortex is located near the caudal pole of the rat brain, caudal to the perirhinal cortex, dorsal to the rhinal sulcus and to the medial entorhinal area (**Figure 1(c)**). Usually the postrhinal cortex arises at the caudal limit of the angular bundle when subicular cells are no longer present in coronal sections (**Figure 4(a)**). At this level, postrhinal cortex is characterized by the presence of ectopic layer II cells at the perirhinal–postrhinal border near the ventral border with the medial entorhinal cortex (**Figure 4(b)**, arrow). Moving caudally, the postrhinal cortex rises dorsally above the caudal extension of the rhinal fissure and wraps obliquely around the

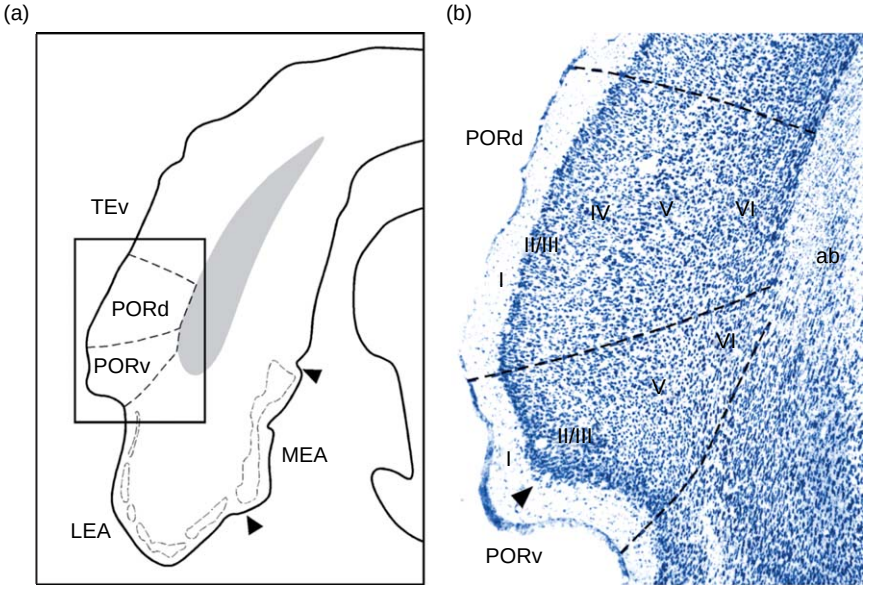

Figure 4 Location and photomicrograph of the postrhinal cortex (POR). (a) Drawing of a coronal section of the rat brain at the level of the rostral limit of the postrhinal cortex. (b) Nissl-stained coronal section showing the septal and temporal subregions of the POR (PORd and PORv, respectively). Layers are labeled I–VI. The septal subregion has a more differentiated laminar pattern. The ventral subregion is characterized by ectopic layer II cells (arrow) that appear near the rostral border with area 36. Abbreviations: ab, angular bundle.

caudal pole of the brain. Visual association cortex, which forms the dorsal border of postrhinal cortex, has a more differentiated laminar pattern and a broader layer IV. The precise location of the dorsal border is difficult to distinguish cytoarchitectonically. A convenient landmark, however, is provided by the parasubiculum. The dorsal border of the postrhinal cortex on the lateral surface tends to be at the same dorsoventral level as the parasubiculum on the medial surface. The medial entorhinal cortex borders the postrhinal cortex ventrally and is easily distinguished by the large layer II cells and distinct laminar look of the cortex.

The cell layers of the postrhinal cortex have a homogeneous look because the packing density of cells is similar across layers (**Figure 4(b)**). In coronal sections, there is a broadening of the deep layers, which is due to the conformation of the region at the caudal pole of the brain (**Figure 4**). In sagittal sections, however, layers II–III, V, and VI each occupy about one-third of the cortical depth. The region can be subdivided into dorsal and ventral subdivisions based on cytoarchitectonic features. In general, the dorsal subregion has a more organized and radial appearance. The primary difference between the two subdivisions is that the dorsal portion has a distinguishable granule cell layer IV. Another difference is that layer V of the dorsal subregion is slightly narrower than in the ventral subdivision.

Retrograde tract tracing studies show that three-quarters of postrhinal afferentation arise in neocortex. The remainder is roughly evenly divided between subcortical and hippocampal afferents. The neocortical connections of the postrhinal cortex distinguish it from the nearby perirhinal cortex, in that cortical input to the postrhinal cortex is strongly dominated by visual and visuospatial inputs. In terms of sensory input, the postrhinal cortex receives almost a third of its total input from visual associational regions. The strongest associational input arises in the posterior parietal cortex. Dorsal retrosplenial cortex also provides a strong projection. The input from frontal associational regions largely arises in ventrolateral orbital frontal cortex. A strong input arises in the caudal and ventral temporal area, which is itself strongly interconnected with visual association cortices. For the most part, all cortical connections are equally reciprocated. The exception is that the postrhinal cortex projects strongly to the perirhinal cortex, but the return projection is substantially weaker.

The subcortical afferents are dominated by the thalamic inputs, which arise predominantly in the lateral posterior nucleus of the thalamus. That projection is reciprocal. There is also input from the anteromedial dorsal thalamic group and the intralaminar nucleus of the thalamus. The input from the amygdala is very small and is mainly from the lateral and basolateral nuclei. The postrhinal cortex also projects back to the lateral and basolateral amygdala nuclei. The inputs from the septum are also relatively small and are dominated by the medial septum.

The postrhinal cortex projects strongly to the medial entorhinal cortex, particularly to the lateral band. The entorhinal projection is weakly reciprocal. Postrhinal cortex has strong reciprocal connections with the septal presubiculum and the parasubiculum. In addition to these parahippocampal connections, there are strong direct connections with the hippocampus. The postrhinal cortex projects directly to the septal CA1 and subiculum, and both projections are returned. Connections with the temporal hippocampus are modest.

3.03.2.2 The Perirhinal Cortex

The perirhinal cortex arises at the caudal limit of the insular cortex and can be distinguished from insular cortex by the absence of the underlying claustrum. It is bordered dorsally by temporal association regions, ventrally by piriform and entorhinal cortex, and caudally by the postrhinal cortex. For most of its rostrocaudal extent, the perirhinal cortex includes the fundus and both banks of the rhinal sulcus (**Figure 1(f)**). At its caudal limit, the region rises dorsal to the fundus. A signature feature of the perirhinal cortex in the rodent and monkey brains is the presence of large heart-shaped cells in deep layer V that appear in both area 36 and area 35 (**Figure 5**).

Perirhinal area 36 is located dorsal to the rhinal sulcus. Although the region has a more prominent laminar structure dorsally than ventrally, area 36 is generally described as dysgranular cortex. The dorsal border of area 36 is best discerned by characteristics of the granular cell layer, layer IV. Area 36 has a fairly rudimentary layer IV as compared to the discrete granular layer of the dorsally adjacent neocortical areas. Another feature of the region is the patchy layer II in which medium-sized cells are organized in clumps or patches. The organization of layer V cells into lines gives the region a radial look, especially dorsally. Layer VI has a bilaminar appearance in that the cells in the deep portion of the layer

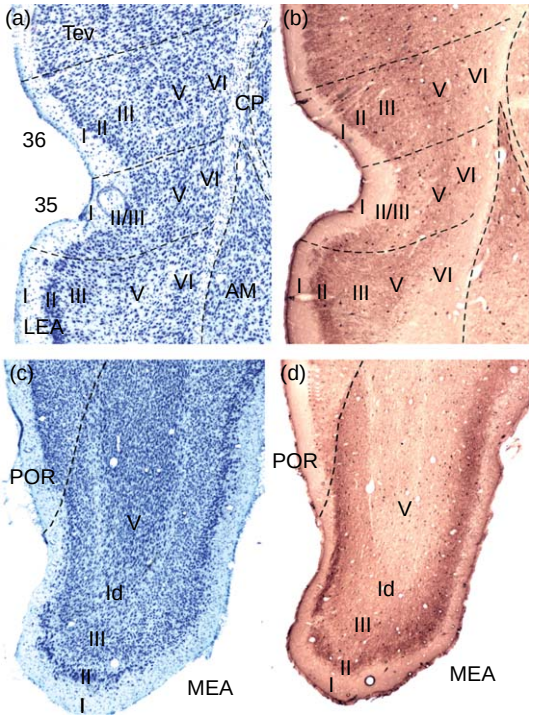

Figure 5 Photomicrographs of the perirhinal (PER), postrhinal (POR) and lateral and medial entorhinal cortices (LEA and MEA). (a) Nissl-stained coronal section showing PER areas 36 and 35 and the LEA. (b) Adjacent section stained for parvalbumin. Heavy staining of layer II in the LEA provides a useful marker for the PER-LEA border. (c) Nissl-stained coronal section showing MEA and POR. (d) Adjacent section stained for parvalbumin. Layers are labeled I–VI. Parvalbumin staining also differentiates the MEA-POR border. Other abbreviations: AM, amygdala; CP, caudate putamen.

are smaller, darker, and more densely packed than the cells in the superficial portion of the layer.

Area 35 is generally characterized by a broad layer I. Layers II and III tend to blend together (**Figure 5**). The region lacks a layer IV and is thus considered agranular cortex. Layer V of area 35 has a disorganized look as compared to the radial appearance in area 36. As in area 36, layer VI has a bilaminate appearance. A general characteristic of area 35 is the organization of its cells into an arcing formation that spans all layers. This feature is most evident below the rhinal sulcus. The entorhinal cortex forms most of the ventral border and can be distinguished from ventral area 35 by the medium to large darkly staining stellate cells of layer II and by the appearance of the lamina dissecans, a cell-sparse area between layers III and V.

The input to the perirhinal cortex is roughly evenly divided between cortical and subcortical structures. The perirhinal cortex receives input from nearly all unimodal and polymodal associational regions of neocortex, but there are subregional differences. For example, area 36 receives roughly equal input from olfactory, auditory, visual and visuospatial, and sensorimotor regions, whereas area 35 is dominated by olfactory input from piriform cortex. There are also subregional similarities and differences in polymodal association input. Area 36 receives the largest cortical input from temporal association regions followed by insular and frontal regions. In contrast, area 35 receives the larger input from insular cortex followed by temporal association and frontal regions. Of course, there is also a heavy intrinsic input from area 36. Areas 36 and 35 each receive only small inputs from posterior associational regions. As would be expected, these associational connections are largely reciprocal.

Perirhinal areas 36 and 35 are also differentiated by subcortical connections. The strongest subcortical connections of area 36 are with the amygdala. The afferent input arises largely in the lateral nucleus, but the basolateral and basomedial nuclei also provide substantial inputs. Substantial thalamic input arises largely in the dorsolateral group and in the reticular thalamic nucleus. In contrast, area 35 receives its strongest subcortical afferents from olfactory structures, primarily from the endopiriform nucleus, but also from the piriform transition area. Other substantial inputs arise in the amygdala, the midline and lateral thalamic groups, and the medial geniculate nucleus of the thalamus.

Like the postrhinal cortex, the perirhinal cortex projects strongly to the lateral entorhinal cortex. The projection arises in area 35 and terminates most heavily in the so-called lateral band of the entorhinal cortex (see following). The entorhinal projection is weakly reciprocated. Area 36 is weakly connected with hippocampal and subicular structures, although these connections may be functionally important. Area 35 receives input back from the septal presubiculum. The strongest projection back to area 35 arises in temporal CA1, but it also receives input from temporal subiculum and presubiculum. Other smaller inputs arise in septal CA1 and the parasubiculum.

3.03.2.3 Entorhinal Cortex

The entorhinal cortex is of considerable interest in memory research. Not only does it provide the major conduit for sensory information to the hippocampal

formation, but a number of recent discoveries also suggest that the region may make unique contributions to the processing of spatial information. The entorhinal cortex is a relatively large and complicated structure, and its connections are topographically organized. Thus, understanding the areal differences in entorhinal structure could provide insight into its role in memory.

In rats and other animals, the entorhinal cortex has been divided into two subdivisions roughly equivalent to modern definitions of the lateral and medial entorhinal areas (LEA and MEA, **Figure 1(f)**) (Brodmann, 1909; Krieg, 1946). The LEA (**Figure 5**, top) is perhaps most easily distinguished from the MEA (**Figure 5**, bottom) by differences in layer II. LEA has a very clumpy layer II as compared to the more homogeneous layer II of the MEA. The sparsely populated layer IV, also called the lamina dissecans, is considered a landmark feature of the entorhinal cortex, but there are subregional differences. In general, the LEA exhibits a less prominent lamina dissecans as compared to the MEA (compare **Figure 5**).

Some time ago, the monkey entorhinal cortex was further subdivided on the basis of structural and connectional criteria (Van Hoesen and Pandya, 1975; Amaral et al., 1987). The rat entorhinal cortex has now been subdivided into six fields according to similar criteria (**Figure 6(a)**) (Insausti et al., 1997). The LEA comprises four fields: the dorsal lateral entorhinal field (DLE), the dorsal intermediate entorhinal field (DIE), the amygdalo-entorhinal transitional field (AE), and the ventral intermediate entorhinal field (VIE). Each field has unique connectional and/or structural characteristics. The medial entorhinal area (MEA) is subdivided into a caudal field (CE) and a medial field (ME). Medially, the MEA is bordered by the parasubiculum. The MEA border with the parasubiculum is marked by a layer II that thickens into a characteristic club-shaped formation.

The intrinsic connections of the entorhinal cortex are organized in a rostrocaudal manner, such that the cells located in each of three bands of the entorhinal area are highly interconnected but do not project outside the band of origin (**Figure 6(b)**) (Dolorfo and Amaral, 1998). Interestingly, each band of intrinsic connectivity spans the MEA and LEA. An important recent discovery about these regions has to do with the relationship of these bands of intrinsic connectivity with the perforant pathway, the entorhinal projection to the dentate gyrus. Briefly, the lateral band projects to the septal half of the dentate gyrus, whereas the intermediate and medial bands project to the third and fourth septotemporal quarters, respectively (**Figure 6(c)**). This connectional topography suggests that functional diversity within the entorhinal cortex may be in register with functional diversity in the hippocampus.

The entorhinal cortex is strongly connected with other parahippocampal region structures. Perirhinal

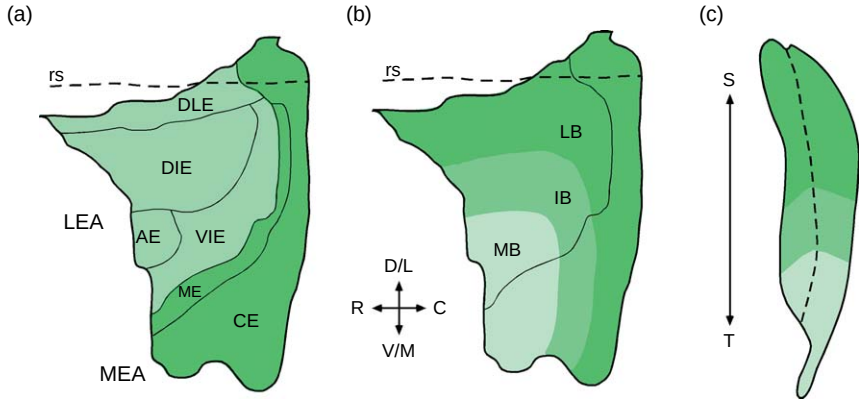

Figure 6 Unfolded maps of the entorhinal cortex and the target of the perforant pathway, the dentate gyrus. (a) Unfolded map of the rodent entorhinal cortex showing the LEA in light green and the MEA in dark green. Further parcellation of each subregion is noted by black lines (Insausti et al., 1997). (b) Unfolded map of the rodent entorhinal cortex showing the lateral (LB) in dark green, the intermediate band (IB) in medium green, and medial band (MB) in pale green. (c) The unfolded dentate gyrus, color coded to denote the terminations of the perforant pathway. The entorhinal LB projects to the septal half of the dentate gyrus, the IB projects to the third quarter, and the MB projects to the temporal quarter. Abbreviations: AE, amygdalo-entorhinal transitional field; CE, caudal entorhinal field; D, dorsal; DLE, dorsal lateral entorhinal field; DIE, dorsal intermediate entorhinal field; L, lateral; M, medial; ME, medial entorhinal field; S, septal; T, temporal; V, ventral.

input arises largely in area 35 and terminates preferentially to the lateral band of the LEA. The postrhinal input arises in all portions of the region and terminates primarily in the lateral band of the MEA. There is a heavy return projection to perirhinal cortex that arises in all layers and all portions of the entorhinal cortex, though the strongest projection arises in the lateral band. Strong inputs originate from the pre- and parasubiculum. The parasubiculum targets the entire entorhinal cortex, septal presubiculum projects more heavily to the MEA, and temporal presubiculum projects more heavily to the LEA. The entorhinal cortex provides modest reciprocal connections with the pre- and parasubiculum (Witter and Amaral, 2004).

The entorhinal cortex has neocortical connections, through weaker than perirhinal and postrhinal cortices. The LEA receives very strong input from the piriform and agranular insular cortices. Medial and orbital frontal regions provide a strong projection. Input from the cingulate, parietal, and occipital cortices is relatively weak. There is little differentiation across the lateral to medial bands. Piriform cortex also projects to the MEA, but the projection terminates in the lateral and intermediate bands. In contrast, the lateral band receives moderate to strong projections from frontal, cingulate, parietal, and occipital cortices. Projections to the medial frontal and olfactory structures tend to arise in the intermediate and medial bands. A very narrow strip of the entorhinal cortex that is positioned closest to the rhinal fissure gives rise to the major projections to other cortical areas, including the lateral frontal, temporal, parietal, cingulate, and occipital cortices.

The entorhinal cortex has widespread connections with subcortical structures, and it is possible that the subcortical afferents are as influential as the cortical afferents. Strong projections arise in claustrum, olfactory structures, the amygdala, and dorsal thalamus. The olfactory input arises in the endopiriform nucleus and the piriform transition area and is stronger to the LEA than the MEA. The dorsal thalamic input arises primarily in the midline thalamic nuclei and is stronger to MEA than to LEA. The LEA and MEA receive input from septal nuclei, though the inputs are relatively small. The amygdala input arises in all nuclei except the central nucleus and amygdalohippocampal area and is stronger to LEA than MEA. In addition, the entorhinal cortex projects to all amygdaloid structures except the nucleus of the lateral olfactory tract and the central nucleus (Pikkarainen and Pitkanen, 1999).

The entorhinal cortex projects to all hippocampal formation structures including the dentate gyrus, fields CA3, CA2, and CA1 of the hippocampus proper, and the subiculum (reviewed in Witter and Amaral, 2004). The entorhinal projections to the dentate gyrus, CA3, and CA2 originate in layer II of the entorhinal cortex. The terminations of the layer II projections exhibit a radial topography in that the LEA terminates in the outer DG molecular layer, whereas the MEA projects to the middle DG molecular layer (**Figure 7**). The projections to CA1 and the subiculum originate in layer III. The terminations of the layer III projections

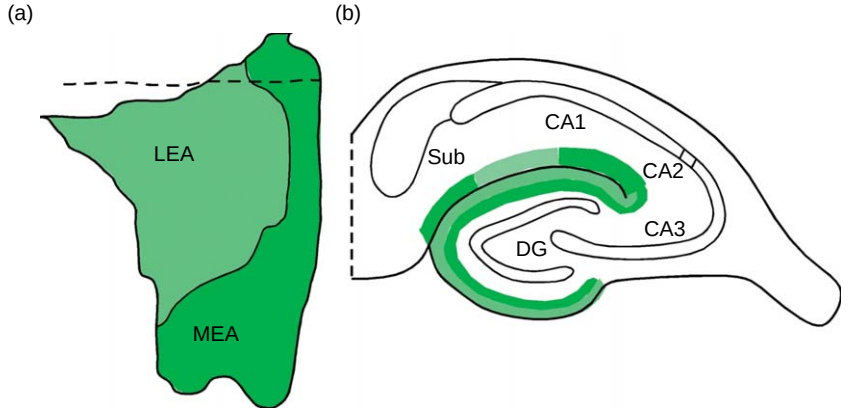

Figure 7 Illustration of the radial and transverse topography of the entorhinal projection to the hippocampal formation. (a) Unfolded map of the entorhinal cortex showing the LEA in light green and the MEA in dark green. (b) Line drawing of a hippocampal section perpendicular to the long axis. Adapted from Witter MP and Amaral DG (2004) Hippocampal Formation. In: Paxinos G (ed.) *The Rat Nervous System,* 3rd ed. San Diego, CA: Academic Press. The terminations of the LEA are in light green, and the terminations of the MEA are in dark green. The projection to the DG exhibits a radial topography, whereas the projection to CA1 and subiculum (sub) exhibits a transverse topography. See text for details.

exhibit a transverse topography such that the LEA projects to distal CA1 and proximal subiculum, and the MEA projects to the proximal CA1 and distal subiculum. The organization of the CA1 and subicular projections back to deep layers of the LEA and MEA roughly reciprocates the forward projections.

3.03.2.4 Presubiculum

The presubiculum is bordered dorsally by retrosplenial cortex, medially by the subiculum, and ventrolaterally by the parasubiculum (**Figures 2(e)**, **2(f)**, and **8(a)**). Areas 48 and 27 according to Brodmann (1909) are both included in the presubiculum. Area 48, the most dorsal extension of the presubiculum, is sometimes called the postsubiculum. Because the presubiculum and this dorsal component exhibit considerable cytoarchitectonic similarities, it may be more appropriate to designate the area collectively with a single term.

Layer II of the six-layered presubiculum is thick and contains small, densely packed, and darkly staining pyramidal cells (**Figure 8(b)**). Cells in layer III are even smaller, round, and also darkly staining. Whereas cells in layer II tend to form clusters, cells in layer III have a more homogeneous look. Layer III is separated from the deep layers by a narrow, sparsely populated gap that is continuous with the lamina dissecans of the parasubicular cortex. Deep to this cell-sparse gap are two layers. Layer V is very thin and contains pyramidal cells. Layer VI is slightly thicker and contains a mixture of cell types.

As it turns out, acetylcholinesterase (AChE) is an excellent marker for the presubiculum. Layer II stains moderately darkly (**Figure 8(c)**). Deep to layer II is a dark band that contains layers III, the cell-sparse gap, and layer V. Layer VI is moderately to lightly stained in AChE preparations. AChE is also a good marker for the parasubiculum.

The presubiculum has extensive associational, commissural, and hippocampal parahippocampal connections (Witter and Amaral, 2004). The septal and temporal parts of the presubiculum are highly interconnected. Connections with the contralateral presubiculum are also extensive, though commissural connectivity may be stronger ventrally than dorsally. The presubiculum provides a weak input to the dentate gyrus and all fields of the hippocampus proper. It is reciprocally connected with the subiculum. The presubiculum projects to superficial layers of the subiculum. The projection to the septal subiculum is moderately strong, and the temporally directed projection is relatively weak. The input from the subiculum terminates in layer I.

Regarding parahippocampal connectivity, the presubiculum projects to superficial layers of the

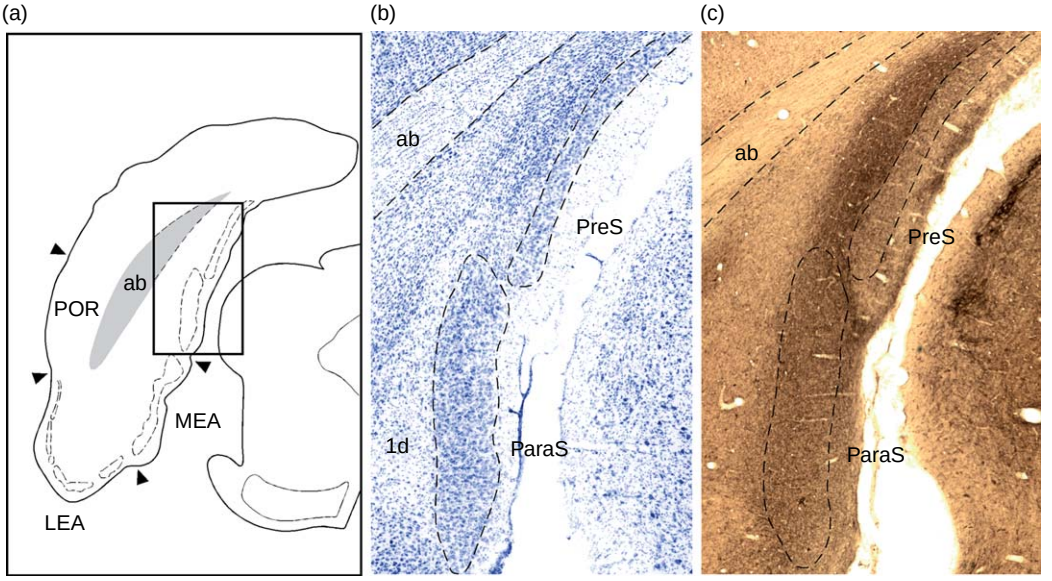

Figure 8 Photomicrographs of the presubiculum (PreS) and parasubiculum (ParaS). (a) Drawing of a coronal section of the rat brain at the level of the angular bundle (ab). The inset designates the areas shown in panels (b) and (c). (b) Nissl-stained coronal section showing the PreS and ParaS. Layer II is outlined for the PreS, and the combined layer II/III is outlined for ParaS. (c) Adjacent section stained for acetylcholinesterase (AChE). AChE provides an excellent marker for these regions.

parasubiculum, but the connections with the entorhinal cortex are by far the strongest. The presubicular–entorhinal projection is bilateral, largely directed to medial entorhinal cortex, and almost exclusively terminates in layer III. Septal presubiculum projects much more heavily to the MEA than the LEA, but temporal presubiculum projects heavily to both entorhinal divisions. Septal presubiculum also provides a moderately heavy input to the postrhinal cortex. The dorsal extension (Brodman's area 48, sometimes termed the postsubiculum) projects massively to postrhinal cortex. Temporal presubiculum projects heavily to the LEA and the MEA and moderately heavily to perirhinal areas 36 and 35. Septal presubiculum receives heavy input from postrhinal cortex and a moderately heavy input from the MEA portion of the lateral band. Temporal presubiculum receives a very heavy input from the MEA portion of the medial band, weak input from the LEA, and virtually nothing from the perirhinal and postrhinal cortices.

The heaviest neocortical input to the presubiculum arises in the granular retrosplenial cortex, but weaker inputs arise in prelimbic cortex, dorsomedial prefrontal areas, and the anterior cingulate cortex (Witter and Amaral, 2004). The primary subcortical inputs are from the dorsal thalamus, specifically, the anteroventral, the anterodorsal, and the laterodorsal nuclei. The presubiculum receives subcortical input from the thalamus, primarily the anterior thalamic nuclei including the anteroventral, anterodorsal, and laterodorsal nuclei. A massive return projection targets the same nuclei. There is also a strong cholinergic input arising from septal nuclei. Finally, the presubiculum has reciprocal connections with the mamillary nuclei of the hypothalamus.

3.03.2.5 The Parasubiculum

For most of its rostrocaudal extent, the parasubiculum is bordered by presubiculum dorsally and the medial entorhinal area ventrally (**Figure 2(e)** and **2(f)**). At more caudal levels, the parasubiculum is interposed between the postrhinal cortex and the medial entorhinal area. A broad, combined layer II/III contains large, densely packed, moderately darkly staining pyramidal cells. This layer is separated from the deep layers by a broad lamina dissecans. Layers V and VI can be distinguished from one another and tend to run continuously with deep layers of the medial entorhinal area. In AChE preparations, layers I and II/III are darkly stained (**Figure 8(c)**). The lamina dissecans and layer V are lightly stained, and layer V is moderately darkly stained.

The parasubiculum has associational connections that project dorsally and ventrally. The ventral projections are heavier and more extensive than the dorsal ones. Commissural projections terminate in layers I and III of the contralateral homotopic region.

The hippocampal input to the parasubiculum arises mainly in the subiculum and terminates in layer I and superficial layer II. There are also return projections to the hippocampal formation. The structure projects directly to the molecular layer of the dentate gyrus. This is especially interesting given that the parasubiculum receives strong inputs from anterior thalamic nuclei. As has been previously noted, the anterior thalamic projection to the parasubiculum provides a pathway by which the anterior thalamus can affect hippocampal processing of incoming information at very early stages.

Like the presubiculum, the parasubiculum exhibits substantial connections with other parahippocampal structures. The parasubiculum projects selectively to layer II of the entorhinal cortex. The entorhinal projection is much heavier to MEA than to the LEA. Interestingly, the parasubicular projection to POR is even heavier than that to the MEA. Parahippocampal inputs arise mainly from the MEA, with the medial band providing the heaviest return projection. There is also a modest presubicular input.

Extrinsic connections of the parasubiculum are few. The only neocortical afferents arise in retrosplenial cortex and visual cortex, and these inputs are quite weak. Other than the input from the anterior thalamus, the only other subcortical afferents arise in the amygdala from the lateral, basal, and accessory basal nuclei.

3.03.3 The Hippocampal Formation

The structures of the hippocampal formation are grouped together partly because of the sequential activation pattern that was identified several decades ago. The entorhinal cortex activates the dentate gyrus via the perforant pathway, the mossy fiber pathway from the denate gyrus activates CA3, and the CA3 Schaffer collaterals activate CA1. Some of the earliest and most famous studies of the structure of the nervous system were conducted by Ramón y Cajal, who used a technique developed by Camillo Golgi for darkly staining a small number of neurons

in the brain. Cajal's elegant studies and drawings, including the rodent hippocampus (**Figure 9**), provided the basis for the neuron doctrine.

Because of the complex architecture of the hippocampus, it is helpful to describe its structure in terms of three axes, the longitudinal, transverse, and radial axes. As previously discussed, we use the term septotemporal for the longitudinal axis of the hippocampus. Along the transverse axis, which is orthogonal to the long axis of the hippocampus, the dentate gyrus can be considered the proximal limit and transverse locations designated according to position relative to the dentate gyrus. Thus, the part of the CA3 lying in the V of the dentate gyrus is proximal CA3, and the part closest to CA1 is distal (**Figure 10**). Similarly, the part of CA1 closest to CA3 is proximal, and so on. Finally, the laminar structure is perpendicular to the radial axis. In this terminology, the molecular layers are superficial and the layers on the opposite side of the principle cell layers are deep.

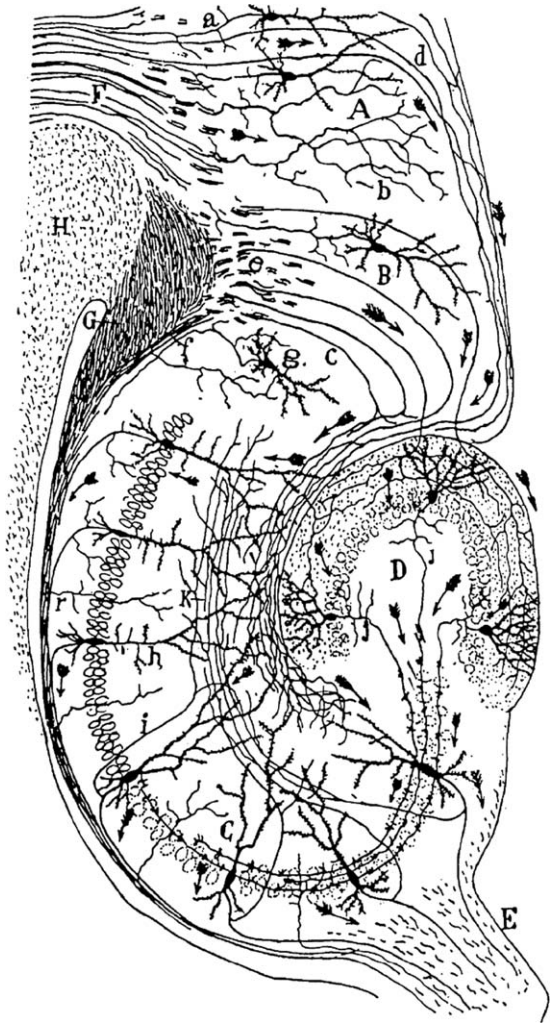

Figure 9 Drawing of the circuitry of the hippocampal formation by Ramón y Cajal (1909). Cajal proposed that the nervous system is made up of countless separate units, or nerve cells composed of dendrites, soma, and axons, each of which is a conductive device. He further proposed that information is received on the cell bodies and dendrites and conducted to distant locations through axons. Abbreviations: A, retrosplenial area; B, subiculum; C, Ammon's horn; D, dentate gyrus; E, fimbria; F, cingulum; G, angular bundle; H, corpus callosum; K, recurrent collaterals; a, axon entering the cingulum; b, cingulum fibers; c-e, perforant path fibers; g, subicular cell; h, CA1 pyramidal cells; i, Schaffer collaterals; collaterals of alvear fibers.

Based primarily on electrophysiological data and mapping of vasculature, Anderson and colleagues (1971) proposed that the hippocampal formation was organized in parallel lamellae stacked along the longitudinal axis. They further proposed that this lamellar organization would permit strips, or slabs, of the hippocampus to function as independent units. Although the lamellar hypothesis shaped research on the hippocampus for years to come and continues to influence modern concepts of hippocampal function, modern neuroanatomical research has revealed that the hippocampal projections are much more divergent than is suggested by the lamellar hypothesis. Indeed, the major hippocampal and dentate associational projections extend along the septotemporal axis as well as the transverse axis.

3.03.3.1 The Dentate Gyrus

The dentate gyrus is three-layered cortex whose principle cell layer is V shaped (**Figure 10**). The molecular layer lies outside the V, and the polymorphic layer lies inside the V. The beginning of the CA3 principle cell layer protrudes into the polymorphic area of the dentate gyrus. This conformation has generated some confusion over the border between CA3 and the dentate gyrus polymorphic layer, as well as the identity of these cells. In earlier nomenclatures, and occasionally in modern reports, the part of CA3 next to the dentate gyrus was sometimes called CA4. With modern techniques for defining connectional characteristics, however, it is now clear that those pyramidal cells belong to CA3.

The dentate granule cell layer contains small, very densely packed, oval cells that have a dark appearance in cell stains (**Figure 10(a)**). Each granule cell has a small number of primary dendrites (one to four) that are covered with spines. The dendrites

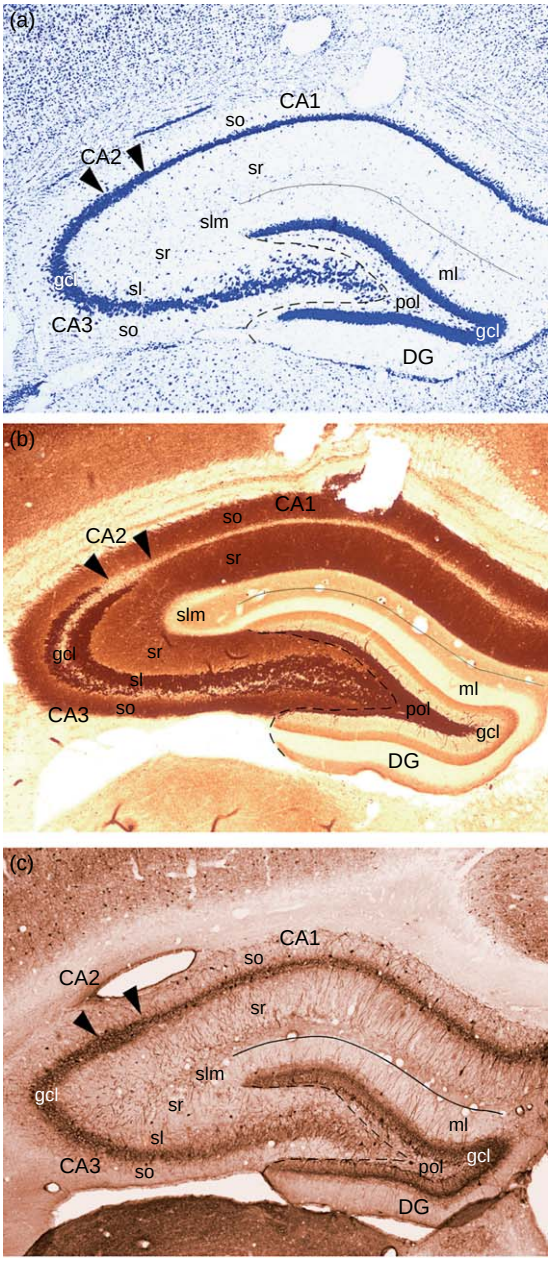

Figure 10 Photomicrographs of the hippocampal formation. (a) Nissl-stained coronal section showing the dentate gyrus (DG) and hippocampus proper, comprising fields CA3, CA2, and CA1. (b) Adjacent section stained for heavy metals using the Timm's method. (c) Parvalbumin-stained section showing the same regions. Layers of the DG are the outer molecular layer (ml), the granule cell layer (gcl), and the polymorphous layer (pol). The CA fields contain the outer stratum lacunosum-moleculare (slm), the stratum radiatum (sr), the gcl, and the stratum oriens (so). CA3 also contains the stratum lucidum (sl). The dashed line demarcates the border between the DG and CA3. The solid line shows the location of the hippocampal fissure and demarcates the border between DG and CA1.

extend into the molecular layer all the way to the hippocampal fissure. In the subgranular region, between the granule cell layer and the polymorphic layer, there are several cell types, most of which are immunoreactive for gamma-aminobutyric acid (GABA). A subset of these cells is also immunoreactive for the calcium-binding protein, parvalbumin (**Figure 10(c)**). The most prominent types are the basket cell and the axo-axonic, or chandelier, cell. The basket cell interneurons are quite large with a single, aspiny apical dendrite extending into the molecular layer and several basal dendrites extending into the polymorphic layer. Axo-axonic cells have a dendritic tree of radial branches extending through the molecular layer. The axon arborizes extensively in the granule cell layer.

The molecular layer contains mostly dendrites from cells of the granule and polymorphic layers. In material stained for heavy metals using the Timm's method, it is possible to visualize the three sublayers of the molecular layer (**Figure 10(b)**). The inner third of the molecular layer, next to the lightly colored granule cell layer, stains a reddish brown. The middle sublayer stains yellow, and the outer sublayer stains orange. Though the molecular layer mostly contains dendrites, there are a few cell types that stain for VIP, GABA, and parvalbumin. One interesting type of GABA-immunoreactive cell, with its soma in the molecular layer, has an axon restricted to the outer two-thirds of the molecular layer. Thus, its terminal field coincides with the perforant path terminations in the dentate molecular layer.

The polymorphic layer contains a number of cell types, but the best characterized is the mossy cell. These large multipolar cells are so named because of their large dendritic spines, the so-called thorny excrescences. The mossy fiber axons from the granule layer terminate on these spines. There are a number of interneurons with somata in the polymorphic layer that make inhibitory connections on the dentate granule cells. One such cell type is the hilar perforant-path (HIPP) associated cell, which has a dendritic tree in the polymorphic layer but extensive axonal arbor in the outer two-thirds of the molecular layer where the perforant path input terminates. Another type is the hilar commissural-associational pathway (HICAP) related cell, which innervates the inner molecular layer, the molecular layer perforant-path (MOPP) associated cell. The dendritic tree and axonal arbor of this cell occupy the outer two-thirds of the molecular layer, where the perforant path input terminates.

The entorhinal cortex provides the only cortical input to the dentate gyrus through the perforant pathway. There is substantial subcortical input from the septal nuclei, the hypothalamus, and the brain stem modulatory systems. The cholinergic input from the septal region originates in the medial septal nucleus and in the nucleus of the diagonal band of Broca. It is topographically organized such that cells in the medial septal areas tend to terminate septally, and cells in lateral septal structures terminate temporally. The projection terminates in the polymorphic layer. The primary hypothalamic input is from the supramamillary area and terminates in a narrow band of the molecular layer just superficial to the granule cell layer. This projection is probably excitatory and appears to target both granule cells and interneurons. The dentate gyrus receives input from each of the modulatory neurotransmitter systems in the brainstem. The noradrenergic input is from the pontine nucleus of the locus coeruleus and terminates in the polymorphic layer. The serotonergic input is from several of the raphe nuclei and also terminates in the polymorphic region. Minor dopaminergic inputs arise in the ventral tegmental area and the substantia nigra.

The only output of the dentate gyrus is the granule cell mossy fiber projection to CA3. Axon collaterals of each cell project to the full extent of the transverse axis. This is the one component of the hippocampal circuitry that does show a lamellar projection pattern. The fibers travel along or within the CA3 pyramidal layer, eventually reaching the stratum lucidum. In addition to the CA3 projection, the mossy fibers give rise to an associational connection consisting of about seven collaterals that terminate in the dentate gyrus polymorphic layer before entering CA3. The mossy fiber axons can be easily identified in Timm's preparations in which they stain very darkly (**Figure 10(b)**).

3.03.3.2 The Hippocampus Proper

The hippocampus proper consists of three fields. Proximal to distal from the dentate gyrus, they are the Ammon's horn fields CA3, CA2, and CA1 (**Figure 10**). Like the dentate gyrus, these fields are a three-layered cortex consisting of a principle layer located between cell-sparse layers. Deep to the principle cell layer is the stratum oriens. Superficial to the principle cell layer are the stratum radiatum and the stratum lacunosum-moleculare. CA3 has an additional thin layer, the stratum lucidum, which lies just superficial to the principle cell layer and deep to the stratum radiatum.

The principal cell layer consists, primarily, of pyramidal cells. The pyramidal cells in CA3 are larger and the layer thicker compared with CA1. The small and often-overlooked field CA2 contains larger pyramids, similar to CA3, but is similar to CA1 in other ways. For example, it lacks mossy fiber input. Each pyramidal cell has an apical dendritic arbor extending upward through the stratum radiatum and the stratum lacunosum-moleculare and a basal dendritic arbor extending into the stratum oriens. CA3 cells proximal to the dentate gyrus have smaller dendritic trees than the cells distal to the dentate gyrus, but overall, the dendritic arbors of cells in CA3 are larger than those in CA1. The dendritic arbors of pyramidal cells in CA2 are mixed, some with large arbors, similar to CA3, and some with small arbors, similar to CA1.

Interneurons undoubtedly play an important role in the regulation of local circuits in the hippocampus proper. Hippocampal interneurons differ in morphology, immunoreactivity, synaptic properties, laminar location, and connectivity. Hippocampal interneurons are GABAergic, but they may also be immunoreactive for somatostatin, neuropeptide Y, vasopressin, cholecystokinin, parvalbumin, calbindin, and calretinin. Most hippocampal interneurons have short axons, but there are also interneurons with long axons that project outside the hippocampal formation. We mention a few types here, but for a full discussion, see Freund and Buzsaki (1996).

One prominent interneuron type in the pyramidal cell layer is the chandelier or axo-axonic cell. The apical dendrites are radially oriented and span all superficial layers to the hippocampal fissure. The basal dendrites form a thick arbor in the stratum oriens. There is also a heterogeneous group of basket cells whose apical dendrites extend into the stratum moleculare and whose extensive basal dendrites span the entire depth of the stratum oriens. The axo-axonic cells and the basket cells are conveniently positioned to receive excitatory input from all afferents of the hippocampus proper.

Some hippocampal interneuron cell types have cell bodies in stratum oriens and innervate principal cell dendrites, similar to those described for the dentate gyrus. The oriens lacunosum-moleculare (O-LM) cells have a dense axonal arbor restricted to the stratum lacunosum moleculare. The dendritic tree is localized to layers that receive recurrent collaterals. There are many other interneuron

types including the bistratisfied, horizontal trilaminar, and radial trilaminar cells.

The CA3 pyramidal cell axons are highly collateralized and project to all CA fields both ipsilaterally and contralaterally. There is also a small collateral projection to the polymorphic layer of the dentate gyrus. CA3 does not, however, project to the subiculum, presubiculum, parasubiculum, or entorhinal cortex. The projection to CA1 is called the Schaffer collateral projection, the projections to CA3/CA2 are called the associational projections, and the projections to contralateral structures are called the commissural projections. The Schaffer collateral projection exhibits a topography such that proximal CA3 cells (closer to the dentate gyrus) tend to project to levels of CA1 that extend farther in the septal than temporal directions. Distal CA3 cells (farther from the dentate gyrus) tend to project farther in the temporal direction. In addition, projections of proximal CA3 cells tend to terminate more superficially in stratum radiatum, whereas distal CA3 cells tend to terminate more deeply in stratum radiatum and in stratum oriens. The associational projections exhibit complex transverse and radial topographies, but in general the CA3-CA3 associational projections terminate extensively along the septotemporal axis (Witter and Amaral, 2004). The pattern of the terminations of the commissural projections mirrors those of the associational projections.

Extrinsic connections of CA3 are not robust except for the substantial projection to the lateral septal nucleus. The major subcortical input to CA3 is cholinergic and arises in the medial septal nucleus and the nucleus of the diagonal band of Broca. There is a GABAergic component of the projection that terminates primarily on the GABAergic interneurons of the stratum oriens. Temporal CA3 receives a minor input from the amygdala basal nucleus, which terminates in the stratum oriens and the stratum radiatum. Inputs from piriform cortex have also been reported. A noradrenergic projection arises in the locus coeruleus, and a serontonergic input arises in the raphe nucleus.

Field CA2 can be differentiated from CA3 by the lack of mossy fiber input and the associated thorny excrescences (**Figure 10(b)**). The pyramidal cell layer also stains more intensely for parvalbumin (**Figure 10(c)**). The intrinsic projections are similar to those of CA3, although the topographies may not be the same. For example, like CA3, CA2 also provides a small collateral projection back to the dentate gyrus. Not much is known specifically about CA2 extrinsic connections, but available evidence suggests that the region is differentiated from CA3 by hypothalamic input from the supramamillary area.

Field CA1 exhibits only a weak associational/commissural connection, a feature that is in striking contrast to the robust associational network present in CA3. This difference has been interpreted as underlying some of the putative functional differences in CA3 and CA1. Other intrahippocampal connections, however, are extensive. CA1 interneurons project to CA3 and to the polymorphic layer of the dentate gyrus. The major projection from CA1, however, is to the subiculum, and that projection exhibits a strict topography. Distal CA1 projects to proximal subiculum, and proximal CA1 projects to distal subiculum. The mid-CA1 projection terminates in midproximodistal subiculum.

Field CA1 receives substantial cortical and subcortical input from extrahippocampal structures. Cortical input arrives from the perirhinal, postrhinal, and entorhinal cortices. Subcortical input to CA1 is grossly similar to the subcortical input to CA3 but differs in the details. The septal input is weaker and terminates in stratum oriens. The input from the amygdala is more substantial, especially to distal CA1. Amygdala input arises in the basal and accessory basal nuclei. There is a prominent input from the nucleus reuniens of the thalamus that terminates in the stratum lacunosum moleculare. Like CA3, CA1 receives weak noradrenergic input from the locus coeruleus and weak serotonergic input from the raphe nucleus. There is also a weak dopaminergic input.

Of the hippocampal CA fields, CA1 has the more robust extrinsic projections. The cortical projections include the perirhinal, postrhinal, entorhinal, retrosplenial cortices, preinfralimbic, and medial prefrontal cortex. In general, the septal half projects more heavily to postrhinal cortex, the medial entorhinal area, and retrosplenial cortex, whereas the temporal half of CA1 projects more heavily to perirhinal cortex, the lateral entorhinal area, and infralimbic cortex. Temporal levels also project to the anterior olfactory nucleus, the hypothalamus, nucleus accumbens, and the basal nucleus of the amygdala.

3.03.3.3 The Subiculum

The subiculum is widely considered the output structure of the hippocampal formation. In this way, it differs from its parahippocampal neighbors, the pre- and parasubiculum, which are considered to be

input structures. Like the CA fields of the hippocampus proper and the dentate gyrus, the subiculum is a three-layered cortex with a deep, polymorphic layer, a pyramidal cell layer containing the principle cells, and a molecular layer, which is continuous with the stratum lacunosum moleculare of field CA1. The subiculum can be distinguished from the proximally situated CA1 and the distally situated presubiculum by a principle cell layer that is more loosely packed. The border with CA1 is further demarcated by the widening of the middle layer of the subiculum.

The principle cell layer contains large pyramidal cells. The basal dendrites terminate in the deep part of the principle layer, and the apical dendrites extend into the molecular layer. The pyramidal cells are large and of uniform shape. Electrophysiological findings suggest that there are two populations of pyramids, though they cannot be distinguished morphologically. So-called regular spiking cells tend to be located superficially, and bursting cells tend to be located deep in the layer. Although both types are projection cells, it is possible that only the bursting cells project to the entorhinal cortex. Among the pyramids are numerous smaller cells, probably representing varied types of interneurons. Perforant pathway fibers contact GABAergic cells that stain for parvalbumin. Not much is known about subicular interneurons, but in general, the population of interneurons appears similar to that observed in field CA1 (Witter and Amaral, 2004).

The associational connections of the subiculum extend temporally from the point of origin and terminate in all layers. There is no commissural projection. There are also local associational connections confined to the pyramidal layer and the deepest part of the molecular layer. The available data suggests that the bursting pyramidal cells form a columnar network that is roughly interconnected.

Connections of the subiculum with other hippocampal structures is limited to input from CA1, which is massive. The projection exhibits a topography such that proximal CA1 projects to distal subiculum, midproximodistal CA1 projects to midsubiculum, and distal CA1 projects to proximal subiculum. The projection is not truly lamellar, however, as any part of CA1 projects to about one-third of the septotemporal extent of the subiculum.

The parahippocampal connections of the subiculum are more diverse, but the best-characterized projection is to deep layers of entorhinal cortex. Septal levels of the subiculum provide substantial input to the lateral and medial entorhinal cortices. Septal subicular input to the postrhinal cortex is equally strong, but input to perirhinal cortex, especially area 35, is modest. Temporal subiculum provides massive input to the entorhinal cortex and moderate input to perirhinal and postrhinal cortices. The subiculum also receives a substantial input from the entorhinal cortex. The entorhinal lateral band projects more strongly to septal subiculum, and the entorhinal intermediate and medial bands project more strongly to temporal subiculum. There is also modest input from the perirhinal and postrhinal cortices. Perirhinal cortex projects relatively more strongly to temporal subiculum, and the postrhinal cortex projects relatively more strongly to septal subiculum. The subiculum also projects heavily to the pre- and parasubicular cortices, though the return projections are modest (O'Mara et al., 2001).

The most prominent neocortical projections are to retrosplenial and prefrontal cortices. The distal and septal part of the subiculum projects to the ventral retrosplenial cortex. The presubiculum projections to frontal areas include the medial orbital, prelimbic, infralimbic, and anterior cingulate cortices. The retrosplenial projection is reciprocated, but available evidence suggests that the frontal projections are not.

The diverse subcortical projections target the septal complex, the amygdala, the nucleus accumbens, the hypothalamus, and the thalamus. All septotemporal levels of the subiculum project to the lateral septum, but the projection arises primarily in the proximal part. Septal input arises mainly in the nucleus of the diagonal band. The amygdala projection arises primarily in the temporal subiculum and targets the posterior and basolateral nuclei. The projection to the nucleus accumbens is topographic such that the proximal part of the septal subiculum projects to rostrolateral nucleus accumbens, and the proximal part of the temporal subiculum projects to the caudomedial nucleus accumbens. The hypothalamic projection also arises primarily in the temporal subiculum. It terminates in the medial preoptic area and the ventromedial, dorsomedial, and ventral premammillary nuclei. Finally, there are documented connections with thalamic nuclei, though the details are not well described. The proximal part of the septal subiculum projects to the anteromedial nucleus of the thalamus, but the distal part projects to the anterior thalamic complex. The latter projection is reciprocated. Temporal subiculum receives input from the nucleus reuniens. Available evidence suggests that the anteroventral nucleus of the thalamus also projects to the subiculum.

3.03.4 Conclusions

3.03.4.1 The Flow of Sensory Information through the Hippocampal System

The entorhinal cortex is widely recognized as the primary way station for sensory information on its way from the neocortex to the hippocampus. Much of the neocortical input arrives by way of the perirhinal and postrhinal cortices, but there are also direct neocortical inputs to the entorhinal cortex. The presubiculum and parasubiculum are also considered input structures for the hippocampal memory system. The distinct patterns of cortical afferentation to parahippocampal structures, the intrinsic connections, and the topography of the parahippocampal–hippocampal connections suggest that parahippocampal structures are involved in the preprocessing of sensory information provided to the hippocampus, and that there is functional diversity within the parahippocampal region. The view that parahippocampal structures have different functions is consistent with emerging evidence that there is also substantial functional diversity among hippocampal formation structures.

In Figure 11, we have attempted to schematize the flow of sensory information through the hippocampal memory system. Beginning with the input structures, perirhinal area 36 receives sensory input from visual, auditory, and somatosensory regions. Longitudinal intrinsic connections integrate across modalities before transmission to perirhinal area 35. This polymodal input to area 35 is joined by olfactory information and then passed on to entorhinal cortex, primarily the lateral band of the LEA. The postrhinal cortex receives visual and visuospatial input from posterior parietal, retrosplenial, and visual association regions, along with a small input from auditory association cortex. That information is integrated and transmitted to entorhinal cortex, primarily to the lateral band of the MEA. Presubiculum is targeted by the subiculum in a topographical manner such that septotemporal levels of the subiculum map onto septotemporal levels of the presubiculum. Subicular input is integrated with direct visuospatial input to the presubiculum, especially the septal component. That information is forwarded to the parasubiculum, the postrhinal cortex, and the MEA.

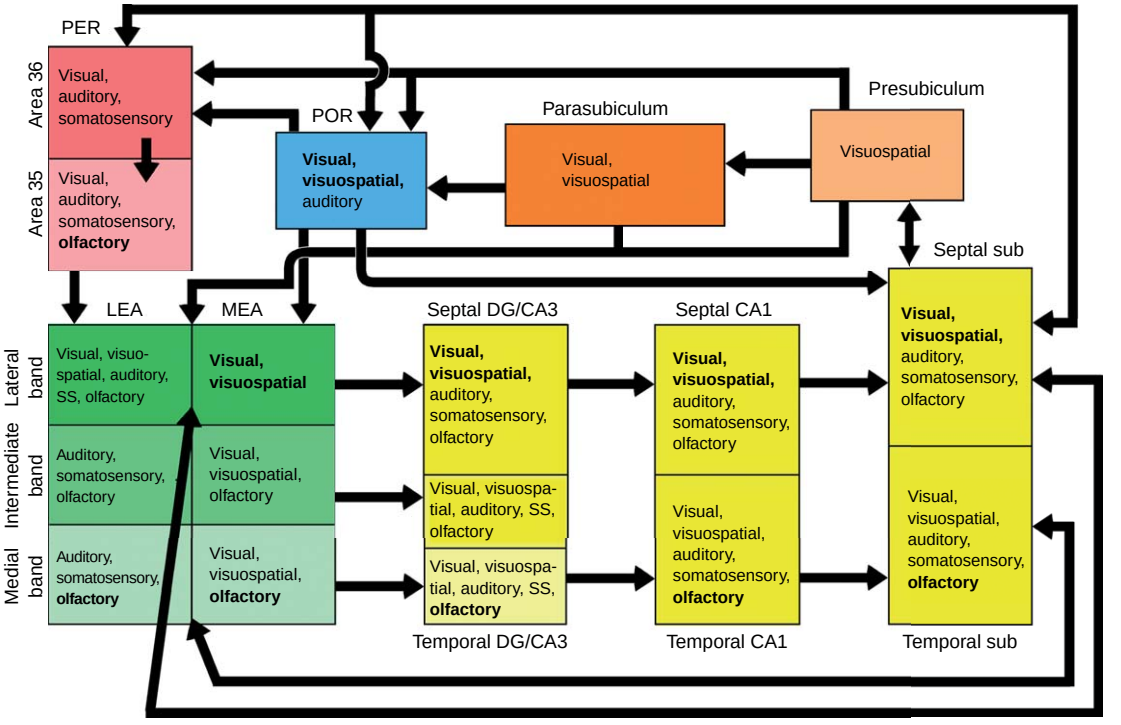

Figure 11 Diagram of the flow of sensory information through the hippocampal memory system. Black arrows indicate the primary pathways by which sensory information traverses the hippocampal memory system. Note that only the stronger connections are indicated and that emphasis is on the feedforward connections as opposed to the feedback connections. Abbreviations: CA, CA field; DG, dentate gyrus; LEA, lateral entorhinal area; MEA, medial entorhinal area; PER, perirhinal cortex; POR, postrhinal cortex; sub, subiculum.

The most septal component of the presubiculum, the area sometimes termed the postsubiculum, projects massively to the postrhinal cortex. Finally, the parasubiculum, which receives direct, but modest, visual and visuospatial input along with its subicular input, projects to postrhinal cortex and the MEA.

To summarize, information from all modalities reaches the full septotemporal extent of the hippocampus, but the degree of processing of different modalities is weighted differently along the septotemporal axis. Visual and visuospatial input is processed and elaborated along a pathway that includes the postrhinal cortex, lateral MEA, the septal hippocampal formation, septal presubiculum, parasubiculum, and then back to postrhinal cortex and lateral MEA. Olfactory information is less segregated but follows a pathway that includes the perirhinal cortex, medial LEA, and temporal hippocampal formation structures. Thus, there appears to be functional diversity in the processing of sensory information that is organized along the septotemporal axis; visual and visuospatial information is predominant in the septal hippocampus, and olfactory information is predominant in the temporal hippocampus.

3.03.4.2 The Comparative Anatomy of the Hippocampal System

As indicated earlier, all components of the parahippocampal region and the hippocampal formation are represented in both the rodent and the primate brain. Many of the connectional principles are also conserved. Taking into account the differences in brain size and sensory processing needs, cortical afferentation of the parahippocampal structures is similar across species. Additionally, the available evidence suggests that the architecture of the perforant pathway is similar in the primate and rodent brains. In the monkey and the rat, the perforant pathway projections to the dentate gyrus, CA3, and CA2 originate in layer II of the entorhinal cortex. Also in both, the projections to CA1 and the subiculum originate in layer III. In addition, the terminations of the projections originating in entorhinal layer III exhibit a transverse topography. The rostral entorhinal cortex in the monkey and the lateral entorhinal area in the rat project to the border of the CA1 and subiculum; the caudal entorhinal cortex in the monkey and the medial entorhinal area in the rat project to proximal CA1 and distal subiculum (Witter, 1986, 1993, Amaral, 1993). The intrinsic connections of the monkey entorhinal cortex also exhibit patterns similar to the lateral to medial bands of intrinsic connectivity observed in the rodent entorhinal cortex. Taken together, the evidence suggests that both the rat and monkey hippocampal memory systems are excellent models for the medial temporal lobe memory system in the human brain.

3.04 Declarative Memory System: Amnesia

L. R. Squire and Y. Shrager, University of California at San Diego, San Diego, CA, USA

3.04.1 Introduction

Memory is not a single entity but is composed of several separate systems (*See* Chapters 1.02, 1.04, 3.02; Squire, 1992; Schacter and Tulving, 1994). Long-term memory can be divided into several parallel memory systems. The major distinction is between declarative and nondeclarative memory. Declarative memory refers to conscious knowledge of facts and events. Nondeclarative memory refers to a collection of nonconscious knowledge systems that provide for the capacity of skill learning, habit formation, the phenomenon of priming, and certain other ways of interacting with the world. The terms 'explicit memory' and 'implicit memory' are sometimes used as well and have approximately the same meanings as declarative and nondeclarative memory, respectively.

The brain is organized such that declarative memory is a distinct and separate cognitive function, which can be studied in isolation from perception and other intellectual abilities. Significant information about how memory is organized has come from the study of patients with memory disorders (amnesia) and from animal models of amnesia (*See* Chapter 3.09). Amnesia (neurological amnesia and functional amnesia) refers to difficulty in learning new information or in remembering the past.

Neurological amnesia is characterized by a loss of declarative memory. It occurs following brain injury or disease that damages the medial temporal lobe or diencephalon. Neurological amnesia causes severe difficulty in learning new facts and events (anterograde amnesia). Patients with neurological amnesia also typically have some difficulty remembering facts and events that were acquired before the onset of amnesia (retrograde amnesia).

Functional amnesia is rarer than neurological amnesia and can occur as the result of an emotional trauma. It presents as a different pattern of anterograde and retrograde memory impairment than neurological amnesia. Functional amnesia is characterized by a profound retrograde amnesia with little or no anterograde amnesia. In some cases, patients fully recover. Functional amnesia is a psychiatric

disorder, and no particular brain structure or region is known to be damaged.

3.04.2 Etiology of Neurological Amnesia

Neurological amnesia results from a number of conditions including Alzheimer's disease or other dementing illnesses (*See* Chapter 3.29), temporal lobe surgery, chronic alcohol abuse, encephalitis, head injury, anoxia, ischemia, infarction, and the rupture and repair of an anterior communicating artery aneurism. The common factor in all of these conditions is the disruption of normal function in one of two areas of the brain – the medial aspects of the temporal lobe, and the diencephalic midline. Bilateral damage results in global amnesia, and unilateral damage results in material-specific amnesia. Specifically, left-sided damage affects memory for verbal material, while right-sided damage affects memory for nonverbal material (e.g., memory for faces and spatial layouts).

3.04.3 Anatomy

Well-studied cases of human amnesia and animal models of amnesia provide information about the neural connections and structures that are damaged. In humans, damage limited to the hippocampus itself is sufficient to cause moderately severe amnesia. For example, in one carefully studied case of amnesia (patient R.B.), the only significant damage was a bilateral lesion confined to the CA1 field of the hippocampus (Zola-Morgan et al., 1986). The severity of memory impairment is exacerbated by additional damage outside of the hippocampus. Thus, severe amnesia results when damage extends beyond CA1 to the rest of the hippocampus and to the adjacent cortex. (Animal studies later elucidated the critical anatomical components of this memory system; see following.) One well-studied case (H.M.) had surgery in 1953 to treat severe epilepsy. Most of the hippocampus and much of the surrounding medial temporal lobe cortices were removed bilaterally (the entorhinal cortex and most of the perirhinal cortex). Although the surgery was successful in reducing the frequency of H.M.'s seizures, it resulted in a severe and persistent amnesia.

It is also possible through structural magnetic resonance imaging (MRI) to detect and quantify the neuropathology in amnesic patients. Many patients with restricted hippocampal damage have an average reduction in hippocampal volume of about 40%. Two such patients whose brains were available for detailed, postmortem neurohistological analysis (patients L.M. and W.H.) proved to have lost virtually all the neurons in the CA fields of the hippocampus. These observations suggest that a reduction in hippocampal volume of approximately 40%, as estimated from MRI scans, likely indicates the near complete loss of hippocampal neurons (Rempel-Clower et al., 1996). The amnesic condition is associated with neuronal death and tissue collapse, but the tissue does not disappear altogether because fibers and glia remain. In patients with larger lesions of the medial temporal lobe, volume reduction as measured by MRI is more dramatic. For example, patient E.P., who became amnesic as a result of viral encephalitis, has damage to all of the perirhinal cortex, all of the entorhinal cortex, virtually all of the hippocampus, and most of the parahippocampal cortex (Stefanacci et al., 2000).

As questions about amnesia and the function of medial temporal lobe structures have become more specific, it has become vital to obtain detailed, quantitative information about the damage in the patients being studied. In addition, single-case studies are not nearly as useful as group studies involving well-characterized patients. In the case of patients with restricted hippocampal damage, one can calculate the volume of the hippocampus itself as a proportion of total intracranial volume. One can also calculate the volumes of the adjacent medial temporal lobe structures (the perirhinal, entorhinal, and parahippocampal cortices) in proportion to intracranial volume. Last, when there is extensive damage to the medial temporal lobe, it is important to calculate the volumes of lateral temporal cortex and other regions that might be affected. It is important to characterize patients in this way in order to address the kinds of questions now being pursued in studies of memory and the brain.

Functional MRI (fMRI) of healthy individuals who are engaged in learning and remembering allows one to ask what brain areas are associated with these memory processes. The same tasks that are administered to amnesic patients can also be administered to healthy individuals while their brain activation is measured. FMRI reveals activation during these tasks of learning and remembering in the same structures that, when damaged, cause amnesia.

To understand the anatomy of human amnesia, and ultimately the anatomy of normal memory, animal models of human amnesia have been established in the monkey (**Figure 1**) and in the rodent. An animal

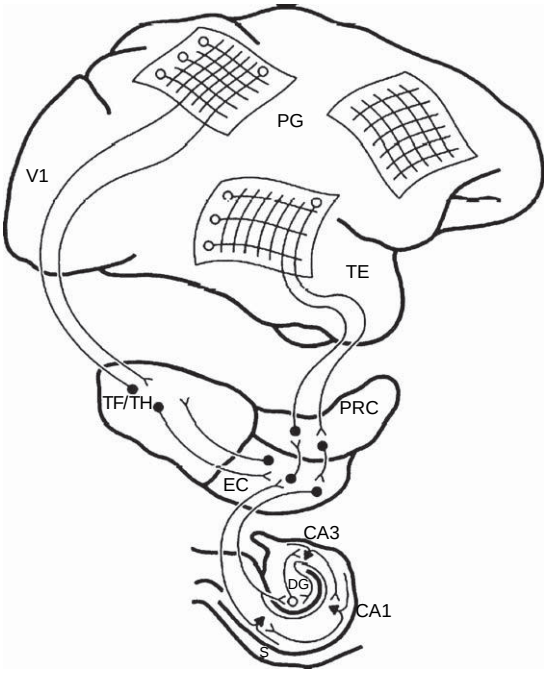

Figure 1 Schematic drawing of primate neocortex together with the structures and connections in the medial temporal region important for establishing long-term memory. The networks in the cortex show putative representations concerning visual object quality (in area TE) and object location (in area PG). If this disparate neural activity is to cohere into a stable, long-term memory, convergent activity must occur along projections from these regions to the medial temporal lobe. Projections from neocortex arrive initially at the parahippocampal gyrus (TF/TH) and perirhinal cortex (PRC) and then at entorhinal cortex (EC), the gateway to the hippocampus. Further processing of information occurs in the several stages of the hippocampus, first in the dentate gyrus (DG) and then in the CA3 and CA1 regions. The fully processed input eventually exits this circuit via the subiculum (S) and the entorhinal cortex, where widespread efferent projections return to neocortex. The hippocampus and adjacent structures are thought to support the stabilization of representations in distributed regions of neocortex (e.g., TE and PG) and to support the strengthening of connections between these regions. Subsequently, memory for a whole event (e.g., a memory that depends on representations in both TE and PG) can be revivified even when a partial cue is presented. Damage to the medial temporal lobe system causes anterograde and retrograde amnesia. The severity of the deficit increases as damage involves more components of the system. Once sufficient time has passed, the distributed representations in neocortex can operate independently of the medial temporal lobe. (This diagram is a simplification and does not show diencephalic structures involved in memory function.)

model of human amnesia was established in the monkey in the early 1980s (Mishkin, 1982; Squire and Zola-Morgan, 1983). Following lesions of the bilateral medial temporal lobe or diencephalon, memory impairment is exhibited on the same kinds of tasks of new learning ability that human amnesic patients fail. The same animals succeed at tasks of motor skill learning. They also do well at learning pattern discriminations, which share with motor skills the factors of incremental learning and repetition over many trials.

Systematic and cumulative work in monkeys, using the animal model, succeeded in identifying the system of structures in the medial temporal lobe essential for memory (Squire and Zola-Morgan, 1991). The important structures are the hippocampal region (hippocampus proper, dentate gyrus, and subicular complex) and adjacent, anatomically related structures (entorhinal cortex, perirhinal cortex, and parahippocampal cortex). The amygdala, although critical for aspects of emotional learning (Davis, 1994; LeDoux, 1996) and for the enhancement of declarative memory by emotion (Adolphs et al., 1997), is not a part of the declarative memory system itself. The consistency between the available neuroanatomical information from humans and the findings from monkeys have considerably illuminated the description of memory impairment and its anatomical basis. These lines of work have also made it possible to pursue parallel studies in simpler animals like rats and mice. As a result, one can now study memory in rodents and have some confidence that what one learns will be relevant to the human condition.

Anatomical connections from different parts of the neocortex enter the medial temporal lobe at different points (Suzuki and Amaral, 1994a, b), which raises the question of whether these medial temporal lobe structures play different roles in declarative memory. For example, visual association cortex projects more strongly to the perirhinal cortex than to the parahippocampal cortex, whereas the parietal cortex projects to the parahippocampal cortex but not to the perirhinal cortex. Further, the hippocampus lies at the end of the medial temporal lobe system and is a recipient of convergent projections from each of the structures that precedes it in the hierarchy. The possibility that different medial temporal lobe structures make different contributions to memory has been addressed in a number of studies in monkeys, comparing performance on memory tasks following damage to different components of the medial temporal lobe. This work has shown that the severity of memory impairment depends on the locus and extent of damage within the medial temporal lobe memory system. Damage limited to the hippocampal region causes significant memory impairment, but damage to the adjacent cortex increases the severity of memory impairment. It is also important to note that the discovery that larger medial temporal lobe lesions produce more severe amnesia than smaller lesions is compatible with the idea that structures within the medial temporal lobe might make qualitatively different contributions to memory function. Indeed, damage to the perirhinal cortex especially impairs object recognition, whereas damage to the parahippocampal cortex especially impairs spatial memory.

Another important brain area for memory is the diencephalon. The important structures include the mediodorsal thalamic nucleus, the anterior thalamic nucleus, the internal medullary lamina, the mamillary nuclei, and the mammillo-thalamic tract. Monkeys with medial thalamic lesions exhibit an amnesic disorder, and monkeys with mammillary nucleilesious exhibit a modest impairment. Because diencephalic amnesia resembles medial temporal lobe amnesia in the pattern of sparing and loss, these two regions likely form an anatomically linked, functional system.

3.04.4 The Nature of Amnesia

Amnesic individuals exhibit significant memory impairment. Yet, despite their memory deficit, patients have intact ability for some forms of new learning and memory (see section 3.04.5.2). Also, they have intact immediate memory and memory for a great deal of information from the past, especially childhood. In addition, patients with neurological amnesia can have intact intelligence test scores, intact language and social skills, and intact perceptual abilities. In fact, amnesic patients can appear quite normal on casual observation. It is only when one interrogates their capacity for new learning of conscious knowledge that the impairment becomes evident.

3.04.4.1 Impairment in Declarative Memory

It is important to appreciate that amnesic patients are not impaired at all kinds of long-term memory. The major distinction is between declarative and nondeclarative memory. Declarative memory is the kind of memory impaired in amnesia. Declarative memory refers to the capacity to remember the facts and events of everyday life. It is the kind of memory that is meant when the term 'memory' is used in ordinary language. Declarative memory can be brought to mind as a conscious recollection. Declarative memory provides a way to model the external world, and in this sense it is either true or false. The stored representations are flexible in that they are accessible to multiple response systems and can guide successful performance under a wide range of test conditions. Last, declarative memory is especially suited for rapid learning and for forming and maintaining associations between arbitrarily different kinds of material (e.g., learning to associate two different words).

3.04.4.2 Anterograde Amnesia

Amnesia is characterized especially by profound difficulty in new learning, and this impairment is referred to as anterograde amnesia. Amnesia can occur as part of a more global dementing disorder that includes other cognitive deficits such as impairments in language, attention, visuospatial abilities, and general intellectual capacity. However, when damage is restricted to the medial temporal lobe or midline diencephalon, amnesia can also occur in the absence of other cognitive deficits and without any change in personality or social skills. In this more circumscribed form of amnesia, patients have intact intellectual functions and intact perceptual functions, even on difficult tests that require the ability to discriminate between highly similar images containing overlapping features (Levy et al., 2005; Shrager et al., 2006). In some patients with memory impairment,

visual perceptual deficits have been described (Lee et al., 2005a,b). In these cases, damage might extend laterally, beyond the medial temporal lobe, and quantitative brain measurements are needed in order to understand what underlies these deficits. Thus, present data support the idea that declarative memory is separable from other brain functions.

Amnesic patients are impaired on tasks of new learning, regardless of whether memory is tested by free (unaided) recall, recognition (e.g., presenting an item and asking whether it was previously encountered or not), or cued recall (e.g., asking for recall of an item when a hint is provided). For instance, in a standard test of free recall, participants are read a short prose passage containing 21 segments. They are then asked to recall the passage immediately and after a 12-min delay. Amnesic patients with damage to the medial temporal lobe do well at immediate recall but are impaired at the delay, usually recalling zero segments (Squire and Shimamura, 1986). Amnesic patients are also impaired on recognition tests, where a list of words is presented and participants try to decide (yes or no) if each word had been presented in a recent study list (Squire and Shimamura, 1986). Last, in a cued recall task, individuals study a list of word pairs, such as ARMY–TABLE. During test, they are presented with one word from each pair (ARMY), and they are asked to recall the word that was paired with it (TABLE). Amnesic patients are impaired on this task as well.

The memory impairment in amnesia involves both difficulty in learning factual information (semantic memory) as well as difficulty in learning about specific episodes and events that occurred in a certain time and place (episodic memory). The term 'semantic memory' is often used to describe declarative memory for organized world knowledge (Tulving, 1983). In recalling this type of information, one need not remember any particular past event. One needs only to know about certain facts. Episodic memory, in contrast, is autobiographical memory for the events of one's life (Tulving, 1983). Unlike semantic memory, episodic memory stores spatial and temporal landmarks that identify the particular time and place when an event occurred. Both episodic memory and semantic memory are declarative.

Formal experiments have compared directly the ability to accomplish fact learning (or semantic memory ability) and event learning (or episodic memory ability). In one experiment, amnesic patients were taught new factual knowledge in the form of three-word sentences (e.g., MEDICINE cured HICCUP). Then, during testing, sentence fragments were presented with the instruction to complete each fragment with a word that had been studied (e.g., MEDICINE cured _____). The amnesic patients were similarly impaired on tests of fact memory (what word completed the sentence fragment) and on tests of event memory (what specific events occurred during the testing session) (Hamann and Squire, 1995). Taken together, the data favor the view that episodic memory and semantic memory are similarly impaired in amnesia (Squire and Zola, 1998). Semantic knowledge is thought to accumulate in cortical storage sites as a consequence of experience and with support from the medial temporal lobe. In contrast, episodic memory is thought to require these cortical sites and the medial temporal lobes to work together with the frontal lobes in order to store when and where a past experience occurred (Janowsky et al., 1989).

Last, the memory deficit in amnesia is global and encompasses all sensory modalities (e.g., visual, auditory, olfactory). That is, memory is impaired regardless of the kind of material that is presented and the sensory modality in which information is presented. For example, recognition memory of amnesic patients was assessed for line drawings of objects (visual), designs (visual), and odors (olfactory) (Levy et al., 2004). The patients were impaired on all three tasks, showing that their impairment spans the visual and olfactory domains. Formal experiments have also demonstrated recognition memory impairment for auditory stimuli.

3.04.4.3 Remembering versus Knowing and Recollection versus Familiarity

Remembering (R) is meant to refer to the circumstance when an item elicits a conscious recollection that includes information about the context in which the item was learned. Knowing (K) is meant to refer to a circumstance when an item appears familiar, but memory for the original learning context is not available (*See* Chapter 2.17; Tulving, 1985). Thorough studies of healthy individuals indicate that in practice, remembering and knowing responses are closely related to the strength of a memory and that items given K responses are often items for which information is also available about the original learning context (Wixted and Stretch, 2004). In any case, formal studies show that both R and K responses are impaired in amnesia. In one such experiment, amnesic patients and control participants were given a

recognition test 10 min after studying words. For each word, participants indicated whether they remembered it (R) or whether they knew that the word was presented but had no recollection about it (K). The patients were impaired for both R and K responses, and they performed like a control group that was tested after 1 week. That is, the patients were similarly impaired for R and K responses (Knowlton and Squire, 1995; also see Manns et al., 2003). Accordingly, the evidence suggests that remembering and knowing are two different expressions of declarative memory.

A distinction closely related to remembering and knowing is recollection and familiarity. Recollection involves remembering the contextual associations of the original learning experience, whereas familiarity does not require any recollection of the original experience. It has sometimes been proposed that recollection relies on the hippocampus, while familiarity can be supported by the adjacent cortex within the medial temporal lobe. In this view, patients with damage limited to the hippocampus should be selectively, or disproportionately, impaired at recollecting information and less impaired at recognizing material when it can be supported by familiarity.

An alternative view is that recognition decisions are based on a unidimensional strength-of-memory variable that combines estimates of recollection and familiarity. Thus, as in the case of remembering and knowing, a capacity for recollection is likely to be associated with strong memories and familiarity with weaker memories (Wixted, 2007). In one study, patients with hippocampal damage were impaired on a recognition memory test, where they gave confidence judgments (scale of 1–6). The results indicated that both processes, recollection and familiarity, were operative in the absence of the hippocampus (Wais et al., 2006). Last, electrophysiological recordings from patients being evaluated for epilepsy surgery found neurons in the hippocampus that responded to familiar images during a recognition test. These familiarity signals were present even when recollection failed (i.e., there was a familiarity signal in the hippocampus regardless of whether any recollection had occurred) (Rutishauser et al., 2006).

3.04.4.4 Retrograde Amnesia

In addition to impaired new learning, damage to the medial temporal lobe also impairs memories that were acquired before the onset of amnesia. This type of memory loss is referred to as retrograde amnesia. Retrograde amnesia is usually temporally graded. That is, information acquired in the distant past (remote memory) is spared relative to more recent memory (Ribot, 1881). The extent of retrograde amnesia can be relatively short and encompass only 1 or 2 years, or it can be more extensive and cover decades. Even then, memories for the facts and events of childhood and adolescence are typically intact. Indeed, severely amnesic patients can produce detailed autobiographical narratives of their early life. These memories were indistinguishable from the memories of healthy individuals with respect to the number of details, the duration of the narratives, and the number of prompts needed to begin a narrative (Bayley et al., 2003, 2005b).

The severity and extent of retrograde amnesia is determined by the locus and extent of damage. Patients with restricted hippocampal damage have limited retrograde amnesia covering a few years prior to the onset of amnesia. Patients with large medial temporal lobe damage have extensive retrograde amnesia covering decades. When damage occurs beyond the brain system that supports declarative memory, which can result from conditions such as encephalitis and head trauma, retrograde amnesia sometimes can be ungraded and extensive and include the facts and events of early life.

Because the study of human retrograde amnesia is based almost entirely on findings from retrospective tests, the clearest data about retrograde amnesia gradients come from studies using experimental animals, where the delay between initial learning and a lesion can be manipulated directly. Findings from such studies make three important points. First, temporal gradients of retrograde amnesia can occur within long-term memory. That is, retrograde amnesia does not reflect simply the vulnerability of a short-term memory that has not yet been converted into a long-term memory. Second, after a lesion, remote memory can be even better than recent memory. Third, lesions can spare old weak memories while disrupting strong recent ones, showing that it is the age of the memory that is critical.

These same points can be illustrated by a study of rabbits given trace eyeblink conditioning. Trace conditioning is a variant of classical conditioning in which the condition stimulus (CS), such as a tone, is presented and terminated, and then a short interval (e.g., 500 ms) is imposed before the presentation of the unconditioned stimulus (US). In normal rabbits, forgetting occurs gradually after training, and retention of the conditioned response is much poorer

30 days after training than after only 1 day. Nevertheless, complete aspiration of the hippocampus 1 day after training abolished the strong 1-day-old memory, whereas the same lesion made 30 days after training had no effect on the weaker 30-day-old memory (Kim et al., 1995).

The sparing of remote memory relative to more recent memory illustrates that the brain regions damaged in amnesia are not the permanent repositories of long-term memory. Instead, memories undergo a process of reorganization and consolidation after learning, during which time the neocortex becomes more important. During the process of consolidation, memories are vulnerable if there is damage to the medial temporal lobe or diencephalon. After sufficient time has passed, storage and retrieval of memory no longer require the participation of these brain structures. Memory is at that point supported by neocortex. The areas of neocortex important for long-term memory are thought to be the same regions that were initially involved in the processing and analysis of what was to be learned. Thus, the neocortex is always important, but the structures of the medial temporal lobe and diencephalon are also important during initial learning and during consolidation.

3.04.4.5 Spatial Memory

Since the discovery of hippocampal place cells in the rodent (O'Keefe and Dostrovsky, 1971), an influential idea has been that the hippocampus creates and uses spatial maps and that its predominant function is to support spatial memory (*See* Chapter 2.11; O'Keefe and Nadel, 1978). Discussions of amnesia have therefore focused especially on the status of spatial memory. It is clear that spatial memory is impaired in human amnesia. Amnesic patients are impaired on tests that assess their knowledge of the spatial layout of an environment, and they are also impaired when asked to navigate to a destination in a virtual environment (Maguire et al., 1996; Spiers et al., 2001). Similarly, the noted patient H.M. was impaired at recalling object locations (Smith, 1988). It is also clear, though, that amnesic patients are impaired on memory tests that have no obvious spatial component, such as recall or recognition of items (Squire and Shimamura, 1986). Furthermore, formal experiments that directly compared spatial and nonspatial memory in amnesic patients showed that the patients were similarly impaired on tests of spatial memory and tests of nonspatial memory. There was no special difficulty with the test of spatial memory (Cave and Squire, 1991).

As is the case with nonspatial memory, remote spatial knowledge is intact. One well-studied patient with large medial temporal lobe lesions and severe amnesia (E.P.) was able to mentally navigate his childhood neighborhood, use alternate and novel routes to describe how to travel from one place to another, and point correctly to locations in the neighborhood while imagining himself oriented at some other location (Teng and Squire, 1999). These findings show that the medial temporal lobe is not needed for the long-term storage of spatial knowledge and does not maintain a spatial layout of learned environments that is necessary for successful navigation. Accordingly, the available data support the view that the hippocampus and related medial temporal lobe structures are involved in learning new facts and events, both spatial and nonspatial. Further, these structures are not repositories of long-term memory, either spatial or nonspatial.

3.04.5 Spared Learning and Memory Abilities

It is a striking feature of amnesia that many kinds of learning and memory are spared. Memory is not a unitary faculty of the mind but is composed of many parts that depend on different brain systems. Amnesia impairs only long-term declarative memory and spares immediate and working memory, as well as nondeclarative memory. Immediate memory and working memory can be viewed as a collection of temporary memory capacities that operate shortly after material is presented. Nondeclarative memory refers to a heterogeneous collection of abilities, all of which afford the capacity to acquire knowledge nonconsciously. Nondeclarative memory includes motor skills, perceptual and cognitive skills, priming, adaptation-level effects, simple classical conditioning, habits, and phylogenetically early forms of experience-dependent behavior like habituation and sensitization. In these cases, memory is expressed through performance rather than recollection.

3.04.5.1 Immediate and Working Memory

Amnesic patients have intact immediate memory. Immediate memory refers to what can be held actively in mind beginning the moment that information is received. It is the information that forms the focus of

current attention and that occupies the current stream of thought. The capacity of immediate memory is quite limited. This type of memory is reflected, for example, in the ability to repeat back a short string of digits. Intact immediate memory explains why amnesic patients can carry on a conversation and appear quite normal to the casual observer. Indeed, if the amount of material to be remembered is not too large (e.g., a three-digit number), then patients can remember the material for minutes, or as long as they can hold it in mind by rehearsal. One would say in this case that the patients have carried the contents of immediate memory forward by engaging in explicit rehearsal. This rehearsal-based activity is referred to as working memory, and it is independent of the medial temporal lobe system (*See* Chapter 2.04). The difficulty for amnesic patients arises when an amount of information must be recalled that exceeds immediate memory capacity (typically, when a list of eight or more items must be remembered) or when information must be recalled after a distraction-filled interval or after a long delay. In these situations, when the capacity of working memory is exceeded, patients will remember fewer items than their healthy counterparts.

The intact capacity for immediate and working memory was well illustrated by patient H.M. when he was asked to remember the number 584. H.M. was left to himself for several minutes, and he was able to retain this information by working out mnemonic schemes and holding the information continuously in mind. Yet, only a minute or two later, after his attention had been directed to another task, he could not remember the number or any of his mnemonic schemes for holding the number in mind.

3.04.5.2 Nondeclarative Memory

Nondeclarative memory refers to a collective of nonconscious knowledge systems, but it is not itself a brain-systems construct. Rather, the term encompasses several different kinds of memory. Nondeclarative forms of memory have in common the feature that memory is nonconscious. Memory is expressed through performance and does not require reflection on the past or even the knowledge that memory is being influenced by past events.

The following examples illustrate that nondeclarative memory is distinct from declarative memory. It is spared in amnesia, and it operates outside of awareness. Nondeclarative forms of memory depend variously on the neostriatum, the amygdala, and the cerebellum and on processes intrinsic to neocortex (**Figure 2**).

3.04.5.2.1 Motor Skills and Perceptual Skills

One can learn how to ride a bicycle but be unable to describe what has been learned, at least not in the same sense that one might recall riding a bicycle on a particular day with a friend. This is because the learning of motor skills is largely nondeclarative, and amnesic

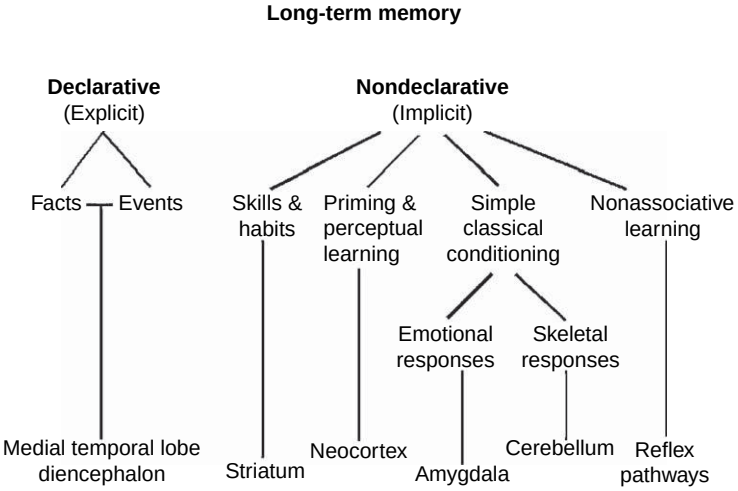

Figure 2 Classification of mammalian long-term memory systems. The taxonomy lists the brain structures thought to be especially important for each form of declarative and nondeclarative memory. In addition to the central role of the amygdala in emotional learning, it is also able to modulate the strength of both declarative and nondeclarative learning.

patients can learn these skills at a normal rate. In one experiment, amnesic patients and control participants performed a serial reaction-time task, in which they responded successively to a sequence of four illuminated spatial locations. The task was to press one of four keys as rapidly as possible as soon as the location above each key was illuminated. The amnesic patients learned the sequence, as did the normal participants, as measured by their decreased reaction times for pressing a key when it was illuminated. When the sequence was changed, the reaction times increased for both groups. Strikingly, the amnesic patients had little or no declarative knowledge of the sequence, though they had learned it normally (Reber and Squire, 1994).

Perceptual skills are also often intact in amnesic patients. These include such skills as reading mirror-reversed print and searching a display quickly to find a hidden letter. In formal experiments, amnesic patients acquired perceptual skills at the same rate as individuals with intact memory, even though the patients did not remember what items were encountered during the task and sometimes did not remember the task itself. For example, amnesic patients learned to read mirror-reversed words at a normal rate and then retained the skill for months. Yet, after they had finished the mirror-reading task, they could not remember the words that they had read, and in some cases they could not remember that they had ever practiced the mirror-reading skill on a previous occasion (Cohen and Squire, 1980).

3.04.5.2.2 Artificial Grammar Learning

Another kind of learning that is intact in amnesia is the learning of artificial grammars. In an artificial grammar–learning task, participants are presented with a series of letter strings that are generated according to a rule system that specifies what letter sequences are permissible. After viewing these letter strings, participants are told for the first time that the letter strings were formed according to a set of rules and that their task is to decide for a new set of letter strings whether each one is formed by the same set of rules as the set they had just studied. Even though individuals often report that they are simply guessing, they are able to classify new letter strings as grammatical or nongrammatical. Amnesic patients classify items as grammatical or nongrammatical as well as healthy individuals, despite being impaired at recognizing the letter strings that were used during the initial training (Knowlton et al., 1992; Knowlton and Squire, 1994, 1996).

3.04.5.2.3 Category Learning

In tasks involving category learning, participants are exposed to several exemplars of a single category. Then, participants try to classify new items according to whether they are or are not members of that category. In addition, participants identify the prototype, or central tendency of the category, as a member of the learned category more readily than the items used during training, even when the prototype itself was not presented. Amnesic patients are also able to classify items according to a learned category, despite a severe deficit in recognizing the items that were used to train the category (Knowlton and Squire, 1993). In one experiment, amnesic patients and control participants were shown a series of dot patterns formed by distorting a randomly generated pattern that was defined arbitrarily as the prototype of the category. Having seen a series of dot patterns, all of which were distortions of an underlying prototype, participants then were able to discriminate new dot patterns that belonged to the training category from other dot patterns that did not. Amnesic patients performed as well as control participants, even though the patients were severely impaired at recognizing which dot patterns had been presented for training. It is worth noting that it has been suggested that a model assuming a single memory system was able to account for the dissociation between categorization and recognition (Nosofsky and Zaki, 1998).

3.04.5.2.4 Priming

Priming refers to an improved ability to identify or produce a word or other stimulus as a result of its prior presentation (*See* Chapter 3.12). The first encounter with an item results in a representation of that item, and that representation then allows it to be processed more efficiently than items that were not encountered recently. For example, suppose that line drawings of a dog, hammer, and airplane are presented in succession, with the instruction to name each item as quickly as possible. Typically, about 800 ms are needed to produce each name aloud. If in a later test these same pictures are presented intermixed with new drawings, the new drawings will still require about 800 ms to name, but now the dog, hammer, and airplane are named about 100 ms more quickly. The improved naming time occurs independently of whether one remembers having seen the items earlier. Amnesic patients exhibit this effect at full strength, despite having poor memory of seeing the items earlier.

The dissociation between intact priming and impaired recognition memory in amnesic patients can be particularly compelling. One study investigated priming in patient E.P., who is so severely amnesic that he exhibits no detectable declarative memory (Hamann and Squire, 1997). E.P. sustained complete bilateral damage to the medial temporal lobe as the result of herpes simplex encephalitis. Two tests of priming were given. In one of the priming tests, word stem completion, participants were shown a short word list, which included, for example, the words MOTEL and ABSENT. Then, they were shown the fragments MOT___ and ABS___, with instructions to form the first word that comes to mind. Participants had a strong tendency (30–50%) to produce the words that were recently presented. (The probability was about 10% that participants would produce these words if they had not been presented recently.) In addition, two parallel tests of recognition memory for words were given: alternative forced-choice and yes–no recognition. E.P. performed entirely normally on the two priming tests but performed at chance (50%) on the recognition tests.

In another experiment, participants saw words slowly clearing from a mask. They tried to identify each word as quickly as possible and then make a recognition judgment (old/new) about whether the word had been presented in a preceding study phase. Amnesic patients exhibited intact fluency (the tendency to label those words that were identified more quickly as old) and intact priming, but their recognition was impaired (Conroy et al., 2005). These results support the idea that priming depends on brain structures independent of the medial temporal lobe, and they show that the combined effects of priming and fluency are not sufficient to increase recognition performance.

3.04.5.2.5 Adaptation-Level Effects

Adaptation-level effects refer to the finding that experience with one set of stimuli influences how a second set of stimuli is perceived (e.g., their heaviness or size). For example, experience with light-weighted objects subsequently causes other objects to be judged as heavier than they would be if the light-weighted objects had not been presented. Amnesic patients show this effect to the same degree as healthy individuals, even when they experience the first set of objects with one hand and then make judgments with the other hand. However, they have difficulty remembering their prior experience accurately (Benzing and Squire, 1989).

3.04.5.2.6 Classical Conditioning

Classical conditioning refers to the development of an association between a previously neutral stimulus (CS) and an unconditioned stimulus (US), and is a quintessential example of nondeclarative memory. One of the best-studied examples of classical conditioning in humans is delay conditioning of the eyeblink response. It is reflexive and automatic and depends solely on structures below the forebrain, including the cerebellum and associated brainstem circuitry (Thompson and Krupa, 1994). In a typical conditioning procedure, a tone repeatedly precedes a mild airpuff directed to the eye. After a number of pairings, the tone comes to elicit an eyeblink in anticipation of the airpuff. Amnesic patients acquire and retain the tone–airpuff association at the same rate as healthy individuals. In both groups, awareness of the temporal contingency between the tone and the airpuff is unrelated to successful conditioning.

In trace conditioning, a brief interval of 500–1000 ms is interposed between the CS and the US. This form of conditioning requires the hippocampus (McGlinchey-Berroth et al., 1997). Formal experiments suggest that trace conditioning is hippocampus dependent because it requires the acquisition and retention of conscious knowledge during the course of the conditioning session (Clark and Squire, 1998). Only those who became aware of the CS-US relationship acquired differential trace conditioning. There was a correlation between measures of awareness taken after the conditioning and trace conditioning performance itself, whereas there was no correlation between awareness and conditioning performance on a delay conditioning task.

3.04.5.2.7 Habit Learning

Habit learning refers to the gradual acquisition of associations between stimuli and responses, such as learning to make one choice rather than another. Habit learning depends on the neostriatum (basal ganglia). Many tasks can be acquired either declaratively, through memorization, or nondeclaratively as a habit. For example, healthy individuals will solve many trial-and-error learning tasks quickly by simply engaging declarative memory and memorizing which responses are correct. In this circumstance, amnesic patients are disadvantaged. However, tasks can also be constructed that defeat memorization

strategies, for example, by making the outcomes on each trial probabilistic. In such a case, amnesic patients and healthy individuals learn at the same gradual rate (Knowlton et al., 1992).

It is also true that severely amnesic patients who have no capacity for declarative memory can gradually acquire trial-and-error tasks, even when the task can be learned declaratively by healthy individuals. In this case they succeed by engaging habit memory. This situation is nicely illustrated by the eight-pair concurrent discrimination task, which requires individuals to learn the correct object in each of eight object pairs. Healthy individuals can learn all eight pairs in one or two test sessions. Severely amnesic patients acquire this same task over many weeks, even though at the start of each session they cannot describe the task, the instructions, or the objects. It is known that this task is acquired at a normal (slow) rate by monkeys with medial temporal lobe lesions, and that monkeys with lesions of the neostriatum (basal ganglia) are impaired. Thus, humans appear to have a robust capacity for habit learning that operates outside of awareness and independently of the medial temporal lobe structures that are damaged in amnesia (Bayley et al., 2005a).

3.04.6 Functional Amnesia

Functional amnesia, also known as dissociative amnesia, is a dissociative psychiatric disorder that involves alterations in consciousness and identity. Although no particular brain structure or brain system is implicated in functional amnesia, the cause of the disorder must be due to abnormal brain function of some kind. Its presentation varies considerably from individual to individual, but in most cases functional amnesia is preceded by physical or emotional trauma and occurs in association with some prior psychiatric history. Often, the patient is admitted to the hospital in a confused or frightened state. Memory for the past is lost, especially autobiographical memory and even personal identity (*See* Chapter 2.46). Semantic or factual information about the world is often preserved, though factual information about the patient's life may be unavailable. Despite profound impairment in the ability to recall information about the past, the ability to learn new information is usually intact. The disorder often clears, and the lost memories return. Sometimes, the disorder lasts longer, and sizable pieces of the past remain unavailable.

3.04.7 Summary

The study of amnesia has helped to understand the nature of memory disorders and has led to a better understanding of the neurological foundations of memory. Experimental studies in patients, neuroimaging studies of healthy volunteers, and related studies in experimental animals continue to reveal insights about what memory is and how it is organized in the brain. As more is learned about the neuroscience of memory, and about how memory works, more opportunities will arise for achieving better diagnosis, treatment, and prevention of diseases and disorders that affect memory.

3.05 Neural Substrates of Remembering – Electroencephalographic Studies

J. L. Voss and K. A. Paller, Northwestern University, Evanston, IL, USA

3.05.1 Introduction

3.05.1.1 Memory Subtypes

Remembering does not refer to a unitary ability. Rather, remembering can be fractionated into a set of component processes that are expressed in different combinations under different circumstances. Analyses of memory in healthy individuals and in patients with memory impairments have revealed a set of distinct memory functions that can be assessed using different memory tests. Various theoretical schemes have been used to categorize the memory phenomena measured in these tests, emphasizing either behavioral, cognitive/representational, neural, or subjective criteria (*See* Chapter 3.02 for an overview). Taxonomies of memory have thus helped to guide research into fundamental questions about memory. Beyond taxonomies, however, we must seek a comprehensive understanding of memory by describing the component processes in both cognitive and neural terms, by clarifying the relationships between cognitive and neural descriptions, and by showing how neurocognitive processes produce memory behavior and associated conscious experiences.

Amnesic patients have specific impairments in declarative memory, the ability to remember facts and events from the past, as assessed in recall and recognition tests. In contrast, other categories of memory phenomena, as listed in **Table 1**, are not impaired in amnesia (*See* Chapters 2.33, 3.04, and 3.12). Expressions of declarative memory tend to coincide with the potential for making the metamemory judgment that memory is being expressed – the awareness of remembering. For these reasons, declarative memory is usually regarded as fundamentally distinct from other expressions of memory.

Information can also be held in awareness for an extended period of time, while rehearsed and/or manipulated. Nonetheless, our emphasis here is on memory phenomena that take place when information that was initially encoded is later brought back to mind after a delay, which is what William James (1890: 648) termed secondary memory. (For a summary of research on primary memory or working memory, *See* Chapter 3.13.)

The neural substrates of remembering can be examined in healthy human volunteers using a variety of noninvasive neuroimaging techniques. In

Table 1 A memory taxonomy based on findings in amnesic patients

Type of memory	*Behavioral outcome*	*Findings in patients with amnesia*
Declarative memory	Recall and recognition of episodes and facts (i.e., episodic memory and semantic memory)	Impaired storage, causing deficits in new learning and in remembering information acquired prior to onset of amnesia
Immediate memory	Information available while kept in mind by continuous rehearsal (e.g., verbal working memory)	Preserved if performance is not supported in part by retrieving declarative memories for the rehearsed information
Nondeclarative memory (a large category that includes nonassociative learning, classical conditioning, category learning, habit learning, as well as the following)		Generally preserved, but with some notable exceptions
Perceptual priming	Speeded or more accurate responses in a priming test, based on item-specific or perceptual representations	Preserved if performance is not contaminated by declarative memory
Conceptual priming	Speeded or more accurate responses in a priming test, based on association-specific or conceptual representations	Preserved in some cases, but further investigation is required, particularly across stimulus domains
Skills	Behaviors that improve gradually with practice, including cognitive skills (e.g., reading mirror-reversed text) and motor skills	Preserved when skill acquisition is accomplished without reliance on declarative memory (i.e., not most skills learned outside laboratory circumstances)

particular, recordings of event-related potentials (ERPs) have been used to monitor the activity of the brain during memory tasks. These experiments have made significant headway in identifying neurocognitive processes that are responsible for memory and in specifying processes engaged in association with different memory feats.

Our goal in this chapter is to examine how ERP research has shed light on various processes. We emphasize memory processes that contribute to declarative memory, but we also include the related memory phenomena of priming (see the section titled 'Using ERPs to contrast memory subtypes'), given that dissociations between priming and declarative memory have provided important clues about why declarative memory is distinctive.

3.05.1.2 The ERP Technique

Neurons in the human brain generate electric fields that vary moment to moment. When these electric fields are sampled via recording electrodes connected to an amplifier system, the resultant electroencephalographic record – the EEG – shows voltage changes over time and can provide indications of the functioning of networks of neurons as cognitive processing unfolds. EEG recordings from electrodes placed on the scalp are used in a variety of clinical and research contexts.

To examine EEG activity associated with stimulus processing, signal-averaging methods applied to EEG recordings can be used to produce ERPs. Whereas ongoing EEG signals can vary in magnitude on the order of tens of microvolts over a few seconds, ERPs can be extracted so as to observe signals much smaller than 1 μV. When a set of EEG responses that are time-locked to a particular class of stimuli is averaged in this way, EEG signals unrelated to stimulus processing tend to decrease because they do not occur at a consistent time relative to the time of stimulus onset. ERPs thus reveal electrical signals produced during the course of stimulus processing, to the extent that such signals are not averaged out due to temporal variability. Signal averaging can be performed with respect to any class of repeated event occurring at a known time. ERPs elicited by stimulus events are viewed as a time series of voltage changes following stimulus onset, which is conventionally referred to as

'time 0.' ERP waveforms thus consist of a series of positive and negative deflections, the timing and waveshape of which vary with the nature of the stimuli and the neural operations performed in response to the stimuli. Some ERPs, such as the brainstem auditory evoked potentials produced during the first 10 ms after a click, have very small amplitudes and require hundreds of stimulus repetitions to obtain a signal-to-noise ratio sufficiently high to permit reliable quantification. Other ERPs, such as some associated with cognitive processing, can be several microvolts in amplitude and occur over a time interval of several hundreds of milliseconds. Typically, averaging over 30–100 stimulus events is required to observe reliable effects of experimental variables in psychological experiments, depending on the amplitude and reliability of the EEG signals in question and on the presence of other EEG signals and EEG artifacts of various sorts (for further methodological details, see Rugg and Coles, 1995; Luck, 2005).

ERPs can be most readily measured by examining the positive and negative deflections (peaks and troughs) that occur at various poststimulus time points. However, the entire waveform is most likely composed of the summation of neural activity from many distinct sets of neurons in the service of many different functions. Ideally, a complex ERP waveform would be decomposed into a series of ERP components, each bearing a unique and systematic relationship to a unitary neurocognitive function. In practice, however, the component structure of an ERP waveform is difficult to discern. Given this strict definition that requires a component to be identified with a unique neurocognitive function, it would be unwise to accept the assumption that each deflection corresponds to a particular component. There may be some cases when a hypothetical component may be adequately measured by examining a deflection. In other cases, deflections are based on the summation of multiple components, which themselves are unknown, such that the amplitude and latency of the composite peak does not provide a valid characterization of any of the individual components. Accordingly, the identification and measurement of specific ERP components can be problematic.

ERP waveforms can nonetheless be quantified in several different ways. Putative components can be identified based on a combination of factors, including latency, polarity, amplitude, distribution, and most importantly, relationships to experimental parameters. ERPs can also be quantified for specific latency intervals without making *a priori* assumptions about the components that might be present, but with an emphasis instead on differences between experimental conditions. When this approach is followed, the experimental manipulations play a critical role in focusing the analysis on neurocognitive functions that can be manipulated across conditions. Valid conclusions can be drawn based on such analyses, given that some conclusions are orthogonal to the challenge of determining whether specific aspects of the ERP display a convincing correspondence with ERP components that have been described previously. Although component identification can be informative, it may not be feasible in memory paradigms when a large number of components overlap with each other in the same time range. Indeed, when subjects engage a wide variety of cognitive transactions over an extended time interval, as is likely the case in many of the interesting paradigms cognitive neuroscientists choose to study, it can be misleading to assume that only a very small number of components have been produced. When a large number of ERP components occur simultaneously, specific ERP components cannot always be isolated from one another and separately characterized.

Accordingly, many ERP investigations in cognitive neuroscience no longer exemplify the strict component-centered approach, wherein a chief experimental goal was to understand an ERP component per se. Instead, difference-centered approaches have become prevalent, whereby experimental variables are manipulated based on theory-driven goals concerning specific neurocognitive functions. This shift from a focus on known ERP components to a focus on the thorough understanding of relationships between cognitive operations and neural events has facilitated a greater dialogue between ERP experimenters and those working with different methodologies. In the context of memory research, bringing together a variety of methods in cognitive neuroscience has been responsible for significant progress.

3.05.1.3 Characterizing ERPs

In ERP investigations of human memory functions, a central analysis question in any experiment is often to determine whether two ERPs differ reliably from one another. In other words, the experimenter may ask whether two or more hypothetical psychological processes are associated with reliably different electrical signals. Experimental contrasts are often based on comparing two conditions distinguished by a task manipulation, stimulus factors, response factors, or

some combination. A difference between ERPs can then be described and displayed (**Figure 1**).

An ERP difference may be statistically significant over a certain time interval. At any given latency, the difference can have a positive or negative polarity. Across a recording epoch, amplitude will vary with a particular wave shape. When an ERP difference between conditions is characterized in this manner, it may appear to correspond to a systematic enhancement of one ERP deflection over a discrete time interval, or it may appear to encompass a different time interval with a unique wave shape.

Another important facet of an ERP difference is the distribution of the potential field across multiple electrode locations on the scalp. This topographic information can help investigators make inferences regarding the responsible neural generators. Such inferences involve many assumptions. Models of electric currents and volume conduction of the head can be used to estimate the scalp topography that would be produced by activity at a certain location in the brain. Despite straightforward procedures for solving this so-called forward problem, the inverse problem of determining the brain sources based only on the scalp topography is not soluble, because many different configurations of intracranial generators can produce the same field on the scalp. Various ERP source-modeling procedures can nevertheless be used when considering the anatomical location of the sources of ERPs, although drawbacks of inferring brain sources based on scalp recordings have been heavily debated (McCarthy and Wood, 1985; Kutas and Dale, 1997; Urbach and Kutas, 2002; Wilding, 2006). When theorizing about ERP sources in the brain, it is therefore extremely helpful to bring multiple sources of evidence to bear on understanding the relevant brain structures or systems.

3.05.1.4 Advantages and Disadvantages of Using ERPs in the Study of Human Memory

ERP methods are noninvasive and relatively inexpensive compared to other neuroimaging methods. As just described, some limited information about relevant neural sources can be extracted from ERP distributions on the scalp. In most circumstances, other methods are preferable for precise neuroanatomical information. ERP waveforms comprise a time-series of voltages between a scalp electrode location and a reference electrode location, so both locations are relevant for determining ERP characteristics. Here we will emphasize results from

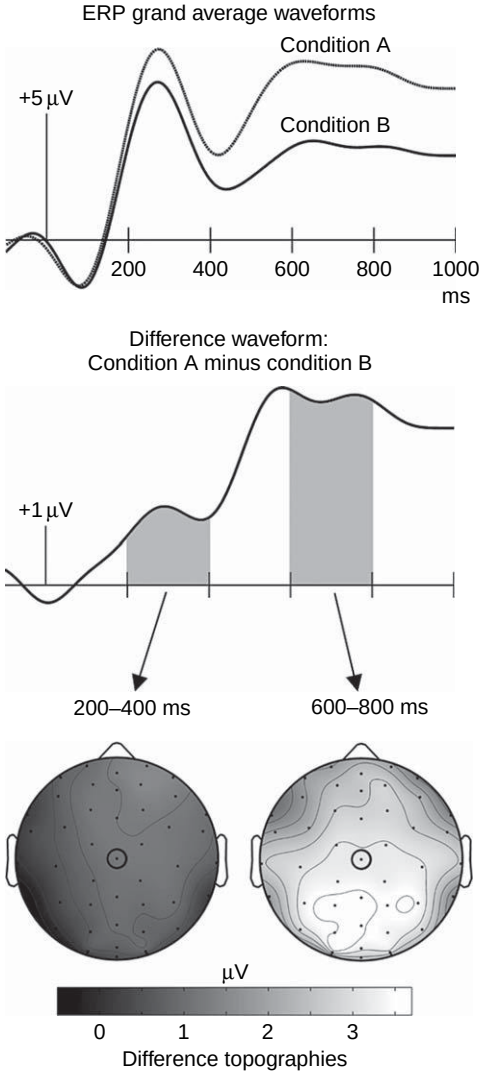

Figure 1 Visualizing ERPs. Waveforms averaged across experimental subjects for two experimental conditions, A and B, are considered at a single electrode (top). These waveforms are plotted with time shown on the x-axis going from left to right, and with voltage on the y-axis. Here, positive potentials are plotted in the upward direction, although some investigators plot amplitudes in the opposite manner. The time course of the difference in amplitude between these conditions can be visualized as a difference wave (middle), or by averaging over latency intervals of interest (gray shading) for many scalp locations and generating images of the voltage differences across the scalp (bottom). These topographic maps schematically represent the distribution of ERP differences between conditions A and B for the two latency intervals. The head is viewed from above, approximated by a circular shape, with anterior scalp regions toward the top. Black dots indicate the locations of recording electrodes. The black circle identifies the electrode location used for the waveforms shown. These images can thus demonstrate both temporal and spatial characteristics of an ERP effect.

recordings using a mastoid or average-mastoid reference, because this recording method is used in a majority of the relevant memory studies. Like any reference that can be used during recording or digitally created afterward, the mastoid reference is not inactive, as potentials generated near this location influence observed ERP effects in accordance with how currents are conducted through tissue to electrode locations.

Like other neuroimaging methods, ERPs do not provide a full view of neural activity. Rather, the EEG is sensitive to activity produced by a restricted set of neurons. These neurons are ones activated synchronously such that extracellular fields produced by their activity can summate. These fields must thus be generated by sets of neurons that are oriented together in such a way to produce electrical fields that will conduct to distant locations where recording electrodes are placed. Much neural activity may be electrically silent at the scalp, in the sense that the EEG may not include signals from some of the active neurons engaged in relevant processing.

A key advantage of ERP methods is that they provide measures of neural activity with very high temporal resolution. The superior temporal resolution of ERPs makes them well suited to examinations of neural events responsible for human memory, which can potentially be monitored by ERPs on a millisecond-by-millisecond basis. Critical memory processes often unfold within the first second after exposure to a stimulus, and ERPs can allow these processes to be resolved in real time and with randomized trial orders. Delivering trials in a predictable manner or blocking experimental trials, as required in positron emission tomography (PET) studies, can severely limit the range of memory phenomena amenable to examination. Extended intertrial intervals can also be undesirable to the extent that such procedures do not adequately constrain the timing of relevant cognitive events. In general, when cognitive events can be tightly time-locked to stimulus presentation and temporal blurring across trials decreased, ERP findings have better signal-to-noise ratios and arguably are most useful. Although randomized event-related designs with short intertrial intervals (Burock et al., 1998) are feasible with functional magnetic resonance imaging (fMRI), ERP signals may be better for isolating brief neurocognitive events or, especially, for defining a series of neurocognitive events that occur closely together in time.

Although ERPs provide temporal resolution that is unsurpassed by that of any other technique in cognitive neuroscience, other neuroimaging modalities that also provide high temporal resolution, including magnetoencephalography (MEG) and monitoring near-infrared optical signals. Such methods hold promise for substantial contributions to the memory literature in the future and may also provide further neuroanatomical insights. Additional information can also be extracted from MEG or EEG signals by conducting analyses in the frequency domain. For example, stimulus events produce reliable EEG oscillations that may reveal insights into neural activity that are complementary to those available from analyses in the time domain. Oscillations that occur in phase with stimulus onset are generally apparent in EEG records and are thus called evoked rhythms. Other oscillations can be time-locked to an event but be out of phase from trial to trial; these are called induced rhythms. A small but steadily increasing body of literature concerns memory-related cyclic EEG and MEG activity (e.g., Klimesch et al., 2001, 2006; Düzel et al., 2003). Prospects for combining ERP methods with frequency-domain analyses of EEG and MEG activity thus hold great promise.

3.05.2 ERPs and Memory Encoding

Experiments examining long-term memory generally employ an encoding phase, during which subjects attempt to commit items to memory, followed after some delay by a test phase, during which the success of memory storage and retrieval is evaluated. ERP measures can be collected both at encoding and at test, informing accounts of the relevant neural processing required during these stages. Given that declarative memories change over time, it will ultimately be important to examine relevant processing that can take place at various times between initial encoding and later retrieval. Less work has been devoted to this challenge.

The focus of most ERP studies of memory has been on explicit memory for episodes. Some studies have examined autobiographical memories formed outside the laboratory, or memories for general semantic knowledge learning over many years. The most commonly used paradigms concern memory for artificial events in a laboratory setting, such as viewing specific words or images. These studies are advantageous because the circumstances of acquisition can be

carefully monitored and controlled. As laboratory studies move closer to accurately simulating real-life memory experiences, it is possible that the artificial nature of this research will become less problematic in placing limitations on interpretations.

3.05.2.1 The Dm Approach

One way to isolate brain events responsible for successful encoding is to acquire ERP responses during encoding and sort trials based on subsequent memory performance (**Figure 2**). This general method was first reported with ERPs by Sandquist and colleagues (1980) and can be traced back to earlier work using skin-conductance methods. Indeed, many sorts of neural signals can be used in subsequent-memory analyses. The term Dm has been used to refer to neurophysiological difference measures found by sorting trials on the basis of subsequent memory performance (Paller et al., 1987). This term provides a convenient way to refer to the various phenomena that can be demonstrated using these methods (e.g., Dm for free recall, Dm for recognition, Dm for pure familiarity) and also avoids prejudging whether the differences reflect variations in a known ERP component. Subsequent-memory analyses can be conducted with different encoding requirements, different types of memory tests, and different retention intervals – and all of these parameters may influence the results. Dm potentials observed with different task, stimulus, and subject parameters can presumably index various neurocognitive operations to the extent that these operations partially determine what information will later be remembered.

Observing reliable Dm effects generally requires that multiple criteria are met, including some inter-item variability in encoding strength such that a sufficient number of items are subsequently remembered and subsequently forgotten. Logically, Dm effects will be greater when ERPs index a larger difference between mean responses in these two conditions. Dm analyses can thus gain power when confidence or other graded measures of retrieval success are considered. Ideally, a substantial polarization will be present in successful versus nonsuccessful encoding operations. Furthermore, temporal dynamics must also be suitable, such that processing that influences later memory performance is well time-locked to stimuli presented for encoding.

In many Dm studies, positive potentials maximal over parietal regions were found to be greater for later-remembered items than for later-forgotten items at approximately 400–800 ms. These effects have sometimes been attributed to ERP components such as P300 or the late positive complex (e.g., Karis et al., 1984; Fabiani et al., 1986). In the past two decades, Dm has been observed in many paradigms, including tests of recall and recognition (reviewed in Wagner et al., 1999; Paller and Wagner, 2002). A favored cognitive hypothesis about these Dm findings is that they reflect superior elaborative encoding for items later remembered. Semantic elaboration is well known to be effective for producing strong episodic memories, and deeper semantic elaboration

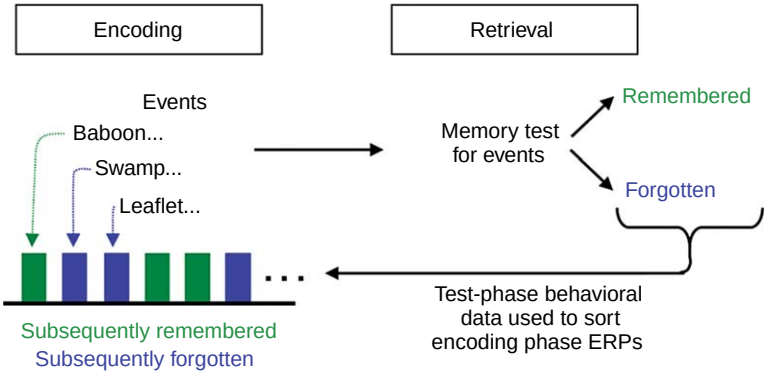

Figure 2 Schematic of the Dm or subsequent-memory methodology. During an encoding phase, neuroimaging measures are recorded while subjects attempt to remember stimuli. During the subsequent retrieval phase, memory tests for these stimuli are administered. Performance on these tests is used to classify study-phase stimuli and corresponding neural measures into two categories, subsequently remembered and subsequently forgotten. A comparison between neural correlates of these two conditions thus yields neurophysiological *d*ifferences computed on the basis of subsequent *m*emory performance, *Dm.* Figure adapted from Paller KA and Wagner AD (2002) Observing the transformation of experience into memory. *Trends Cogn. Sci.* 6: 93–102, with permission.

often corresponds with larger late posterior potentials. The nature of Dm effects due to elaboration can differ depending on the nature of the elaborative processes, however, in that frontal slow waves rather than late parietal-maximum positive potentials have been observed when subjects attempt to remember lists of unrelated words by generating novel associations to create relationships among items (Fabiani et al., 1990; Friedman, 1990). Creating novel associations likely requires a larger contribution from working memory processes supported by frontal cortex compared to elaborating on the inherent meaning of a single word.

In a recent study with faces, results revealed distinct Dm effects depending on the type of memory retrieval possible during the subsequent memory test (Yovel and Paller, 2004). As shown in **Figure 3**, a robust Dm that was bilaterally symmetric at posterior scalp locations was found to predict later recollection (when subjects could recall information previously associated with the face), whereas a smaller right-sided Dm predicted later familiarity (when subjects recognized the face but could retrieve no additional information).

Based on another type of Dm demonstrated in a few studies with words, it appears that left-frontal potentials starting at approximately 500 ms can be sensitive to the amount of information bound into a memory trace at encoding (reviewed in Friedman and Johnson, 2000). The magnitude of these potentials

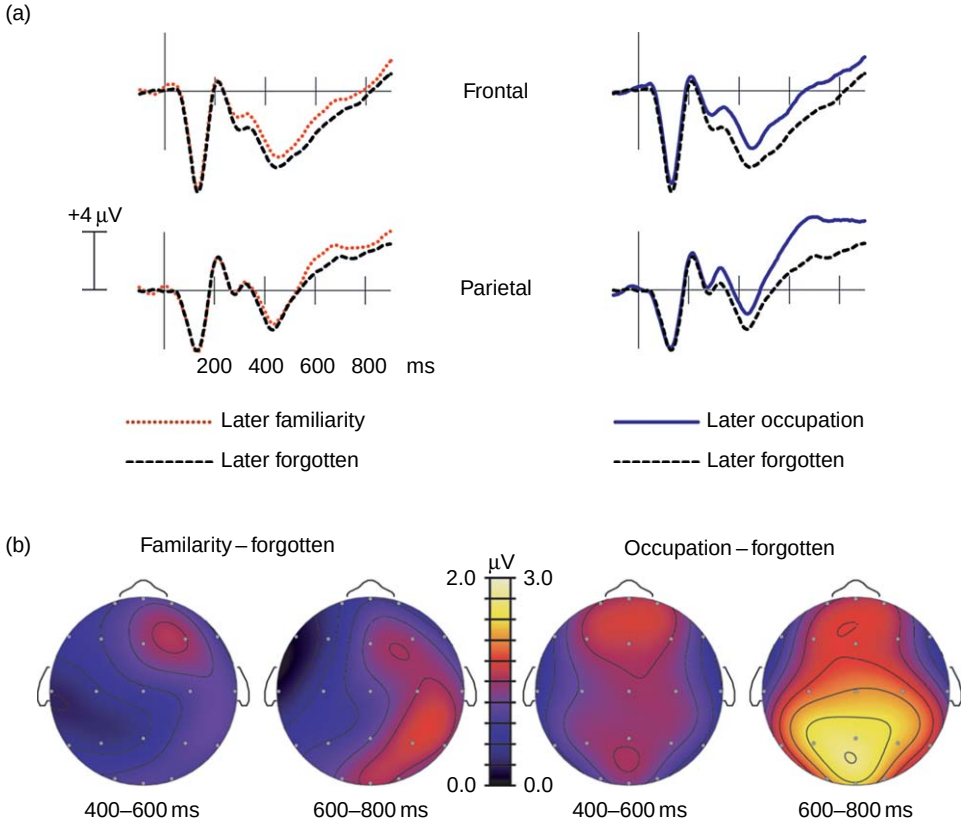

Figure 3 Representative Dm effects for two categories of memory. Two different memory experiences can be assessed after people learn to associate novel faces with randomly assigned occupations. Yovel and Paller (2004) categorized trials according to whether faces were forgotten or remembered with reference to the face alone with no contextual retrieval (familiarity) or remembered with retrieval of both the face and the paired occupation (recollection). ERPs were recorded when subjects studied these face/occupation pairs, and relatively more positive ERPs were found to predict later memory. These Dm effects are displayed at two representative electrodes in (a), and the scalp topography of these effects appears in (b). Scalp maps are of the head viewed from above, with anterior oriented toward the top. Comparing the two effects, Dm for recollection exhibited a bilateral topography with larger amplitudes spanning a longer time interval, whereas Dm for familiarity was smaller, briefer, and restricted to right posterior locations. Figure adapted from Yovel G and Paller KA (2004) The neural basis of the butcher-on-the-bus phenomenon: When a face seems familiar but is not remembered. *Neuroimage* 21: 789–800, with permission.

may be proportional to the amount of information remembered subsequently. One hypothesis is that these sustained positive potentials reflect the operation of strategic encoding processes.

In addition to stimulus-evoked neural processing that leads to later remembering, tonic brain activity that precedes the onset of a stimulus has also been linked to the efficacy of memory encoding. For example, in a study reported by Otten and colleagues (2006), ERPs over the front of the head were more negative for subsequently remembered versus subsequently forgotten items in the interval preceding stimulus onset by several hundred milliseconds. These electrophysiological findings have an important implication for investigations of encoding using other methods such as fMRI; anticipatory as well as stimulus-locked neural activity could be blurred together due to the poor temporal resolution of fMRI. Procedures are thus needed to separate fMRI correlates of these dissociable cognitive events. Although anticipatory Dm activity has not been extensively investigated, one compelling hypothesis is that it reflects working memory control operations, given that such operations can lead to better encoding of a declarative memory.

Gonsalves and Paller (2000b) showed that ERPs at encoding can reflect mistaken memories as well as accurate ones. ERPs were found to reflect the vivid visual imagery when subjects visualized the referent of a word, and this activity was found to be relevant to false remembering. Trials were categorized according to whether or not subjects subsequently claimed (erroneously) to have seen a picture of the visualized object, revealing that these posterior ERPs were predictive of whether or not a false memory for that item would happen in the test phase. ERPs thus revealed encoding activity that was partially responsible for the later mistake. In contrast, large and more widespread ERPs were predictive of accurate memory for viewed pictures.

On the whole, Dm effects may index a group of encoding operations that lead to superior memory, including detailed perceptual analysis, rote rehearsal, semantic elaboration, mental imagery, and so on. Further research is needed to clarify how Dm varies as a function of stimulus materials and type of memory test, and to precisely specify the relationship between these electrical measures and specific encoding operations. A fruitful approach for future neuroimaging studies, for example, would be to directly manipulate hypothetical mnemonic processes to determine the relative contribution of different operations to Dm effects. The usefulness of this approach for advancing explanations of memory formation can be exemplified by a recent fMRI investigation (Reber et al., 2002). Subjects were instructed to intentionally remember some words and intentionally forget others. By virtue of this directed-forgetting manipulation, fMRI correlates of the differential intention to remember were identified in addition to standard Dm effects based on retrieval success. fMRI Dm effects commonly include increased activity in both inferior prefrontal cortex and the medial temporal lobe (MTL). Although encoding condition and the probability of successful subsequent memory retrieval were correlated in this study, prefrontal activity was preferentially associated with encoding effort, whereas MTL activity was preferentially associated with success. Results thus identified the specific contribution to encoding of mnemonic operations guided by the intent to remember a word and supported by left inferior prefrontal cortex. In this way, future studies could examine the gamut of effective encoding operations in order to use Dm analyses to dissect the neurocognitive processes that support memory formation.

3.05.2.2 Intracranial Dm Effects

Electrodes implanted into the brains of patients who are candidates for surgery to remove an epileptic focus provide a special opportunity to combine the real-time temporal resolution of the ERP technique with superior spatial localization. This approach has limitations, however, in that activity can only be sampled from a limited number of brain regions, as electrodes are placed only where required for clinical purposes. In addition, generalizability can be questioned because recordings are made from a small number of individuals who have typically taken antiseizure medication for many years to try to control abnormal electrical activity in the brain. Results can nonetheless be used to inform theoretical accounts of the neural basis of memory formation.

In an ERP study reported by Fernandez and colleagues (2002), recordings were made from two areas within the MTL: the hippocampus and an adjacent cortical region near the rhinal sulcus. Based on research with amnesic patients and with nonhuman animals, the hippocampus, together with adjacent parahippocampal, entorhinal, and perirhinal cortical regions, has been considered as essential circuitry that is critical for the formation of declarative memories, in conjunction with widespread neocortical

regions that are ultimately responsible for memory storage (*See* Chapter 3.03; Squire et al., 2004). Potentials recorded from the rhinal region (entorhinal and/or perirhinal cortex) and hippocampus predicted subsequent free recall of visual words. The rhinal Dm peaked approximately 400–500 ms after word onset and was thought to be associated with the extent to which words were processed semantically. The hippocampal Dm, in contrast, started later and was taken to reflect the successful binding of multiple features into memory following semantic analysis.

These results support the notion that distinct MTL regions perform unique mnemonic operations. Other intracranial ERP studies have demonstrated a range of phenomena that may also reflect important memory functions (Heit et al., 1988; Grunwald et al., 1998; Allison et al., 1999; Guillem et al., 1999; Paller and McCarthy, 2002; Trautner et al., 2004; Engel et al., 2005; Viskontas et al., 2006). For example, a complex pattern of rhinal-hippocampal synchronization and desynchronization was found via frequency-domain analyses of the same intracranial data (Fell et al., 2001). EEG synchronization in various other brain locations has also been observed to correlate with subsequent memory performance (Sederberg et al., 2003, 2006). Furthermore, single-unit firing patterns in the hippocampus have been shown to vary as a function of subsequent memory performance (Cameron et al., 2001). Further studies are required to replicate and extend these various findings in order to elaborate on the information processing steps that are performed by neurons in each MTL region, as well as to explore the temporal dynamics of interactions across multiple brain regions. ERP measures of memory formation, in combination with findings from these other methods, will be very important for delineating the distinct contributions to memory formation dependent on different brain processes and regions.

3.05.3 ERPs and Memory Retrieval

Whereas veridical memory performance is only possible if some information was initially encoded, the nature of memory is also a function of events taking place at the time of retrieval. Furthermore, the most interesting distinctions between types of memory (e.g., declarative memory and priming) and between memory processes (e.g., recollection and familiarity) are largely realized at retrieval. This is the time when one can engage in the conscious experience of remembering that can approximate reliving a past event.

3.05.3.1 Identifying Correlates of Recognition

In most ERP studies of memory retrieval, electrophysiological responses are recorded while recognition is tested. In a recognition test for episodes studied during an encoding phase, subjects must discriminate old (repeated) items from novel items. ERP correlates of episodic memory (sometimes termed episodic memory effects or old/new effects) are commonly identified by contrasting ERP responses elicited by old items to those elicited by new items. Much effort in ERP studies of memory has been devoted to attempting to elucidate the specific memory processes that give rise to old/new effects.

Measures of neural activity obtained when people remember episodes are often interpreted in light of theories that posit two distinct recognition processes: recollection and familiarity (*See* Chapters 2.17, 2.23). Recollection involves the recognition that an event has occurred in the past along with the retrieval of specifics regarding the prior occurrence, thereby guiding the conscious experience of remembering. In contrast, familiarity denotes recognition of prior occurrence that remains unsubstantiated by retrieval of any specific detail. Familiarity can lead to a feeling of knowing in the absence of the ability to bring to mind any additional information. Recollection and familiarity are connected with the concepts of source memory and item memory, in that source memory concerns the spatiotemporal context and various other features that can support recollection, whereas familiarity for a stimulus might be driven by retrieval limited to item memory.

An experimental procedure known as the remember/know paradigm has been employed extensively in attempts to identify neural correlates of recollection and familiarity. Subjects are cued to introspectively classify their recognition of old stimuli as 'remember' if specific study-phase detail is simultaneously brought to mind or as 'know' if no such detail is retrieved. The remember/know response categories have been taken as generic indices of recollection and familiarity, respectively. Under some experimental conditions, however, remember/know responses may correspond to varying degrees of memory strength instead of qualitatively different memory processes (Eldridge et al., 2002). In addition, it is possible that results

obtained from this procedure are highly influenced by nonmnemonic variables, such as the capacity to introspect accurately. Great care is thus needed in applying this method. Confidence in results can be increased with convergent support from multiple methods, such as with memory judgments based on source information.

Indeed, a useful approach to separating ERP components related to recollection and familiarity is to test memory for specific source information based on the experimental context at encoding. For example, subjects may encode words spoken by either a male or female voice and later be tested with visual words and asked to recall the original gender. In general, correct source retrieval can be used to indicate recollection. Incorrect source retrieval with correct recognition, however, is not always a good indicator of familiarity, given that recollection may be supported by retrieval of information other than the specific source information in question.

Distinct ERP effects have been linked to three types of mnemonic processes associated with memory retrieval. These findings are outlined in the following three sections.

3.05.3.2 Recollection and Source Memory

The most consistently reported finding in recognition studies is that ERP amplitudes to old items are greater than those to new items from approximately 400–800 ms over much of the scalp. These effects typically show a maximal difference over midline or left parietal scalp locations. The amplitude of these differences generally increases with increasing memory strength based on various behavioral indices (e.g., recognition confidence). Compared to recognized items (hits), both old items that are forgotten (misses) and new items that are correctly identified (correct rejections) tend to elicit smaller ERPs.

Early investigations of these old/new ERP effects endorsed a variety of hypotheses concerning their functional significance, including associations with memory strength (Johnson et al., 1985), relative familiarity (Rugg, 1990), contextual retrieval (Smith and Halgren, 1989), and processes that do not contribute to recognition judgments (Rugg and Nagy, 1989). Despite this lack of consensus about the meaning of these ERPs during these years, a common assumption was that the effects included modulation of two ERP components: N400 potentials and P300 potentials (e.g., Halgren and Smith, 1987).

An early study that convincingly associated ERPs with recollection utilized a levels-of-processing manipulation at study (Paller and Kutas, 1992). Behavioral results showed that this manipulation influenced recall and recognition performance, with superior memory following semantic encoding that required visual imagery compared to encoding that focused attention on letter information. In contrast, the same level of priming (**Table 1**) was observed on an implicit memory test of word identification for both encoding tasks. ERPs recorded during the implicit memory test were compared between the two conditions defined by the task assigned at encoding, and corresponding differences were interpreted as ERP correlates of recollection. This ERP difference based on encoding task began at a latency of 500 ms and was only present for words that were successfully identified in the test phase. Unlike typical old/new ERP effects, this effect could not be attributed to differences associated with priming because priming was matched between the encoding conditions. Furthermore, behavioral evidence obtained at debriefing showed that subjects noticed that words from the encoding phase appeared during the word-identification test, even though this was irrelevant to their task. In other words, subjects were cognizant of specific contextual information with respect to some of the words in the word-identification test that repeated from earlier in the experiment. The authors thus inferred that incidental recollection took place during the test phase, particularly when word meaning had been encoded deeply, and that ERPs were sensitive to the differential processing associated with recollection.

Further studies using the same strategy in experimental design have substantiated the association between ERPs and recollection and extended the results to the use of other encoding tasks and memory tests (Paller et al., 1995), words presented in the auditory modality (Gonsalves and Paller, 2000a), and other types of stimuli such as faces (Paller et al., 1999). These late parietal ERPs can thus be taken as signals of the successful retrieval of episodic memories linked with conscious remembering (reviewed in Friedman and Johnson, 2000; Paller, 2000).

Results from remember/know as well as source-memory paradigms have also been used to associate late parietal ERPs with recollection. Late parietal ERP amplitudes are often found to be greater for remember compared to know responses and know responses compared to new trials. Importantly, there have not been convincing demonstrations that

the distribution of late parietal ERPs differ between remember and know responses, indicating that these ERPs may index a neurocognitive operation that differs only quantitatively between recollection and familiarity conditions (e.g., Smith, 1993). Similarly, correct source judgments elicit greater late parietal amplitudes compared to incorrect source judgments, and incorrect source judgments greater than new trials, without qualitative differences in scalp distribution (e.g., Wilding and Rugg, 1996; Trott et al., 1999).

In addition to corroborating the connection between recollection and late posterior potentials, many experiments have targeted ERP correlates of source and item memory in order to understand contextual memory in its own right. Experimental contexts have included: speaker gender (Senkfor and Van Petten, 1998); performed, watched, or imagined actions (Senkfor et al., 2002); background figures (Guo et al., 2006); spatial location (Van Petten et al., 2000); and stimulus color (Cycowicz et al., 2001), among others.

Results from memory-disordered patients have also confirmed associations between successful episodic retrieval and late positive ERPs. Amnesic patients exhibited impaired conscious recognition as well as reduced or absent late positive amplitudes (e.g., Olichney et al., 2000, 2006). In addition, administration of benzodiazepine drugs to healthy subjects prior to encoding created a temporary state of amnesia, and following this manipulation, both recollection and late parietal potentials were severely disrupted (e.g., Curran et al., 2006a). Taken together, evidence taken from a variety of experimental paradigms thus converges on the conclusion that recollection is a distinct expression of memory that reliably occurs with a particular ERP signature (**Figure 4**).

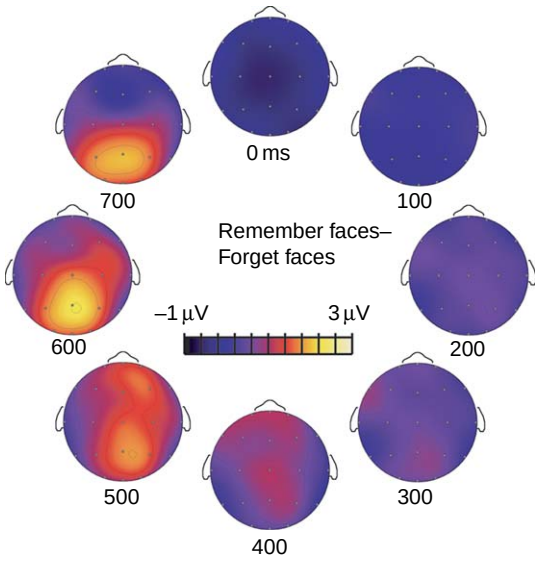

Figure 4 Late positive potentials index conscious recollection. Posterior, positive potentials from 300 to 800 ms after the presentation of faces that were previously encoded with the instruction to remember (Remember faces) were greater than for faces that were encoded with the instruction to forget (Forget faces). At encoding, each Remember face was presented with a short biographical vignette. Subjects were highly accurate at recollecting this information when cued by the corresponding face at test. Behavioral results showed that recognition was better for Remember faces than for Forget faces, whereas priming did not differ. Thus, these late positive potentials index recollective processing uncontaminated by priming. Data are from Paller KA, Bozic VS, Ranganath C, Grabowecky M, and Yamada S (1999) Brain waves following remembered faces index conscious recollection. *Brain Res. Cogn. Brain Res.* 7: 519–531.

3.05.3.3 Postretrieval Processing

Another memory phenomenon may be indexed by positive potentials at prefrontal scalp locations beginning approximately 500 ms after stimulus onset and extending for up to several seconds. These potentials often display a right-sided distribution. They do not index retrieval success, in that they tend to be similar for both successful and unsuccessful retrieval attempts. Instead, these frontal potentials are thought to index effortful retrieval processing, manipulation of working-memory contents, and/or postdecisional mnemonic processing such as further evaluation.

The functional significance of these late frontal potentials was difficult to decipher, partly due to the absence of a direct connection with retrieval success. Experimental manipulations of retrieval demands, however, were useful for clarifying the cognitive operations indexed by these potentials. In one study, images of common objects were encoded, and these objects were presented again at test in either the identical format or perceptually altered (Ranganath and Paller, 1999). Subjects performed one of two tests that differed in the demands placed on effortful retrieval of perceptual detail. In the highly demanding test, subjects responded 'old' only to objects in the identical format, whereas in the less-demanding test, objects were to be endorsed as old regardless of any format alterations. Late frontal potentials were larger in the highly demanding test than in the

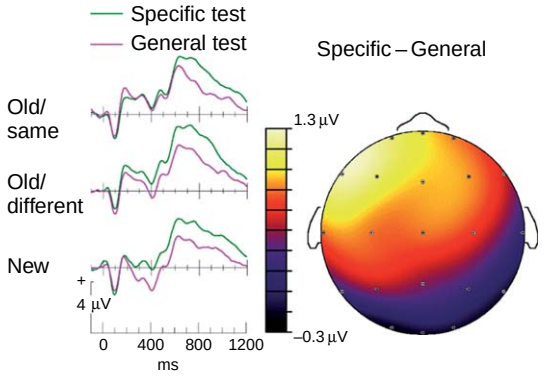

Figure 5 Late frontal potentials associated with retrieval processing. ERPs to drawings of common objects were compared between a highly demanding (specific) recognition test and a less-demanding (general) recognition test. Waveforms (left) showed a relative positivity for the specific test compared to the general test for all three stimulus classes in the experiment: objects that were perceptually identical to one in the study phase (old/same), objects that were perceptually altered from one in the study phase (old/different), and entirely novel object pictures. The corresponding ERP topography was computed over all conditions for the latency interval from 500 to 1200 ms. These late frontal potentials were maximal over the left anterior scalp, but in other experiments have also been found to be bilaterally symmetric or maximal over right anterior scalp. Figure adapted from Ranganath C and Paller KA (1999) Frontal brain potentials during recognition are modulated by requirements to retrieve perceptual detail. *Neuron* 22: 605–613, with permission from Elsevier.

less-demanding test for both categories of old stimuli as well as for new stimuli (**Figure 5**). These potentials thus appeared to track retrieval effort as manipulated across these two recognition tests. Subsequent investigations have confirmed this interpretation (Ranganath et al., 2000; Ranganath and Paller, 2000; Leynes, 2002), supporting the view that late frontal potentials track strategic processing that accompanies retrieval, a process likely mediated by prefrontal cortex. Hemispheric loci of late frontal potentials can also vary as a function of retrieval demands, with a right-to-left shift accompanying an increase in the complexity of the retrieved information (Johnson et al., 1997; Nolde et al., 1998).

3.05.3.4 Recognition with Pure Familiarity

Attempts to associate the memory experience of familiarity with specific ERPs have been most controversial. Results from many studies have been taken to indicate that familiarity is generically indexed by negative potentials peaking approximately 400 ms poststimulus, an N400-like potential with reduced amplitudes (i.e., more positive ERPs) for old compared to new items, especially at anterior locations. Beginning with the work of Düzel and colleagues (1997), many researchers have proposed that the frontal N400 old/new effect indexes recognition with familiarity, in contradistinction to recollection (reviewed in Curran et al., 2006b). Whereas late posterior potentials are greater in circumstances in which recollection is greater (for example, following semantically deep vs. semantically shallow encoding tasks), the frontal N400 old/new effect is generally found to be insensitive to such manipulations (e.g., Rugg et al., 1998a,b). In addition, frontal N400 potentials have been associated with phenomenological familiarity as indexed by the remember/know paradigm (e.g., Düzel et al., 1997; Woodruff et al., 2006) and have been found not to scale with the amount of recollection during tests of source memory (e.g., Wilding, 2000). In sum, frontal N400 potentials are sensitive to recognition success but not to manipulations that effect recollection, and thus are widely described in the extant ERP literature as a general correlate of familiarity.

On the other hand, there is reason to doubt this generalization about frontal N400 potentials, because the majority of findings used to argue in favor of this association are indirect (see following and Paller et al., 2007, for a review). Specifically, the logic of interpretation has generally been that frontal N400 potentials reflect recognition memory and do not behave as a neural correlate of recollection, and so the inference made has been that they therefore index familiarity. A direct challenge to this fragile interpretation arose with the identification of intact N400 repetition effects in amnesic patients (Olichney et al., 2000). A reasonable generalization is that amnesia disrupts familiarity, in the sense that a patient with severe amnesia does not behave as if people and various objects they encounter feel familiar. This generalization also stands on sound empirical footing (Knowlton and Squire, 1995; Yonelinas et al., 1998). Thus, one might expect patients with amnesia to exhibit reduced N400 old/new effects if these effects indeed index familiarity. Olichney and colleagues (2000) thus suggested that frontal N400 potentials might instead reflect the operation of conceptual implicit memory processes that can be engaged incidentally during recognition testing. In general, special steps are necessary to isolate the contribution of separate but potentially co-occurring

memory phenomena to neural correlates of recognition memory, as discussed in detail in the next section.

Several studies have examined the phenomenon of familiarity without recollection using faces, as in the classic example described by Mandler (1980) as the butcher-on-the-bus phenomenon. The butcher's face may seem extremely familiar yet not be identified when seen in an unusual context, such as on the bus, whereas in the butcher's shop, familiarity is more likely to occur together with memory for additional episodic and semantic information that uniquely identifies the specific person. Yovel and Paller (2004) used a variation of the remember/know paradigm to segregate trials for separate analyses of recollection and familiarity. Recognition with familiarity, compared to correct rejections of new faces, co-occurred with late positive ERPs that were maximal at midline parietal locations; recognition with recollection co-occurred with late positive ERPs that were much larger in amplitude, spanned a longer time interval, and showed a slightly more anterior topography. MacKenzie and Donaldson (2007) conducted a similar study and found statistically significant topographic differences; familiarity was associated with late posterior ERPs and recollection with larger and more anterior ERPs. However, a third study (Curran and Hancock, 2007) used a more heterogeneous mixture of faces (i.e., faces with different racial and ethnic features) and failed to replicate this pattern, instead attributing an N400 effect to familiarity for faces. Of course, it is plausible that characteristics of the people shown could influence the extent to which repeated faces engage conceptual priming, although this idea deserves further study. In sum, most studies of familiarity experiences during face processing associated familiarity with late posterior ERPs, not with the earlier frontal N400 potentials described in prior studies that used words or nameable objects. Further studies are needed to determine whether this divergence can be explained by showing that familiarity entails different neural events for verbal versus facial stimuli, that heterogeneity of face stimuli plays a crucial role, or whether alternative interpretations of frontal N400 potentials are viable.

Results from a limited number of studies can be taken as tentative evidence that familiarity may be indexed by potentials occurring earlier than frontal N400s (Tsivilis et al., 2001; Curran and Dien, 2003; Duarte et al., 2004; Friedman, 2004; Diana et al., 2005). These potentials occur between 100 and 300 ms, but otherwise closely resemble FN400 potentials – frontal ERPs to old items are more positive than to new items. Like FN400 potentials, these earlier frontal potentials have been associated with familiarity based on indirect evidence: the effect is present in association with phenomenological reports of familiarity and does not scale with recollection. More evidence is needed to determine if these potentials indeed index familiarity as opposed to other potentially co-occurring memory phenomena, such as various forms of priming and the initiation of memory search (e.g., Diana et al., 2005).

3.05.4 Using ERPs to Contrast Memory Subtypes

Memory performance undoubtedly reflects the operation of a variety of neural systems (*See* Chapter 3.02). Multiple memory systems or processes make variable contributions to performance on different mnemonic tasks. ERP investigations are especially well-suited for identifying the occurrence of these variable contributions and thereby disentangling the operation of distinct memory components. Indeed, we must first come to understand these separate components before we can work out how their interactions ultimately produce memory abilities.

Here we will highlight one distinction that has been particularly amenable to investigation with ERPs, that between explicit memory and forms of implicit memory known collectively as priming. In an explicit memory test, specific reference is made to remembering information learned earlier. In an implicit test of memory, in contrast, no reference is made to learning episodes, but rather, memory is demonstrated via a change in performance in a certain task due to a prior event that may or may not be consciously remembered. Contrasts between these two broad categories of memory phenomena have been very prominent in memory research over the past two decades (*See* Chapters 3.12, 2.33). Performance on explicit memory tests is typically disrupted in cases of amnesia, as described earlier. On the other hand, many types of implicit memory have been shown to be preserved in amnesia. Priming is a form of implicit memory that is indexed behaviorally as faster or more accurate responses on specialized priming tests, independent of conscious memory for study episodes. The most common types of priming tests are used to measure perceptual priming (also called item-specific implicit memory).

These behavioral effects are thought to reflect facilitated or more fluent perceptual processing of the physical features of repeated items, distinct from accessing a memory for the full episode in which the item occurred. A different set of mechanisms may be responsible for some types of priming (i.e., conceptual priming, novel-information priming, new-association priming, association-specific priming, or cross-domain priming), and in some of these cases priming may not be preserved in amnesia, although this is a topic currently under active investigation.

When memory tests are given to healthy individuals, performance may be guided by explicit memory, implicit memory, or by some combination. In this sense, memory tests may not be 'process-pure.' In addition to acknowledging that behavioral measures in memory tests can reflect multiple memory processes, it is important to note that neural measures such as ERPs are liable to be influenced by multiple memory processes as well. Moreover, neural measures can reflect memory processes whether or not those processes influence behavioral performance. In either implicit or explicit memory tests, ERPs can reflect neurocognitive processes responsible for both types of memory. Experimental manipulations that selectively influence the operation of distinct components of memory are thus essential. Other-wise, ERP or other neuroimaging results cannot be unequivocally associated with one type of memory versus another.

3.05.4.1 Direct Comparisons between Recollection and Perceptual Priming

Isolating neural correlates of perceptual priming uncontaminated by those of conscious remembering is problematic because of the difficulty of preventing subjects from recalling prior episodes during priming tests. Similarly, the automatic processing that supports perceptual priming may occur during recognition tests, ven if behavioral measures of priming are not obtained, and this processing can potentially be reflected in neural measures accompanying recognition.

In order to isolate ERP correlates of perceptual priming, Paller and colleagues (2003) used a condition in which faces were encoded only to a minimal extent such that priming occurred in the absence of recognition. Subjects viewed each face for 100 ms at a central location while simultaneously a yellow cross was shown unpredictably in one of the four quadrants 1.8° from fixation. While maintaining central fixation, subjects attempted to discriminate between two subtly different types of yellow crosses, and further stimulus processing was disrupted via backward masking. On a subsequent test, recognition of these minimally processed faces was not significantly better than chance. Perceptual priming for these faces, however, was observed behaviorally on two implicit memory tests. The logic of this design was thus that ERPs elicited by these faces could conceivably reflect neural events responsible for perceptual priming, whereas contributions from recognition processes would be negligible. Faces in another condition were presented for a longer duration, without disruptive perifoveal visual discriminations or backward masking, and were recognized at above-chance levels. These two conditions thus provided a direct comparison between ERPs associated with conscious memory for faces and ERPs associated with perceptual priming. Recognition-related neural correlates included late positive potentials (**Figure 6(a)**), closely resembling responses previously associated with face-cued recollection (Paller et al., 1999; Paller, 2000), whereas perceptual priming was associated with a relative ERP negativity over anterior recording electrodes from approximately 200–400 ms after face onset (**Figure 6(b)**). Spatiotemporally distinct ERPs of opposite polarities were thus associated with conscious remembering versus perceptual priming. This pattern of neuroimaging findings complements neuroanatomical dissociations identified in amnesic patients; the results imply that implicit access to memory is supported by processing within a network of brain regions that is qualitatively distinct from that supporting conscious access to memory.

Evidence for the independence of implicit and explicit memory can also be derived from contrasts between neural correlates of encoding responsible for later perceptual priming versus recollection. Schott and colleagues (Schott et al., 2002) used deep/semantic versus shallow/nonsemantic encoding conditions, followed by an ingenious two-stage procedure to assess memory. Three-letter word stems were presented in an explicit memory test (i.e., cued recall), but subjects were encouraged to guess if they could not remember a studied word so that priming might also occur. After each stem was completed, subjects indicated using strict criteria whether they recognized the word from the encoding phase. Trials were categorized as showing priming if the subject produced the word at the completion stage but failed to endorse it as an old word (i.e., priming-without-

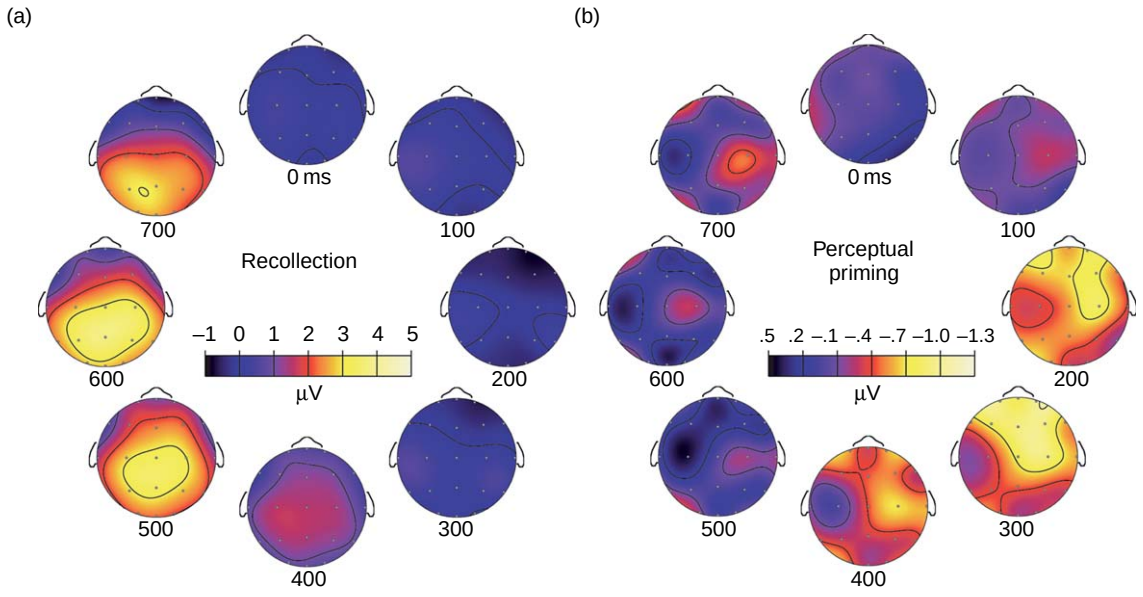

Figure 6 ERP correlates of recollection and perceptual priming. The ERP difference between recollected faces and new faces is displayed in (a). The difference between primed but not remembered faces and new faces is displayed in (b). Differences are averaged over 100-ms intervals starting at the latency indicated underneath each topographic map. Light colors indicate positive difference potentials in (a) and negative difference potentials in (b). Figure adapted from Paller KA, Hutson CA, Miller BB, and Boehm SG (2003) Neural manifestations of memory with and without awareness. *Neuron* 38: 507–516, with permission from Elsevier.

recognition). Trials were categorized as remembered when the correct response was made at both stages and as forgotten if not produced at the completion stage. Subsequent-memory analyses thus revealed a Dm for priming that took the form of a relative ERP negativity over central and fronto-central locations approximately 200–400 ms after word onset (resembling ERP correlates of perceptual priming identified during memory testing, e.g., Paller et al., 2003). Furthermore, Dm for priming was distinct from ERP differences between deep versus shallow encoding as well as from Dm for recognition, which both included relatively positive potentials at later intervals with different topographies. Collectively, these results (along with those from a follow-up study using fMRI, Schott et al., 2006) constitute critical first steps in characterizing the neurocognitive relationship between expressions of explicit memory and expressions of perceptual implicit memory.

3.05.4.2 Identification of Neural Correlates of Conceptual Priming

Another form of priming known as conceptual priming can occur whenever meaningful stimuli are repeated. Behavioral measures of conceptual priming are similar to those of perceptual priming in that they can occur in the absence of awareness of remembering and typically take the form of faster or more accurate responses to a specific stimulus. These alterations of behavioral responses are thought to reflect facilitated processing of stimulus meaning, and they potentially support some of the short-term mnemonic operations that are preserved in amnesia, such as language comprehension.

Because the neural processing that supports conceptual priming can occur whenever meaningful stimuli are repeated, regardless of whether a behavioral test of conceptual priming is provided, it is possible that neural activity associated with conceptual priming occurs incidentally during tests of recognition memory for meaningful stimuli. As reviewed above, frontal N400 potentials at retrieval have been postulated to index the explicit memory capability termed familiarity. The finding that similar potentials are intact in amnesic patients (Olichney et al., 2000), however, raised the possibility that frontal N400s instead reflect a form of memory that is not disrupted in amnesia. Olichney and colleagues (2000) proposed that residual conceptual priming in amnesic patients could be reflected by frontal N400 potentials. It is thus possible that frontal N400

potentials do not index familiarity but instead reflect conceptual priming that occurs concurrently with explicit memory (Paller et al., 2007). Further work is needed to disentangle these two memory functions.

One recent study directly examined this issue by using celebrity faces to elicit neural correlates of conceptual priming and explicit memory (Voss and Paller, 2006). Conceptual priming was manipulated by presenting associated biographical information along with a subset of celebrity faces. Later, electrophysiological recordings were obtained while subjects rapidly discriminated celebrity faces from other faces. Evidence for conceptual priming consisted of faster and more accurate responses to the subset of faces previously presented with biographical information. A baseline was provided by a counterbalanced set of celebrity faces that were previously presented without corresponding biographical information. Electrophysiological responses were obtained during the discrimination test and were characterized according to both conceptual priming and ratings of explicit memory for celebrities obtained in the last phase of the experiment. Conceptual priming was strongly associated with frontal N400 potentials (**Figure 7**), whereas explicit memory was related to late positive potentials at posterior locations.

These results attest to the likelihood that neural activity related to conceptual implicit memory is commonly produced in memory experiments designed to monitor explicit memory. Therefore, this contamination of neural signals is also possible in studies using other methods to measure brain activity, such as fMRI. Furthermore, the hypothesis that frontal N400 potentials are unique neural signatures of familiarity must be called into question, because it might partially (or entirely) reflect the operation of implicit memory. Much work will be needed to accurately elucidate the neural substrates of these memory processes, but doing so is critical for understanding the neural substrates of familiarity and of priming. This approach further highlights the necessity of employing experimental manipulations and multiple behavioral measures that can allow for valid associations between neuroimaging measures and memory functions, such that this information can be used to build an accurate characterization of the brain processes that support human memory performance.

3.05.5 Future Contributions of ERP Studies to Memory Research

Much progress has been made in identifying component processes of human memory capabilities and characterizing corresponding neural substrates of memory. However, there is much more to be learned so as to demystify the cognitive, biological, and phenomenological facets of memory. Given that a memory cue can unleash such a rapid flood of relevant neural events that precipitate remembering, ERP techniques have an important role to play in this endeavor.

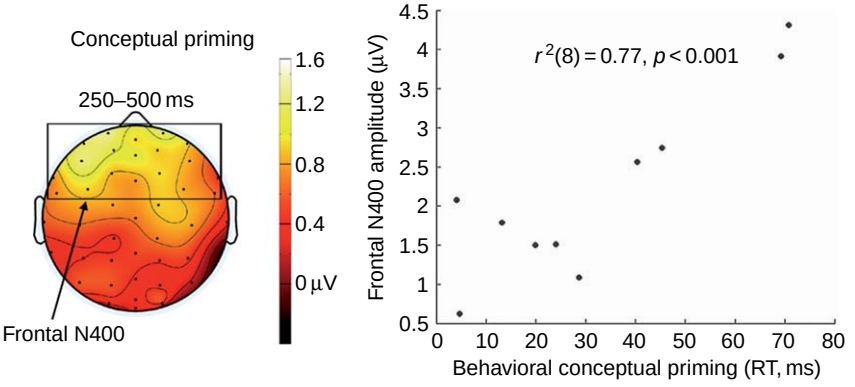

Figure 7 Neural correlates of conceptual priming include frontal N400 potentials. The ERP contrast between famous faces based on whether corresponding conceptual information was primed in an earlier phase of the experiment is shown topographically for the latency interval from 250 to 500 ms (left). The frontal N400 effect is indicated. The magnitude of these potentials (quantified in each subject at the electrode exhibiting the greatest frontal N400 conceptual priming effect) was correlated across subjects with the magnitude of conceptual priming indexed behaviorally (right). RT, reaction time. Data are from Voss JL and Paller KA (2006) Fluent conceptual processing and explicit memory for faces are electrophysiologically distinct. *J. Neurosci.* 26: 926–933.

One theoretical keystone involves identifying factors that make implicit and explicit expressions of memory unique. ERPs have been extremely useful in this regard and thus have a continuing role to play in conjunction with other methods of cognitive neuroscience. In addition to elucidating differences between conscious and nonconscious memory expressions, a deeper understanding of this issue will allow us to characterize how these distinct forms of memory interact in a variety of situations to drive memory performance. Whereas our understanding of such interactions has hitherto derived primarily from behavioral evidence obtained from healthy individuals and memory-impaired patients, physiological data are also needed. Valid descriptions of the neural bases and neural dynamics of explicit and implicit forms of memory are essential for understanding their functional relationships.

The detailed theoretical account of memory that can be achieved in this manner will ultimately be important for maximizing our memory capabilities in everyday life. Among the possible practical applications of memory research, possibilities for memory rehabilitation are critical in neurological and psychiatric diseases that affect memory and during the course of healthy aging. Much of human experience revolves around bringing to mind events from the past. Explorations of remembering via electrical recordings of brain activity may thus lead to a better understanding of ourselves.

3.06 Structural Basis of Episodic Memory

L. Nyberg, Umeå University, Umeå, Sweden

3.06.1 Introduction

In 1972 Endel Tulving introduced the concept of episodic memory (Tulving, 1972). Over the years the definition of episodic memory has been revised several times. A recent definition states that:

> Episodic memory is a recently evolved, late-developing, and early-deteriorating past-oriented memory system, more vulnerable than other memory systems to neuronal dysfunction, and probably unique to humans. It makes possible mental time travel through subjective time, from the present to the past, thus allowing one to reexperience, through autonoetic awareness, one's own previous experiences. Its operations require, but go beyond the semantic memory system [*See* Chapter 2.28]. Retrieving information from episodic memory (remembering or conscious recollection) is contingent on the establishment of a specific mental set, dubbed 'episodic retrieval mode.' Episodic memory is subserved by a widely distributed network of cortical and subcortical brain regions that overlaps with but also extends beyond the networks subserving other memory systems. (Tulving, 2002, p. 5)

Numerous studies of nonhuman species have aimed at examining aspects of episodic memory, and much has been learned from such studies (Squire and Knowlton, 1995; Morris and Frey, 1997; Eichenbaum, 2000). Some studies, in particular, have gone a long way toward meeting core aspects of the definition of episodic memory (e.g., Clayton and Dickinson, 1998). It nevertheless remains controversial whether experimental protocols in nonhuman species really tap episodic memory or are rather probing semantic (factual, knowledge) memory (Murray, 1996). Indeed, many memory tasks that seemingly tax episodic memory can in fact be solved by means of the semantic memory system. For example, learning and memory of paired associates are typically seen as episodic memory tasks, but if learning takes place over multiple sessions, retrieval may well be based on semantic rather than episodic memory. In that case, retrieval would not be characterized in terms of remembering or conscious recollection, but rather as knowing. In short, according to a strict definition, if and only if retrieval can be defined as involving reexperiencing through autonoetic awareness previous experiences, then one can claim to have taxed episodic memory (*See* Chapter 2.26). A comprehensive discussion of

issues related to the phylogenetic history of episodic memory and whether or not it is unique to humans goes beyond the scope of this chapter.

The crucial role of autonoetic awareness for episodic memory, relative to other memory systems, has been related to the slow ontological development of episodic memory (Wheeler et al., 1997). That age-related memory decline appears earlier for episodic than for semantic memory (Nyberg et al., 2003) may have to do with its putative reliance on a multitude of brain regions, some of which show age-associated changes (Hedden and Gabrieli, 2004). Similarly, that many brain regions seem to be engaged during retrieval likely accounts for why episodic memory is more vulnerable than other memory systems to various forms of neuronal dysfunction (Tulving, 2002). The main purpose of this chapter is to provide an empirical overview of brain regions that have been found to be engaged by episodic memory. To set the stage for this review, a brief discussion of component processes of episodic memory will follow next.

3.06.2 Episodic Memory Is Not a Unitary Construct: Component Processes

The current definition of episodic memory puts focus on retrieval of information, with a special emphasis on 'retrieval mode.' Similarly, in this chapter, the focus will be on episodic memory retrieval. Needless to say, though, retrieval is critically dependent on encoding/learning/acquisition of information (henceforth encoding) and the subsequent consolidation of such information.

Encoding is a complex construct. It can be guided by intention, such as when one meets a person and attempts to encode her/his name. It can also be an incidental process and occur as a by-product of other activities. The latter type may be the more common form of encoding, such as when one is attending a dinner party. Afterward one will be able to remember much of what happened at the party, who said what, and so on. This is so despite the fact that most people do not sit at dinner parties intentionally trying to memorize. It is not clear what determines what will be encoded into memory, but how attention-capturing or novel an event is seems to be one deciding factor (Ranganath and Rainer, 2004; Nyberg, 2005). How novel events are experienced is determined by previous experiences; hence encoding and retrieval operations are closely integrated. A neurobiological model for such integration has been proposed (Fernandez and Tendolkar, 2006).

To be stored over time, encoded information must undergo a consolidation process. This takes place at different macroscopic and time scales (Frankland and Bontempi, 2005). Fast morphological changes are needed for initial stabilization of memories and include restructuring of existing synaptic connections and growth of new ones. At the systems level, consolidation refers to a gradual reorganization of brain regions that support memory. Traditionally, it has been assumed that, once consolidated, a memory will remain stable and be relatively immune to insults. More recent research has challenged this view by showing that memory retrieval (i.e., reactivation of consolidated memories) can induce changes at the neural level (Nadel and Land, 2000; Frankland and Bontempi, 2005). These findings are in good agreement with psychological theories that memories are dynamic and subject to change (Schacter et al., 1998).

The main component process of episodic memory is retrieval. Retrieval, as the other processes, is best seen as an umbrella term for a set of subprocesses. In the definition of episodic memory given above, one subprocess was mentioned: retrieval mode. In his theory on the elements of episodic memory, Tulving (1983, 1984) argued that two necessary conditions must be met for retrieval to occur. One condition is that the system must be in the retrieval mode, and the other that an appropriate retrieval cue must be present. Retrieval mode has more precisely been described as a neurocognitve set that serves to hold a segment of one's personal past in focal attention and treats incoming information as retrieval cues for events in the past (Lepage et al., 2000). In an everyday situation, this mode might be instantiated by a question about what one did during the past vacation. Retrieval cues may then be self-generated or induced by additional questions. If information actually is retrieved from memory, which is believed to result from interactions between cues and stored information ('ecphory'), an additional element of retrieval is induced: remembering or conscious recollection. If information is not retrieved, strategic search processes may be elicited, and for both successful and unsuccessful retrieval attempts some form of monitoring processes is needed. In short, retrieval of episodic memories is most likely the result of several interacting subprocesses, and in the subsequent discussion of brain regions underlying episodic retrieval, when possible, specific retrieval processes will be considered. Functional brain

imaging studies are critical in this regard, as this technique allows component processes to be studied separately (e.g., it is possible to first examine how the brain is activated during encoding and subsequently during retrieval). It should be stressed that most if not all of the regions that will be discussed are not uniquely activated during episodic retrieval. The issue of relations among memory systems will be discussed later on in the chapter.

3.06.3 Episodic Memory – Brain Structures

3.06.3.1 The Temporal Lobe

3.06.3.1.1 The hippocampus and medial temporal cortex

It is natural to begin the review of brain structures implicated in episodic memory by discussing the hippocampus. Following the seminal paper by Scoville and Milner (1957), numerous papers have tried to determine the functional role of the hippocampus. It has been shown that lesions to the hippocampus impair episodic and semantic (declarative) memory (*See* Chapter 3.04) but leave other nondeclarative systems intact (Cohen and Squire, 1980). Further studies have examined the functional role of specific hippocampal subregions as well as nearby areas in the medial-temporal cortex (Squire and Knowlton, 1995; Eichenbaum, 2000). By now, some authors refer to multiple temporal lobe systems, such as the perirhinal versus hippocampal systems (Brown and Aggleton, 2001). Of these, the hippocampal system is more closely linked to episodic memory 'proper' by being related to remembering rather than knowing and to recollection of episodes (Brown and Aggleton, 2001), whereas perirhinal cortex seems more related to semantic memory processes (Murray and Bussey, 1999).

3.06.3.1.2 Lateral temporal cortex

Regions of lateral temporal cortex also subserve mnemonic functions. Perirhinal cortex extends from medial to lateral temporal cortex (Murray and Bussey, 1999), where it borders ventrolateral temporal regions of the ventral visual pathway. The activity in ventral temporal regions is modulated by stimulus familiarity (Desimone et al., 1995) and formed associations between visual stimuli (Fujimichi et al., 2004) and may thus be seen as critical for aspects of semantic memory. Interactions of lateral temporal and medial temporal regions may underlie episodic memory (Eichenbaum, 2004), with additional top-down contributions from frontal regions (Persson et al., 2002; see also the section titled 'The frontal lobe').

3.06.3.1.3 The amygdala

The amygdala is a key brain region for various forms of emotion, notably fear (LeDoux, 1994). The amygdala is not part of the core medial temporal memory system but has extensive connections with medial temporal as well as several other cortical and subcortical regions. Through such connections the amygdala seems able to emotionally influence various forms of cognition, including episodic memory (Phelps, 2004; LaBar and Cabeza, 2006). In episodic memory one such influence is the enhanced memory for emotionally arousing information. Such enhancement may in part reflect encoding and consolidation processes, but amygdala activation has specifically been related to recollecting emotional stimuli (Sharot et al., 2004) and to the successful retrieval of 1-year-old emotional memories (Dolcos et al., 2005). Thus, in interaction with other brain regions and neuromodulatory systems, the amygdala serves to emotionally flavor recollected episodic information (Markowitsch, 1995).

3.06.3.2 The Frontal Lobe

Lesions to the frontal lobes do not generally lead to amnesia, but frontal regions have direct or indirect connections with many cortical and subcortical areas, and a role for frontal cortex in various forms of learning and memory has been recognized for quite some time (*See* Chapter 3.14; Luria, 1973; Stuss and Benson, 1984). Of main concern here is that episodic memory impairment has been linked to frontal lobe damage (Wheeler et al., 1995). Frontal patients tend to be impaired on episodic recognition as well as recall tasks, with a more pronounced impairment for recall. That a deficit is seen on recognition tasks suggests that the frontal lobes contribute to the encoding of information, while the stronger reduction for frontal patients on recall tests indicates that frontal regions make a distinct contribution to retrieval processes. As noted earlier, functional brain imaging allows separate study of brain systems activated during the encoding and retrieval stages, and the results from such studies support a role for frontal regions in both encoding and retrieval of episodic information (Tulving et al., 1994; Nyberg et al., 1996a).

Frontal lobe contributions to episodic memory have been referred to as working-with-memory

(Moscovitch, 1992), or processes that control and optimize memory encoding and retrieval rather than storage *per se* (Fletcher and Henson, 2001). Indeed, the degree of activity in frontal regions during incidental encoding predicts subsequent episodic memory performance (Wagner et al., 1998). Several processes, mediated by frontal regions, may contribute to successful memory encoding, including generation, maintenance, and selection/organization of information (Fletcher and Henson, 2001).

At retrieval, frontal activity can reflect a number of processes as well. Retrieval mode, as was mentioned in the definition of episodic memory and in the earlier discussion of component processes of episodic memory, has been linked to several distinct frontal lobe regions, notably in the right hemisphere (Lepage et al., 2000). A defining feature of retrieval-mode type of activations is that they should be present in conditions of high as well as low levels of recollection (Lepage et al., 2000; **Figure 1**), whereas other processes and corresponding frontal activations depend on the level of retrieval success (Fletcher and Henson, 2001; Rugg, 2004). If a retrieval attempt fails, such as when one cannot remember the name of a person, additional search processes may be initiated. If the retrieval attempt succeeds, it may be necessary to verify that the retrieved information is correct. And for both these outcomes, failure and success, there is a need for

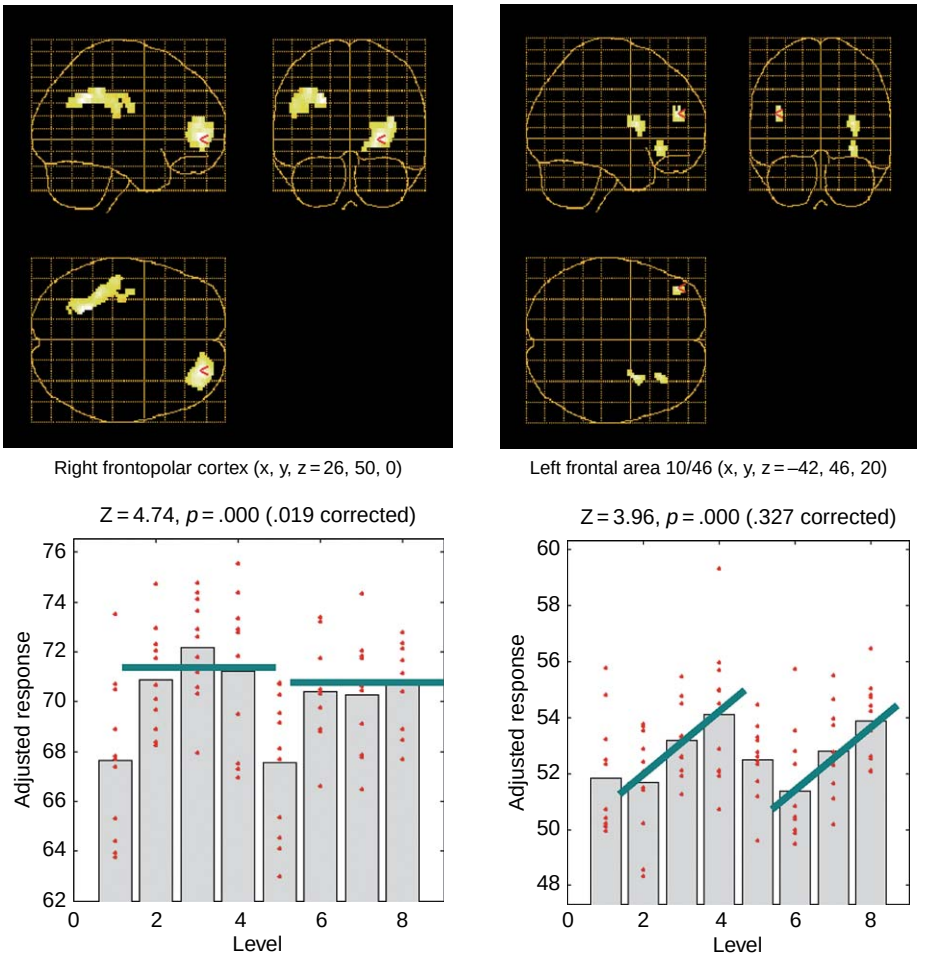

Figure 1 The left panel shows increased activity in right frontal cortex during episodic memory. The bar graph shows that right frontal cortex is associated with increased activity during verbal retrieval conditions of low, intermediate, and high target density (bars 2–4) relative to verbal encoding (bar 1). A similar pattern is seen for picture retrieval (bars 6–8) relative to picture encoding (bar 5). This pattern relates right prefrontal cortex to retrieval mode. By contrast, activity in a region of left frontal cortex (right panel) was modulated by retrieval success, as illustrated by the bar graph. Adapted from Nyberg L, Persson J, Habib R, et al. (2000) Large scale neurocognitive networks underlying episodic memory. *J. Cogn. Neurosci.* 12: 163–173, with permission.

monitoring the fate of the retrieval attempt. Specific regions of the frontal cortex seem to be involved in such component processes of episodic retrieval (Nolde et al., 1998; Cabeza and Nyberg, 2000; Buckner and Wheeler, 2001; Fletcher and Henson, 2001).

Episodic memory is typically classified as an explicit form of memory (Squire and Knowlton, 1995), and if explicit is defined in terms of intentional retrieval processes (Schacter et al., 1989), the recruitment of frontal regions critically contributes to explicit memory. More generally, frontal contributions to episodic memory are closely related to the concept of cognitive control (Wagner et al., 2004). For example, frontal activity is greater when participants have to identify target items among equally familiar distracter items than when they can base their response on stimulus familiarity alone (Persson et al., 2002; **Figure 2**), thereby relating increased levels of cognitive control to increased frontal activity (see also Fujimichi et al., 2004).

3.06.3.3 The Parietal Lobe

The parietal cortex is typically discussed in relation to various forms of attention. In a review of brain-imaging studies, it was found that parietal regions are often activated both in studies of selective attention and episodic memory retrieval (Cabeza and Nyberg, 2000). This observation suggests that, at least in part, parietal influences to episodic memory reflect attentional processes. However, activity in parietal regions is frequently modulated by level of retrieval success (Cabeza and Nyberg, 2000), indicating that parietal regions may indeed subserve mnemonic processes. This notion is further supported by findings that lateral and medial parietal regions show higher activity when old compared to when new stimuli are presented, and individuals correctly recognize the old information and correctly reject the new information (old/new effects; Wagner et al., 2005). Furthermore, the degree of activity seems to be modulated by recollective experience.

There are likely anatomical connections between regions of the parietal lobe and the medial-temporal lobe system that underlie various mnemonic processes (Wagner et al. 2005). Candidate processes that could account for the old/new parietal effect include attention to internal representations and the active representation of retrieved information. A related account of parietal (and frontal) activations was provided in a study of cross-domain similarities in brain activation patterns (Naghavi and Nyberg, 2005). Based on similarities in activation patterns for attention, working memory, episodic memory retrieval, and conscious perception (**Figure 3**), it was suggested that parietofrontal activity may reflect integration among multimodal distributed representations. Further research is needed to determine whether this activation pattern generalizes beyond the visual stimulus modality.

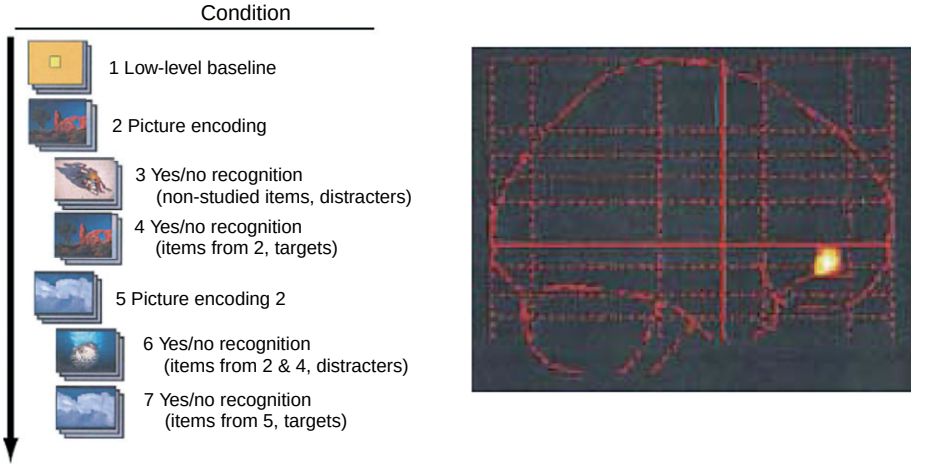

Figure 2 The left panel outlines the design of the experiment. By comparing recognition of old versus new pictures (condition 4 vs. 3) and recognition of old targets with equally familiar distracter items (condition 7 vs. 6), the demands on cognitive control could be varied (higher in the second than in the first comparison). Higher levels of cognitive control were associated with increased activity in left frontal cortex (right panel). Adapted from Persson J, Habib R, and Nyberg L (2002) Decreased activity in inferotemporal cortex during explicit memory: Dissociating priming, novelty detection, and recognition. *NeuroReport* 13: 1–5, with permission.

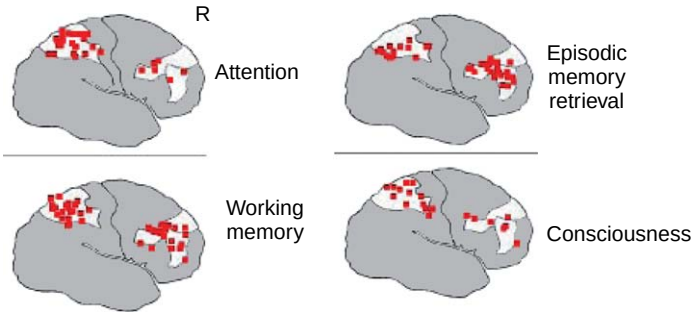

Figure 3 Overlapping patterns of frontoparietal activity in brain-imaging studies of attention, episodic retrieval, working memory, and visual consciousness. Adapted from Naghavi HR and Nyberg L (2005) Common fronto-parietal activity in attention, memory, and consciousness: Shared demands on integration? *Conscious. Cogn.* 14: 390–425, with permission.

3.06.3.4 Other Structures

3.06.3.4.1 Modality-specific cortical areas

In the discussion of regions of lateral temporal cortex it was mentioned that specific areas have been found to be engaged during episodic retrieval of visual information. This seems to be a general pattern that extends to other cortical regions and kinds of episodic information, such as parietal cortex for spatial information, occipital cortex for visual information, and motor cortex of the frontal lobe for information about activities (Buckner and Wheeler, 2001; Nyberg, 2002). The sites of retrieval-related activity overlap with how the brain was activated during initial perception/encoding. For example, regions of the parietal cortex that are engaged during spatial perception are subsequently reactivated during episodic retrieval of spatial information (Persson and Nyberg, 2000; **Figure 4**).

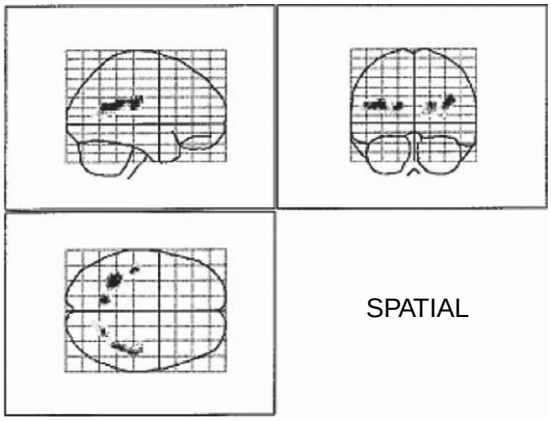

Figure 4 Areas of parietal cortex that were activated during both encoding and retrieval of spatial information. Adapted from Persson J and Nyberg L (2000) Conjunction analysis of cortical activations common to encoding and retrieval. *Microsc. Res. Tech.* 51: 39–44, with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

As suggested by theoretical models (Damasio, 1989), sites where overlapping activity is observed during encoding and retrieval may identify distributed sites of memory storage (Nyberg, 2002). Thus, the involvement of modality-specific regions during episodic memory may relate to 'ecphory' (i.e., an interaction between retrieval cues and stored information that results in actual retrieval of information). The hippocampus has been assigned an important role in integrating the distributed regions that jointly define a stored episodic memory (Teyler and DiScenna, 1986; Alvarez and Squire, 1994; McClelland et al., 1995; Nadel and Moscovitch, 1997).

3.06.3.4.2 Thalamus and the mammillary bodies

Damage to the medial portions of the diencephalon, notably the dorsomedial nucleus of the thalamus and the mammillary bodies, can cause diencephalic amnesia (Butters and Stuss, 1989). Butters and Stuss remarked that diencephalic amnesia may also result from damage to fiber tracts that connect the diencephalon with medial temporal lobe regions (a disconnection syndrome; see also Warrington and Weiskrantz, 1982). More recently, Vann and Aggleton (2004) provided support for the latter perspective by arguing that the mammillary bodies contribute to mnemonic processing through their projections to temporal regions.

It has been stressed that from the perspective of behavioral criteria there is striking similarity between diencephalic amnesia and medial temporal lobe amnesia, presumably due to close anatomical connections (Squire and Knowlton, 1995). For

example, both groups display similar forgetting rates. Therefore, the diencephalon may be seen as belonging to the same functional system as the medial temporal lobe complex (Squire and Knowlton, 1995).

3.06.3.4.3 The basal ganglia

The basal ganglia are part of the motor system. Patients with basal ganglia disorders, such as Huntington's or Parkinson's disease, show various forms of motor deficits. Critically, patients with basal ganglia deficits can exhibit cognitive deficits as well, including episodic memory impairment (Knowlton, 2002). The nature of episodic deficits is reminiscent of that seen in patients with frontal lobe damage, such as relatively greater impairment on more demanding tests of recall than on more supported recognition tests (Wheeler et al., 1995; cf. the section titled 'The frontal lobe'). This overlap in results patterns after lesions to the basal ganglia and the frontal lobe can be attributable to strong interconnections of the basal ganglia with most regions of the frontal lobe, via the limbic and the associative network (Yin and Knowlton, 2006).

3.06.3.4.4 The cerebellum

A final region to be mentioned is the cerebellum. This region is strongly associated with the coordination of movement. However, the cerebellum is not only connected with motor cortical areas but also with asserted cognitive regions (**Figure 5**), and the cerebellum has been argued to contribute to cognitive processing (Schmahmann, 1996). Increased activity in the cerebellum has specifically been observed during conscious episodic memory, and it was proposed that the cerebellum interacts with the cerebrum in a corticocerebellar network that initiates and monitors the conscious retrieval of episodic memories (Andreasen et al., 1999). Furthermore, deficient episodic memory in schizophrenia may, in part, stem from altered cerebellar activity (Achim and Lepage, 2005). Collectively, these findings indicate that the cerebellum should be considered a part of the brain network that subserves episodic memory.

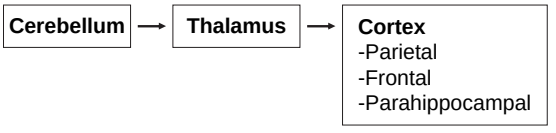

Figure 5 Schematic view of connections of the cerebellum with cortical areas that have been associated with mnemonic processes.

3.06.4 Relation Between Episodic Memory and Other Systems

Traditionally, most research activities have used the dissociation logic to define what is unique for various memory systems (Nyberg and Tulving, 1996). More recently, overlap in activity has begun to attract increased interest (Cabeza and Nyberg, 2003). In a multivariate analysis of brain-imaging data associated with measures of episodic memory, semantic memory, working memory, as well as nonmemory control tasks, similarities between episodic and semantic memory were observed (**Figure 6**; Nyberg et al., 2002). Commonly recruited regions for both episodic and semantic memory were located in left frontal cortex and right cerebellum (*See* Chapter 3.07). In addition, similarities were noted among measures of episodic and working memory, including right frontal and medial and lateral parietal cortex (**Figure 6**; Nyberg et al., 2002). These observations of overlap are in line with several other recent findings (Wagner, 1999; Cabeza and Nyberg, 2003) and also in keeping with the current definition of episodic memory, stating that episodic memory is subserved by a network of brain regions that overlaps with the networks that subserve other memory systems (Tulving, 2002). Assessment of regional overlap across a range of tasks can help to constrain the functional contribution of brain regions and define core cognitive component processes (Nyberg, 2006).

A controversial issue is whether some brain regions are specifically recruited by episodic memory tasks. This relates to the suggestion that the network subserving episodic memory extends beyond those subserving other systems (Tulving, 2002). The hippocampus, as was noted earlier, holds a special role in theories on the structural basis of episodic memory and has been referred to as a 'bottleneck structure,' as hippocampal damage leads to massive and enduring impairment of episodic memory (Markowitsch, 1995). The critical role of the hippocampus is closely related to its importance for conscious awareness (Squire et al., 2004), the core defining feature of episodic memory (Tulving, 2002). However, the performance on tasks that are *not* accompanied by awareness has been found to be impaired by hippocampal lesions (Chun and Phelps, 1999), indicating that hippocampal activation in and of itself is not a definite signature of episodic conscious memory (Eichenbaum, 1999; Squire et al., 2004). Instead, what may underlie the type of

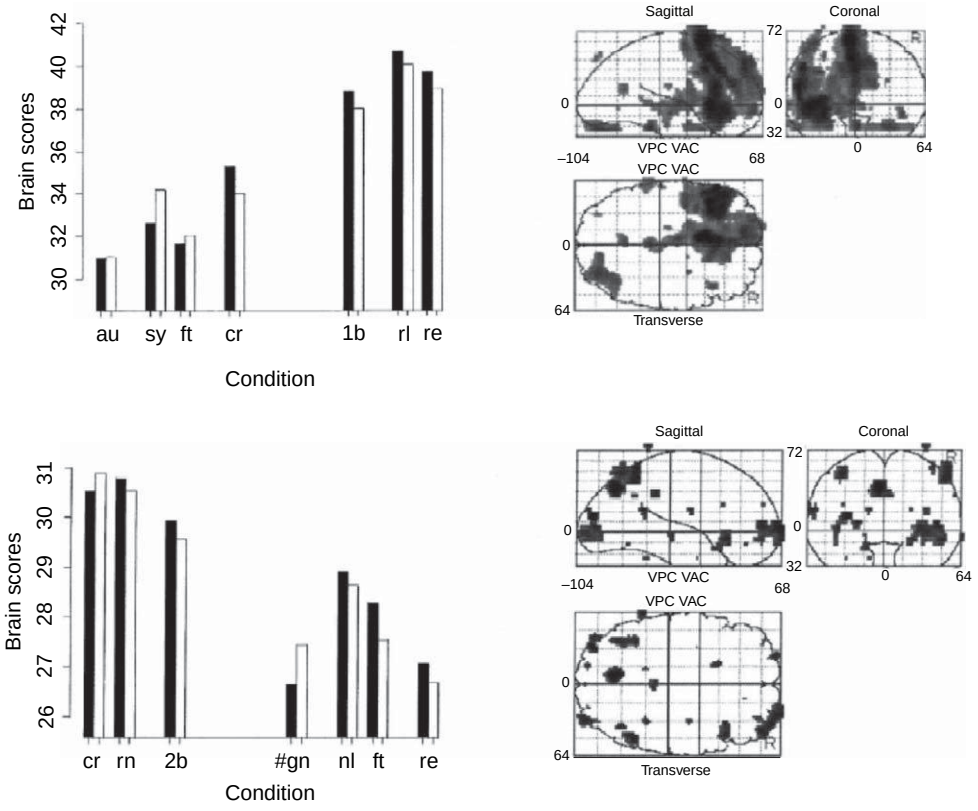

Figure 6 The top left panel shows how a multivariate analysis grouped tests of episodic (au, autobiographical memory; cr, cued recall) and semantic (sy, synonym generation; ft, fact retrieval) memory, and the top right panel shows brain regions that were jointly activated by episodic and semantic test. The lower panels show corresponding data for a grouping of tests of episodic (rn, recognition) and working (2b, 2-back test) memory. 1b, 1-back test; rl, read low demands (same word repeated); re, read; gn, random-number generation; nl, living/non-living categorization; VPC, VAC, posterior and anterior commissures. Adapted from Nyberg L, Petersson KM, Cabeza R, Forkstam C, and Ingvar M (2002) Brain imaging of human memory systems: Between-systems similarities and within-system differences. *Cogn. Brain Res.* 13: 281–292, with permission.

conscious awareness that signifies episodic memory is interactions among the hippocampus and other brain regions (Eichenbaum, 1999). In addition to the hippocampus, certain frontal regions have been suggested to have a special status in episodic memory by underlying the mental time travel component of episodic memory (Tulving, 2002). In particular, much discussion has concerned the role of anterior frontal cortex, corresponding to Brodmann's area 10, in particular in the right hemisphere. Right area 10 is frequently activated during episodic memory retrieval, but also by other tasks such as complex tests of working memory (MacLeod et al., 1998; Cabeza and Nyberg, 2000). Thus, as for the hippocampus, the evidence does not support a selective role of right area 10 in episodic memory (Ramnani and Owen, 2004), but it still remains a viable hypothesis that the frontopolar cortex, through interactions with other regions, critically contributes an episodic component to past and ongoing behavior (Koechlin et al., 2003). The crucial importance of considering network interactions is discussed further in the following section.

3.06.5 Interactions Among Episodic Memory Structures

It has been argued that all aspects of memory retrieval, including episodic retrieval, can be viewed as the activation of a network memory, i.e., increased firing of the neuronal ensembles that define the network (Fuster, 1997). In the review of episodic memory

brain structures, connections among several regions were highlighted, including:

- connections within temporal cortex (1) among different medial temporal regions; (2) between hippocampus and amygdala; and (3) among medial and lateral temporal regions;
- connections between medial-temporal and (1) parietal cortex; (2) modality-specific cortices; and (3) diencephalon;
- connections between frontal regions and cortical and subcortical areas such as (1) temporal cortex; (2) basal ganglia; and (3) cerebellum.

Although anatomical pathways have been identified for these connections, and although many of these regions have been found to be coactivated in brain-imaging studies of episodic memory, relatively little is still known about actual interregional interactions during task performance. This is so despite the fact that a network perspective has been emphasized for many years by several authors. One prominent example is the suggestion that amnesia might be seen as a disconnection syndrome in which frontal and temporal regions are functionally separated following lesions in thalamus and the mammillary bodies (Warrington and Weiskrantz, 1982). Most likely, the reason for the poor state of knowledge when it comes to regional interactions is methodological – it is difficult to measure and quantify such interactions. However, several lines of research substantiate the critical role of interactions (Simons and Spiers, 2003).

One source of evidence is animal studies that convincingly have shown that disruption of critical pathways has a profound impact on task performance (Hasegawa et al., 1998; Tomita et al., 1999; Gaffan et al., 2002). The findings of these studies substantiate the importance of frontotemporal interactions during memory retrieval. Computational models have also provided important information about regional interactions. This includes information about interactions among medial-temporal subregions (Norman and O'Reilly, 2003), interactions among hippocampus and modality-specific regions (Alvarez and Squire, 1994; McClelland et al., 1995; Norman and O'Reilly, 2003), and interactions between the basal ganglia and the frontal cortex (Atallah et al., 2004).

One further source of evidence comes from functional brain-imaging studies in humans, in which various connectivity approaches to data analysis are used (Büchel and Friston, 1997; McIntosh, 2000; Simons and Spiers, 2003). With these analytical tools, brain-imaging data can be used to quantify interactions and compare the strength of interregional connections between experimental conditions (Simons and Spiers, 2003, **Figure 7**). To date, the number of published imaging studies on episodic memory in which some form of connectivity analysis was used is quite low. However, important contributions have been made (Köhler et al., 1998; Büchel et al., 1999; Krause et al., 2000), and continued methods development (Lee et al., 2006) should pave the way for forthcoming contributions. Prefrontal-medial temporal interactions, in particular, should be critical to examine further for component processes of episodic memory retrieval (Simons and Spiers, 2003). Such examination should include variability in the degree to which a network is activated – both with

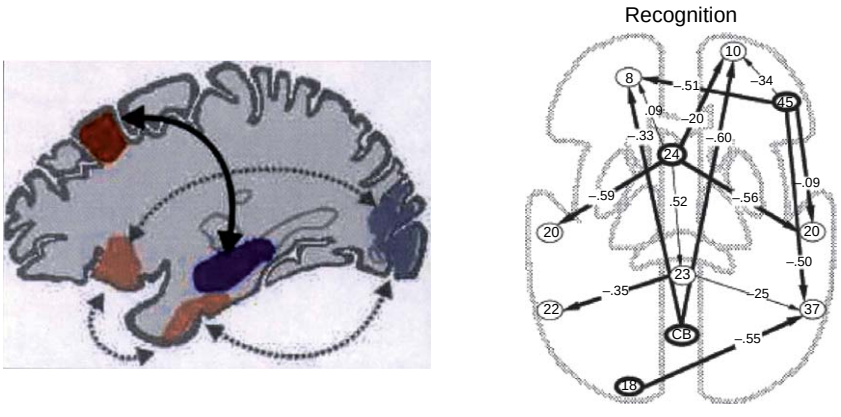

Figure 7 Illustration of connectivity approach to the analysis of functional brain imaging data. After having identified a set of regions and their connections (anatomical model; left), structural equation modeling can be used to estimate functional influences among regions of the network (right). Adapted from Nyberg L, McIntosh AR, Cabeza R, et al. (1996b) Network analysis of positron emission tomography regional cerebral blood flow data: Ensemble inhibition during episodic memory retrieval. *J. Neurosci.* 16: 3753–3759, with permission.

regard to the activation degree of its constituent elements at a given time and to variability in network activity over repeated ignitions (Fuster, 1997).

3.06.6 Variableness in the Structural Basis of Episodic Memory

The notion of a structural basis of episodic memory may give the impression that a static, fixed constellation of brain regions is recruited during retrieval. However, there is much evidence that the structural basis is quite variable or dynamic. One source of variation comes from the type of retrieval test that is used. As has been noted, less supported tests (e.g., free recall) generally tax some brain regions to a greater extent than more supported tests (e.g., recognition), such as frontal cortex, basal ganglia, and cerebellum. Also, there is some evidence that partly different brain regions are recruited during retrieval of information acquired in the laboratory compared to retrieval of real-life episodes (autobiographical memory). Depending on the testing conditions, autobiographical memory may be more similar in terms of its neural basis to semantic than episodic memory (Nyberg et al., 2002), or may more strongly activate the hippocampus and recollective processes than laboratory tests (Cabeza et al., 2004). Similarly, hippocampal activation has been found to be contingent on whether or not retrieval is accompanied by conscious recollection, such that hippocampal activity is specifically associated with recollective experience (remembering vs. knowing; Eldridge et al., 2000).

Another source of variation relates to practice or experience. There is converging evidence from several studies that network activity is strongly influenced by practice on a task, such that the degree to which different network elements are activated tends to decrease as a function of practice (Chein and Schneider, 2005). Regions that consistently show practice-related reductions are located in frontal and parietal cortices, and such reductions may reflect attenuated demand on supervisory control functions (Chein and Schneider, 2005). A related effect is that brain regions are recruited during retrieval in a time-dependent manner depending on the stage of memory consolidation (Maviel et al., 2004). Furthermore, the episodic memory system and related brain regions may be recruited during the initial stages of learning, whereas other systems and brain regions come into play at later stages of learning (Poldrack et al., 2001). All of these kinds of time- or practice-related effects will serve to induce variability in the brain structures that are engaged during episodic retrieval.

Yet another source of variation, which has not been extensively studied, is individual variability. Such variability may reflect genetically induced differences in personality and cognitive processes as well as between-person differences in real-life experiences (Fossella and Posner, 2004). The idiosyncratic nature of episodic memory may make it especially prone to show individual differences in the associated memory network (Fuster, 1997), and particularly so for network components that reflect memory storage. Future studies are called for that examine the brain bases of various forms of variability (MacDonald et al., 2006).

3.06.7 Summary and Future Directions

In summary, the main goal of the present chapter was to discuss the structural basis of episodic memory. We are still in the early stages of exploration, and many sources of variability must be taken into account, but a network of episodic-retrieval structures can tentatively be outlined (**Figure 8**; Damasio, 1989; Markowitsch, 1995; Fuster 1997). The activation of this network could start with a question, such as 'What did you do last Saturday evening?' This question would serve as a cue eliciting episodic retrieval mode and corresponding frontal activity. Signals from the frontal cortex, reflecting active retrieval, would then reach regions of the temporal lobe via subcortical pathways and trigger neuronal ensembles in the hippocampus that store sparse representations of past episodes. These ensembles would in turn activate specific neocortical sites, and in the case of emotional information, the amygdala, to reactivate memory traces. Feedback projections to the hippocampus would underlie recollective experience. The parietal cortex may represent retrieved information such that it is accessible for conscious processing, including monitoring and verification processes mediated by the frontal lobe. Additional search processes, if necessary, are subserved by the frontal cortex along with the basal ganglia and the cerebellum. This may initiate another memory network loop, as indicated by the dashed line in **Figure 8** from stage 6 to stage 1. Alternatively,

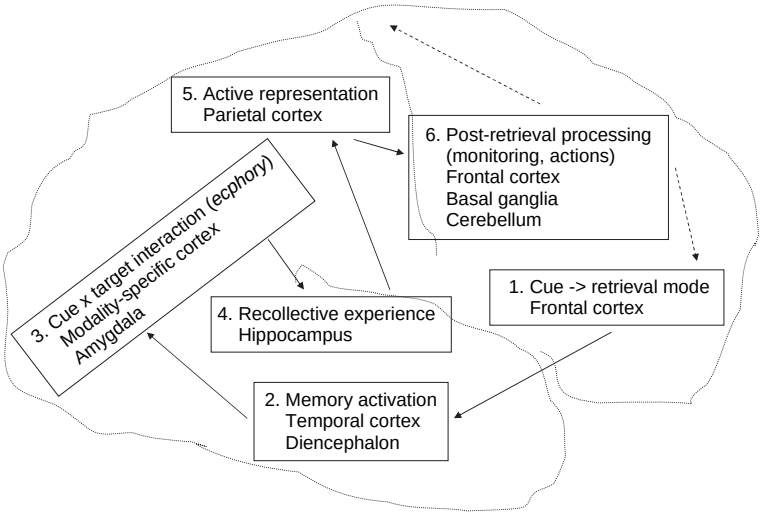

Figure 8 Schematic diagram of the episodic retrieval network. Both regions and component processes of retrieval are indicated. Arrows denote connections and information flow.

based on the output from the retrieval network, some form of action might be taken (represented in Figure 8 by the dashed line from stage 1 toward the motor cortex).

Obviously, future studies are needed to revise and refine this tentative episodic-retrieval network. Important issues to take into account include the following: (1) anatomical pathways – an interesting possibility is that *in vivo* studies of white matter connections can be used to study brain networks (Bürgel et al., 2006); (2) neuromodulation – the functioning of memory networks is modulated by various neurotransmitters such as dopamine (Bäckman and Farde, 2001; Meyer-Lindenberg et al., 2005; Schott et al., 2006); (3) temporal information – electromagnetic brain imaging techniques (Rugg, 2004) and advanced functional magnetic resonance imaging paradigms (Donaldson, 2004) can yield unique information about the timing and temporal profile of retrieval processes such as retrieval mode (Marklund et al., 2007); and (4) concepts – conceptual analysis is a crucial determinant of progress in defining the structural basis of episodic memory (Tulving, 2000).

3.07 Structural Basis of Semantic Memory

A. Martin and W. K. Simmons, National Institute of Mental Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Published by Elsevier Ltd.

3.07.1 Introduction

Semantic memory refers to a major division of long-term memory that includes knowledge of facts, events, ideas, and concepts. Thus, semantic memory covers a vast cognitive terrain, ranging from information about historical and scientific facts, to details of public events and mathematical equations, to the information that allows us to identify objects and understand the meaning of words. This chapter focuses on our current understanding of how semantic memories, especially object concepts, are represented in the brain. As we discuss later, ideas about the neural systems underpinning conceptual knowledge have a long history in behavioral neurology and neuropsychology dating back at least to the late nineteenth century. In recent times, however, the idea of semantic memory as a distinct memory system began in 1972 with Endel Tulving's distinction between semantic and episodic memory (Tulving, 1972). Although the notion of episodic memory has undergone considerable evolution since that original formulation (for a brief history see Tulving, 2002), it remains helpful to describe the properties of semantic memory in relation to episodic memory. In current formulations, episodic memory can be thought of as synonymous with autobiographical memory. Episodic memory is the system that allows us to remember (consciously recollect) past experiences (Tulving, 2002) and perhaps may also be critical for imagining and/or simulating future events (Hassabis et al., 2007; Schacter and Addis, 2007). Semantic memories, in contrast, are devoid of information about personal experience. Unlike episodic memories, semantic memories lack information about the context of

learning, including situational properties like time and place, and personal dimensions like how we felt at the time the event was experienced. Remembering that you had cereal and toast for breakfast, that you read the newspaper, and that you had a slight headache is dependent on episodic memory. Knowing and, indeed, being able to visually recognize objects like cereal, toast, and newspaper, as well as understanding the words you are now reading, is dependent on semantic memory. In relation to episodic memory, semantic memory is considered to be both a phylogenically and an ontologically older system. In fact, rather than arising as an independent evolutionary development, it is commonly assumed that episodic memory emerged as an add-on or embellishment to semantic memory (Tulving, 2002). Although many animals, especially mammals and birds, acquire information about the world, they are assumed to lack the neural machinery to consciously recollect detailed episodes of their past. Finally, although retrieval of semantic memory often requires explicit, conscious mediation, the organization of semantic memory can also be revealed via implicit tasks such as semantic priming (e.g., Neely, 1991).

The idea that our semantic and episodic memories were dependent on a distinct neural substrate was perhaps first proposed by the American neurologist J.M. Nielsen (1958). As Nielsen noted, amnesia came in two types. One type, which he termed temporal amnesia, was defined by a loss of memory for personal experiences. The other type, which he termed categorical amnesia, was defined by a loss of acquired facts. Nielsen further noted that there were different varieties of categorical amnesias, including amnesias for animate objects and amnesias for inanimate objects (Nielsen, 1946, 1958), presaging a distinction that is prominently highlighted later in this chapter. Nielsen also maintained that the temporal (episodic) and categorical (semantic) amnesias could occur in isolation, thereby noting that their respective neural substrates might be at least partially independent (Nielsen, 1958). Indeed, studies of patients with conceptual deficits have provided some support for Nielsen's claim (Hodges and Graham, 2001; Simons et al., 2002). However, before discussing those patients, we first discuss studies of semantic memory in patients with profound amnesias resulting from damage to the medial temporal lobes. These studies have provided evidence that medial temporal lobe structures play a critical role in acquiring and retrieving both semantic and episodic memories.

3.07.2 Semantic Memory and the Medial Temporal Lobe Memory System

Studies of patients with impaired episodic memory resulting from damage to the medial temporal lobes have established three broadly agreed-on facts about the functional neuroanatomy of semantic memory. First, like episodic memory, acquisition of semantic memories is dependent on medial temporal lobe structures, including the hippocampal region (CA fields, dentate gyrus, and subiculum) and surrounding neocortex (parahippocampal, entorhinal, and perirhinal cortices). Damage to these structures results in deficient acquisition of new information about vocabulary and famous individuals (e.g., Gabrieli et al., 1988; Hamann and Squire, 1995; Verfaellie et al., 2000, patient SS) and public events (Manns et al., 2003), and the extent of this deficit is roughly equivalent to the deficit for acquiring personal information about day-to-day occurrences.

However, despite broad agreement that acquiring semantic memories requires medial temporal lobe structures, there is disagreement concerning the role of the hippocampal region. One position holds that the hippocampus is necessary for acquiring semantic information (for discussion, see Squire and Zola, 1998). In contrast, others have argued that acquisition of semantic memories can be accomplished by the surrounding neocortical structures alone; participation of the hippocampus is not necessary (for discussion, see Mishkin et al., 1998). Recent studies seem to favor the hippocampal position by showing that carefully selected patients with damage limited to the hippocampus are impaired in learning semantic information about public events (Manns et al., 2003). One potentially important caveat to this claim comes from studies of individuals who have sustained damage to the hippocampus at birth or during early childhood (Vargha-Khadem et al., 1997). These cases of developmental amnesia have disproportionately better semantic than episodic memories, suggesting that the hippocampus may not be necessary for acquiring semantic information. For example, cases of developmental delay resulting from hippocampal damage, although failing to provide accurate descriptions of their daily activities (episodic memory), were able to acquire normal language and social skills, keep up with their schoolwork, and perform in the average range on standard measures of vocabulary and general knowledge (Vargha-Khadem et al., 1997). These findings

pose a clear challenge to the standard hippocampal model of declarative memory. Although discussion of this important issue is outside the purview of this chapter, it is certain that a reconciliation of this issue will depend on detailed and direct comparison of adult onset and developmental amnesias with regard to the extent of medial temporal lobe damage and its behavioral consequences.

The second major finding established by studies of amnesic patients is that the medial temporal lobe structures have a time-limited role in the retrieval of semantic memories, which is, in turn, presumably related to a prolonged consolidation process (Squire and Alvarez,1995; but see Moscovitch et al., 2005, for a critique of prolonged consolidation and a reappraisal of the role of the hippocampus in memory retrieval). Evidence in favor of the claim of a time-limited role for the hippocampal region in retrieving semantic memories comes from studies assessing the status of information acquired prior versus after the amnesia onset. Such studies have revealed that, for example, public event knowledge is temporally graded, with increasing accuracy for events further in time from the onset of the amnesia (Kapur and Brooks, 1999; Manns et al., 2003). The length of this temporally graded amnesia, however, can be surprisingly long and probably varies as a function of type of information tested and testing method. For example, in the Manns et al. study, the temporal gradient for news events lasted from 10 to 15 years when evaluated by a test of recall but less than 5 years when evaluated by a recognition test (Manns et al., 2003).

Studies of object and word knowledge are also consistent with the claim that the hippocampus has a time-limited role in retrieving semantic memories. Conceptual information about the meaning of objects and words known to be acquired decades prior to amnesia onset remains intact as assessed by both explicit and implicit tasks. Patients with damage to the hippocampal region are unimpaired on tests of object naming, object property verification, and object category sorting (e.g., Schmolck et al., 2002) and show normal semantic priming (Cave and Squire, 1992).

The third major finding established by studies of amnesic patients is that semantic memories of all types are stored in the cerebral cortex. Most importantly for our present concerns, impaired knowledge about objects and their associated properties acquired prior to amnesia onset is not related to medial temporal lobe damage but rather to the extent of damage to cortex outside this region (e.g., Levy et al., 2004).

3.07.3 Cortical Lesions and the Breakdown of Semantic Memory

Studies of semantic memory in amnesia have concentrated largely on measures of public event knowledge. The reason for this is that these tasks allow memory performance to be assessed for events known to have occurred either prior to or after amnesia onset. These measures also allow performance to be evaluated for events that occurred at different times prior to amnesia onset to determine whether the memory impairment shows a temporal gradient – a critical issue for evaluating theories of memory consolidation (Moscovitch et al., 2005). However, because these patients have either no or, more commonly, limited damage to regions outside the medial temporal lobes, they are not informative about how semantic information is organized in the cerebral cortex. To address this issue, investigators have turned to patients with relatively focal lesions compromising different cortical areas. In contrast to the studies of amnesic patients, these studies have focused predominantly on measures designed to probe knowledge of object concepts.

3.07.3.1 Object Concepts

An object concept refers to the representation (i.e., information stored in memory) of an object category (a class of objects in the external world) (Murphy, 2002). The primary function of a concept is to allow us to quickly draw inferences about an object's properties. That is, identifying an object as, for example, a 'hammer' means that we know that this is an object that is used to pound nails, so we do not have to rediscover this property each time the object is encountered (see Murphy, 2002, for an extensive review of cognitive studies of concepts).

A major feature of object concepts is that they are hierarchically organized, with the broadest knowledge represented at the superordinate level, more specific knowledge at an intermediary level commonly referred to as the 'basic level,' and the most specific information at the subordinate level (Rosch, 1978). For example, 'dog' is a basic-level category that belongs to the superordinate categories 'animal' and 'living things' and has subordinate categories such as 'poodle' and 'collie.' As established by Eleanor Rosch and colleagues in the 1970s, the basic level has a privileged status (Rosch et al., 1976; Rosch, 1978). It is the level used nearly

exclusively to name objects (e.g., 'dog' rather than 'poodle'). It is also the level at which we are fastest to verify category membership (i.e., we are faster to verify that a picture is a dog than that it is an animal or a poodle). It is also the level at which subordinate category members share the most properties (e.g., collies and poodles have similar shapes and patterns of movement). Finally, the basic level is the easiest level at which to form a mental image (you can easily imagine an elephant but not an animal). As discussed next, studies of patients with cortical damage have documented the neurobiological reality of this hierarchical scheme and the central role of the basic level for representing objects in the human brain.

3.07.3.2 Semantic Dementia and the General Disorders of Semantic Memory

Several neurological conditions can result in a relatively global or general disorder of conceptual knowledge. These disorders are considered general in the sense that they cut across multiple category boundaries; they are not category specific. Many of these patients suffer from a progressive neurological disorder of unknown etiology referred to as semantic dementia (SD) (Snowden et al., 1989; Hodges et al., 1992). General disorders of semantic memory are also prominent in patients with Alzheimer's disease (who typically have a greater episodic memory impairment than SD patients) (Martin and Fedio, 1983) and can also occur following left hemisphere stroke, prominently involving the left temporal lobe (e.g., Hart and Gordon, 1990).

The defining characteristics of semantic dementia, initially described by Elizabeth Warrington in the mid-1970s, are relatively isolated deficits on measures designed to probe knowledge of objects and their associated properties (Warrington, 1975). These deficits include impaired object naming (with errors typically consisting of semantic errors – retrieving the name of another basic level object from the same category, or retrieving a superordinate category name), impaired generation of the names of objects within a superordinate category (i.e., semantic category fluency), and an inability to retrieve information about object properties – including sensory-based information (shape, color) and functional information (motor-based properties related to the object's customary use – but may include other kinds of information not directly related to sensory or motor properties) (Warrington, 1975; Martin and Fedio, 1983; Patterson and Hodges, 1995). In contrast to modality-specific agnosias, the impairment is not limited to stimuli presented in a single modality like vision but, rather, extends to all tasks probing object knowledge regardless of stimulus presentation modality (visual, auditory, tactile) or format (words, pictures). In agreement with studies of the psychological nature of concepts, the semantic deficit reveals a hierarchical structure. Broad levels of knowledge are often preserved, whereas specific information is impaired. Thus, these patients can sort objects into superordinate categories, having, for example, no difficulty indicating which are animals, which are tools, which are foods, and the like (Warrington, 1975; Martin and Fedio, 1983). Their primary difficulty manifests as a problem distinguishing among the basic level objects as revealed by impaired performance on measures of naming and object property knowledge. For example, when confronted with a picture of a specific basic level object like 'camel,' these patients often produce the name of another object from the same conceptual category (e.g., 'goat') or a superordinate term ('animal') (Warrington, 1975; Martin and Fedio, 1983).

Recent studies have expanded our understanding of SD in two important ways: one related to location of neuropathology, the other to functional characteristics of the disorder. The initial neuropathological and imaging studies of SD indicated prominent atrophy of the temporal lobes, especially to the anterolateral sector of the left temporal lobe, including the temporal polar cortex, the inferior and middle temporal gyri, and the most anterior extent of the fusiform gyrus (Hodges and Patterson, 1996). However, recent advances in neuroimaging that allow for direct and detailed comparison of brain morphology in SD patients relative to healthy control subjects have shown that the atrophy extends more posteriorally along the temporal lobe than previously appreciated (Mummery et al., 2000; Gorno-Tempini et al., 2004; Williams et al., 2005). In fact, the amount of atrophy in ventral occipitotemporal cortex, including the posterior portion of the fusiform gyrus, has been reported to be as strongly related to the semantic impairment in SD as is atrophy in the most anterior regions of the temporal lobes (Williams et al., 2005).

The other major advance in our understanding of SD is that it is not as global a conceptual disorder as initially thought. Rather, certain domains of knowledge may be preserved, and the pattern of impaired and preserved knowledge appears to be related to the locus of pathology. Specifically, left-sided atrophy seems to impair information about all object categories except person-specific knowledge

(i.e., information about famous people), which in turn is associated with involvement of the right anterior temporal lobes (Thompson et al., 2004). Also relatively spared is knowledge of number and mathematical concepts (Cappelletti et al., 2005), a domain strongly associated with left posterior parietal cortex (Dehaene et al., 2003).

3.07.3.3 Category-Specific Disorders of Semantic Memory

Although case reports of relatively circumscribed knowledge disorders date back over 100 years, the modern era of the study of category-specific disorders began in the early 1980s with the seminal reports of Warrington and colleagues (Warrington and Shallice, 1984; Warrington and McCarthy, 1987). Category-specific disorders have the same functional characteristics as SD, except that the impairment is largely limited to members of a single superordinate object category. For example, a patient with a category-specific disorder for 'animals' will have greater difficulty naming and retrieving information about members of this superordinate category relative to members of other superordinate categories (e.g., tools, furniture, flowers). Similar to patients with SD, patients with category-specific disorders have difficulty distinguishing among basic level objects (e.g., between dog, cat, horse), thereby suggesting a loss or degradation of information that uniquely distinguishes members of the superordinate category (e.g., four-legged animals) (for recent collection of papers on these patients see Martin and Caramazza, 2003).

A variety of category-specific disorders have been reported such as relatively circumscribed deficits for knowing about fruits and vegetables (Hart et al., 1985; Crutch and Warrington, 2003). However, consistent with Nielsen's clinical observations (Nielsen 1946, 1958), most common have been reports of patients with relatively greater knowledge deficits for animate entities – especially animals, than for a variety of inanimate object categories. Although less common, other patients show the opposite dissociation: a greater impairment for inanimate manmade objects – including common tools – than for animals and other living things (for extensive review of the clinical literature, see Capitani et al., 2003).

3.07.3.3.1 Models of category-specific disorders

Two major theoretical positions have been advanced to explain these disorders. Following the explanation posited by Warrington for her initial cases, most current investigators assume that category-specific deficits are a direct consequence of an object property-based organization of conceptual knowledge, an idea that was prominent in the writings of Karl Wernicke, Sigmund Freud, and other behavioral neurologists during the late nineteenth and early twentieth centuries. The central idea is that object knowledge is organized in the brain by sensory (e.g., form, motion, color, smell, taste) and motor properties associated with the object's use (Martin et al., 2000), and in some models other functional/verbally mediated properties such as where an object is typically found (for discussion of sensory/functional models, see Forde and Humphreys, 1999). In this property-based view, category-specific semantic disorders occur when a lesion disrupts information about a particular property or set of properties critical for defining and for distinguishing among category members. Thus, damage to regions that store information about object form, and form-related properties like color and texture, will produce a disorder for animals. This is because visual appearance is assumed to be a critical property for defining animals and because the distinction between different animals is assumed to be heavily dependent on knowing about subtle differences in their visual forms. A critical prediction of sensory-/motor-based models is that the lesion should affect knowledge of all object categories with this characteristic, not only animals. In a similar fashion, damage to regions that store information about how an object is used should produce a category-specific disorder for tools and all other categories of objects defined by how they are manipulated. Cognitive studies with normal individuals on the relationship between and among object features and attributes show broad consistency with the known patterns of category-specific disorders, thus providing additional evidence in support of property-based models (Cree and McRae, 2003).

The alternative to these property-based theories is the domain-specific view championed most recently by Alfonso Caramazza and colleagues (Caramazza and Shelton, 1998; Caramazza and Mahon, 2003). On this account, our evolutionary history provides the major constraint on the organization of conceptual knowledge in the brain. Specifically, the theory proposes that selection pressures have resulted in dedicated neural machinery for solving, quickly and efficiently, computationally complex survival problems. Likely candidate domains offered are animals, conspecifics, plant life, and possibly tools (for a detailed discussion

of these models, see Caramazza, 1998). Property-based and category-based accounts are not mutually exclusive. For example, it is certainly possible that concepts are organized by domains of knowledge, implemented in the brain by large-scale property-based systems (Mahon and Caramazza, 2003). Much of the functional neuroimaging evidence to be discussed later is consistent with this view.

3.07.3.3.2 Functional neuroanatomy of category-specific disorders

There is considerable variability in the location of lesions associated with category-specific disorders for animate and inanimate entities. Nevertheless, some general tendencies can be observed. In particular, category-specific knowledge disorders for animals are disproportionately associated with damage to the temporal lobes (Gainotti, 2000). The most common etiology is herpes simplex encephalitis, a viral condition with a predilection for attacking anteromedial and inferior (ventral) temporal cortices (Adams et al., 1997). Category-specific knowledge disorders for animals also have been reported following focal, ischemic lesions to the more posterior regions of ventral temporal cortex, including the fusiform gyrus (Vandenbulcke et al., 2006). In contrast, category-specific knowledge disorders for tools and their associated actions have been most commonly associated with focal damage to lateral frontal and parietal cortices of the left hemisphere (Tranel et al., 1997; Gainotti, 2000). However, it is important to stress that the lesions in patients presenting with category-specific knowledge disorders are often large and show considerable variability in their location from one patient to another (Capitani et al., 2003). As a result, these cases have been relatively uninformative for questions concerning the organization of object memories in cerebral cortex. In contrast, recent functional neuroimaging studies of the intact human brain have begun to shed some light on this thorny issue.

3.07.4 The Organization of Conceptual Knowledge: Neuroimaging Evidence

3.07.4.1 Neuroimaging of Semantic Memory

For nearly two decades cognitive neuroscientists have used positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) to explore the functional neuroanatomy of semantic memory. Although the particular methods, experimental paradigms, and stimuli vary widely, the general tack taken in most studies has been to compare brain activity when subjects engage in tasks requiring the encoding or retrieval of conceptual information (e.g., Is this object a man-made artifact?) versus the activity associated with equally difficult nonconceptual processing (e.g., Does this object's name contain the letter b?), using the same stimuli. The neuroanatomical claims made by these studies are further strengthened when subsequent research observes activity in the same brain regions using stimuli that are conceptually related (e.g., judging whether objects are artifacts) but physically different (e.g., seeing photographs vs. hearing sounds vs. reading names of artifacts). Such findings demonstrate that the regions are responding to the stimuli's conceptual content rather than their physical characteristics. As we will see, however, this does not mean that objects' physical properties are unimportant to their neural representations. On the contrary, using a variety of concepts and object categories, it has been well documented that object concepts are represented in the brain as distributed property circuits, whereby the information most relevant to real-world interactions with an object is stored in the same sensorimotor regions active when that information was acquired.

Studies comparing conceptual to nonconceptual processing consistently identify three brain regions – the left ventrolateral prefrontal cortex (VLPFC) and the ventral and lateral regions of the temporal lobes. A large functional neuroimaging literature demonstrates that the VLPFC serves as a control center for semantic memory, guiding retrieval and postretrieval selection of concept property information stored in other brain regions (Bookheimer, 2002; Martin, 2001; Thompson-Schill, 2003). These functional neuroimaging findings are consistent with neuropsychological findings with patients who, subsequent to left inferior frontal lesions, exhibit word retrieval difficulties while retaining conceptual knowledge for those same words (Baldo and Shimamura, 1998; Thompson-Schill et al., 1998). Information about this region's role in semantic memory has been augmented by recent functional neuroimaging studies that find distinct mechanisms within the VLPFC for information retrieval and selection among competing alternatives (Badre et al., 2005). Although claims for dissociable retrieval and selection subregions in VLPFC remain controversial, there is wide agreement that this region's primary role is to control and manipulate information stored elsewhere (Gold et al., 2005, 2006).

3.07.4.2 Object Concepts as Sensorimotor Property Circuits

In addition to the VLPFC, a significant body of research demonstrates that various property regions located in or near perceptual cortex store information about object concepts. In particular, these studies find that the posterior ventral and lateral temporal lobes are particularly important for storing information about object concepts (Martin and Chao, 2001; Thompson-Schill, 2003; Martin, 2007). We will see that important clues about how knowledge is represented in the human brain come from how information is organized within these regions.

As described earlier, cases of category-specific deficits point toward a central role for property information in the organization of semantic memory. Early functional neuroimaging research using PET imaging supported these lesion study findings. Using a property production task in which subjects were required to generate a word describing a specific property of a visually presented object, Martin and colleagues (Martin et al., 1995; also see Chao and Martin, 1999; Wiggs et al., 1999) demonstrated that producing color-associate words (e.g., saying 'yellow' in response to an achromatic picture of a pencil or to its written name) elicited activity in the fusiform gyrus just anterior to regions activated when subjects passively viewed color stimuli. In contrast, producing action word associates (e.g., saying 'write' in response to a pencil) elicited activity in premotor cortex as well as a region of the left posterior middle temporal gyrus (pMTG) just anterior to primary visual motion-selective cortex MT/V5. Similar effects have now been observed for other property modalities as well, with sound, touch, and taste properties activating the corresponding auditory, somatosensory, and gustatory cortical regions (Kellenbach et al., 2001; Goldberg et al., 2006).

Functional neuroimaging findings demonstrating that retrieving object property information activated regions near perceptual and motor cortex are highly suggestive of the sensorimotor hypotheses generated in the literature on category-specific disorders. More recently, however, strong evidence for these accounts has come from fMRI studies demonstrating direct overlaps in the neural bases of knowledge, perception, and action. For example, Simmons et al. (in press) demonstrated a direct overlap in the neural bases of color perception and color knowledge retrieval. Using an attention-demanding task requiring fine-grain discriminations among color hues, they first mapped the brain regions underlying color perception. Next, in separate scanning runs, they presented subjects with a verbal property verification task in which they indicated whether color or motor property words could be true of a concept word. Using the color perception task as a functional localizer, they observed that the most color-responsive region in the perception task, located in the left fusiform gyrus, was also activated for color knowledge retrieval relative to retrieving motor knowledge (**Figure 1**). Evidence for direct overlaps between knowledge retrieval and sensorimotor

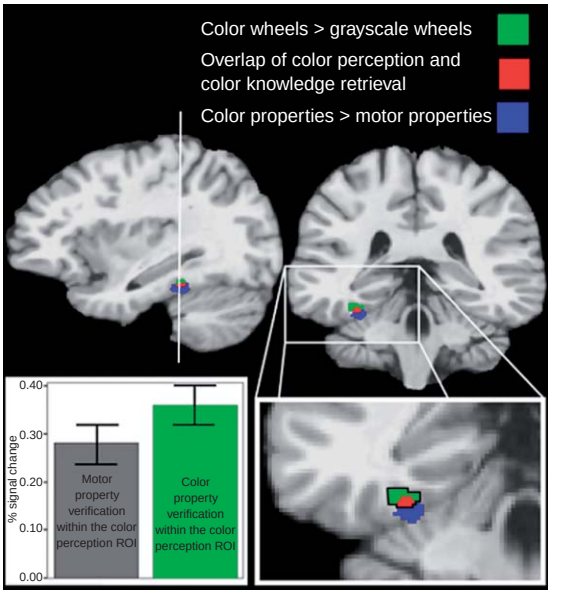

Figure 1 Overlap in perceptual and conceptual color processing. On top, the figure depicts sagittal and coronal sections from the N27 template brain warped to Talairach space (template available in AFNI). The functional overlays represent Talairach-normalized group data from the random effects analysis. Green patches indicate regions where activity was greater for processing color than grayscale wheels in the color perception task ($p < 0.0001$). Blue patches indicate regions where activity was greater for verifying color properties than motor properties in the knowledge retrieval task ($p < 0.01$ with a cluster size of at least 108 mm^3). The red patch in the left fusiform gyrus indicates the region of overlap between the two tasks. The inset bar graph demonstrates that within the left fusiform ROI, where color perception produced a greater response than grayscale perception (in other words, within the combined green and red patches), the average BOLD response to color property words in the property verification task was greater than the response for motor property words ($p = 0.006$). The *y*-axis indicates percent signal change relative to signal baseline, with error bars representing ± 1 standard error of the subject means. Adapted from Simmons WK, Ramjee V, Beauchamp MS, McRae K, Martin K, Martin A, and Barsalou LW (in press) A common neural substrate for perceiving and knowing about color. *Neuropsycholgia*.

property systems are not limited to color properties. For example, Pulvermuller and colleagues have demonstrated that simply reading words referring to actions performed with a particular body part (e.g., lick, kick, pick) activated the corresponding motor cortex (e.g., face, foot, and hand representations, respectively) (Hauk et al., 2004).

Together, these findings support claims that knowledge about a particular object property, such as its color or the actions associated with it, resides in the same sensorimotor regions that are active when that information is experienced in the external world. If this is correct, then object categories should have predictable neural representations based on their multimodal property profiles. This appears to be the case. For example, the most salient properties of appetizing foods are how they look, how they taste, and how rewarding they are to eat. Using fMRI, Simmons et al. (2005) demonstrated that viewing images of appetizing foods (e.g., cookies, pizza) while performing a low-level picture repetition detection task was enough to elicit bilateral activity in ventral occipitotemporal regions tuned to represent object form information (e.g., how objects look). Consistent with the sensorimotor account of knowledge representation, the researchers also observed activity in regions of the right insula/operculum (primary gustatory cortex) and left orbitofrontal cortex (OFC) (secondary gustatory cortex) activated in prior fMRI studies when subjects received tastants orally in the scanner (**Figure 2**).

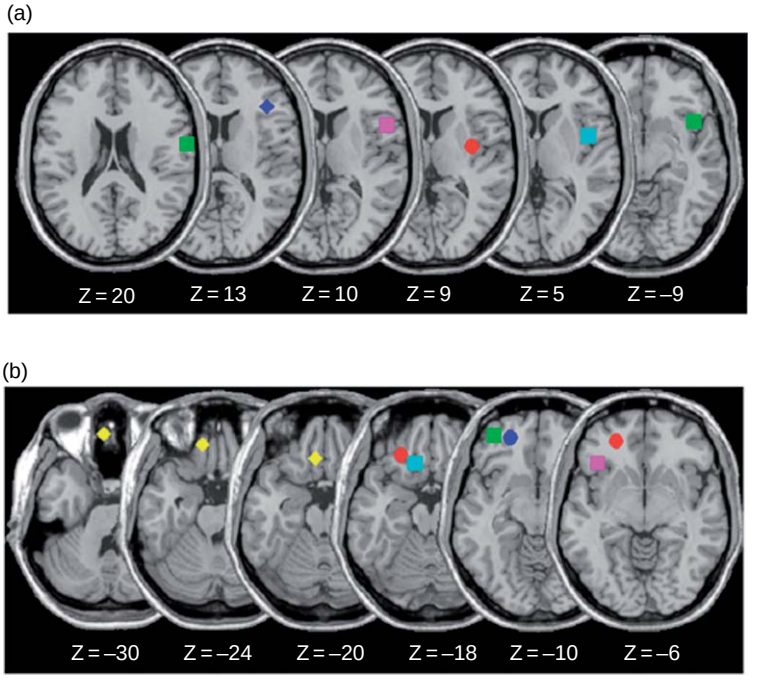

Figure 2 (a) Locations of peak right hemisphere insula/operculum activations reported in taste perception studies. (b) Locations of peak left orbitofrontal cortex (OFC) activations across various tasks. The green squares in the insula/operculum at $Z = 20$ and $Z = -9$ represent peak activations observed when participants taste sucrose, whereas the green square in the lateral OFC at $Z = -10$ is the peak activation in the area observed to respond to the combination of gustatory and olfactory stimuli, and thus it is a likely candidate for being the center of flavor representation (de Araujo et al., 2003b). The blue diamond in the insula/operculum at $Z = 13$ indicates an area of common activation when participants tasted either glucose or salt (O'Doherty et al., 2001b). The pink squares in the insula/operculum at $Z = 10$ and in the OFC at $Z = -6$ indicate the peak activations observed when participants taste umami (de Araujo et al., 2003a). The aqua squares in the insula/operculum at $Z = 5$ and in the OFC at $Z = -18$ represent peak activations when participants tasted glucose (Francis et al., 1999). Yellow diamonds in the inferior medial OFC represent peak activations observed when participants receive abstract rewards (O'Doherty et al., 2001a). The blue circle in the OFC at $Z = -10$ represents peak activation observed when participants verify the taste properties of concepts using strictly linguistic stimuli (Simmons, Pecher, Hamann, Zeelenberg, and Barsalou, Poster presented at the Annual Meeting of the Cognitive Neuroscience Society, New York, NY, April 2003). Finally, the red circles in the insula/operculum at $Z = 9$ and in the OFC at $Z = -18$ and $Z = -6$ indicate the activation peaks observed in the present study when participants viewed food pictures. When necessary, coordinates reported in other studies were converted from Talairach to MNI space. Adapted from Simmons WK, Martin A, and Barsalou LW (2005) Pictures of appetizing foods activate gustatory cortices for taste and reward. *Cereb. Cortex* 15: 1602–1608.

These findings demonstrate that information about object-associated properties is stored and represented across numerous property regions in the brain, rather than in a single unitary semantic memory storehouse. In addition, the property regions that compose a concept's neural representation overlap with the brain regions mediating that property's perception. Findings to this effect provide strong evidence that at least some aspect of object knowledge is maintained in a modality-specific, perceptual format (Barsalou, 1999). This stands in stark contrast to accounts describing human knowledge solely in terms of amodal, propositional, and linguistic formats that bear arbitrary relationships to the perceptual experiences through which the information was acquired (Fodor, 1975; Pylyshyn, 1984; Kintsch, 1998).

3.07.4.3 Object Categories in the Brain

The vast majority of studies examining the neural bases of object concept knowledge have presented subjects with photographs of exemplars from various object classes. Given that a large body of monkey neurophysiology and human neuroimaging evidence indicates that the occipitotemporal cortex plays a central role in object perception (Grill-Spector, 2003; Grill-Spector and Malach, 2004), it is unsurprising that in these studies the different object categories invariably activate this region. This does not imply, however, that the ventral occipitotemporal cortex is an undifferentiated object-processing system. Rather, comparisons between classes of objects demonstrate that local regions within the ventral occipitotemporal cortex are particularly responsive to some categories relative to others. Perhaps the most well-known category-responsive brain region is the fusiform face area (FFA), which responds reliably and selectively to face stimuli (Kanwisher et al., 1997; see Kanwisher and Yovel, 2006, for review). Other frequently studied object categories include environmental scenes (places), which reliably activate a region in parahippocampal cortex (Aguirre et al., 1998; Epstein and Kanwisher, 1998), as well as animals and tools, each activating lateral and medial fusiform cortex, respectively (Chao et al., 1999; see Martin and Chao, 2001, and Martin, 2007 for reviews).

The topographic relations among these category-responsive ventral temporal regions are a topic of much research interest. Clearly, distinct categories are associated with activation peaks in particular regions. fMRI pattern analysis techniques, however, have demonstrated that they are also associated with distinct neural signatures across large swaths of ventral occipitotemporal cortex (Haxby et al., 2001; Spiridon and Kanwisher, 2002; Cox and Savoy, 2003). For now, it remains an open question as to how central these nonpeak areas are in the cognitive representation of concepts from any particular category (Haxby et al., 2001; Spiridon and Kanwisher, 2002; Reddy and Kanwisher, 2006). In contrast, however, to this debate about the distributedness of concept representation within a single brain region, human functional neuroimaging evidence leaves little room for debate as to whether conceptual information is distributed across brain regions. Conceptual knowledge is unequivocally distributed throughout the brain, and some of the best evidence to this effect comes from the study of two broad classes of knowledge: animate entities and tools.

3.07.4.4 Two Case Studies in Category Representation: Animate Entities and Tools

Motivated by category-specific deficits for animals and tools reported in the neuropsychological literature, many functional neuroimaging studies have focused on defining the neural substrate underlying knowledge of animate entities and small, manipulable artifacts such as tools. As we will see, these studies have shown that tasks involving animate objects (i.e., people and animals) are associated with activity in the distributed neural circuit engaged while perceiving animate entities' most salient properties, namely, what they look like and how they move. For example, Chao et al. (1999) demonstrated that naming pictures or reading words denoting animal concepts activated lateral regions in the fusiform gyrus (located along the ventral surface of the temporal lobes and including the FFA), as well as the posterior extent of the superior temporal sulcus (pSTS), located laterally along the temporal lobe (**Figure 3**). In contrast, these authors demonstrated that performing these tasks with manipulable artifacts (e.g., tools) activates a distributed neural circuit underlying not only what these objects look like and how they move but also their function-associated motor properties, including medial regions in the fusiform gyrus, the pMTG, and in a later study, posterior parietal and ventral premotor regions (Chao and Martin, 2000).

The fusiform region activated by animal and tool stimuli is part of a larger object-form processing stream stretching along the ventral surfaces of the

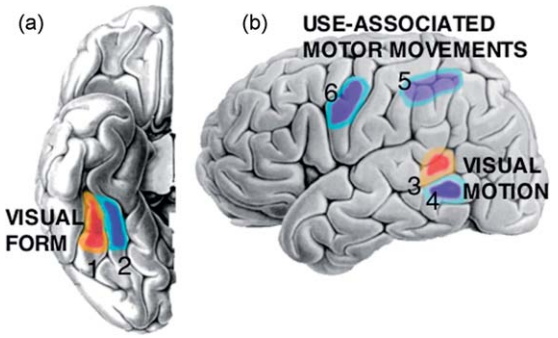

Figure 3 Schematic illustration of regions exhibiting category-related activity for animate entities such as animals and people (red) and manipulable artifacts such as tools (blue). (a) Ventral view of the right hemisphere showing relative location of regions assumed to represent visual form and form-related properties like color and texture of animate entities (1. lateral region of the fusiform gyrus, including, but not limited to, the fusiform face area) and tools; (2. medial region of the fusiform gyrus). (b) Lateral view of the left hemisphere showing relative location of regions assumed to represent biological motion typical of animate entities (3. pSTS) and rigid motion vectors typical of tools (4. pMTG). Also shown are the relative locations of the posterior parietal (5. typically centered on the intraparietal sulcus) and ventral premotor (6.) regions of the left hemisphere assumed to represent information about the motor movements associated with using tools.

occipital and temporal lobes (Ungerleider and Mishkin, 1982). Within this so-called ventral visual stream the form features of visual inputs are processed in a hierarchically organized manner, with more anterior regions representing higher-order information about what objects look like (Riesenhuber and Poggio, 1999; Grill-Spector and Malach, 2004). In contrast, the lateral temporal regions activated by animal and tool stimuli are located immediately anterior to the much-studied visual motion area V5/MT (Watson et al., 1993).

Although the location of these category-responsive regions relative to form and motion processing areas was suggestive as to their functional significance, the clearest evidence for the specific functions played by these two regions in conceptual processing *per se* comes from the work of Beauchamp and colleagues. In a series of studies, subjects were shown static and moving stimuli of humans (photographs and video clips of people performing actions such as jumping, walking, and sitting) and manipulable objects (e.g., photographs and video clips of tools such as hammers, saws, and scissors, moving in characteristic ways) (Beauchamp et al., 2002, 2003). As expected, the two classes of stimuli activated distinct regions in the ventral and lateral temporal lobes (**Figure 4**). Beauchamp et al. (2002) observed that in the fusiform gyrus, lateral regions responded more strongly to depictions of humans, and medial regions responded more to manipulable objects. Importantly, however, both regions responded equally to their preferred stimuli, regardless of whether those stimuli were static or dynamic. In a subsequent study, Beauchamp et al. (2003) observed that the lateral and medial fusiform responded much more to videos of humans and tools, respectively, than they did to point-light displays of humans and tools that lacked the form and color features of the video stimuli, but which maintained their motion vectors. Taking these two sets of findings together, we can infer that the lateral and medial fusiform regions are not modulated by motion but, rather, respond to the form features characterizing object concepts from their preferred categories – form features that are present in both static and dynamic depictions of an object.

Unlike the ventral temporal cortex, lateral temporal regions were more responsive to dynamic than static stimuli, with the pSTS and pMTG exhibiting strong category selectivity. The pSTS responded more strongly to dynamic depictions of human actions than to tool motion. This finding is consistent with monkey neurophysiology and human fMRI studies demonstrating that this region is particularly tuned to flexible, fully articulated motion vectors that characterize biological motion (Oram and Perrett, 1994; Puce et al., 1998; Grossman and Blake, 2001; Pelphrey et al., 2005). In contrast, relative to human actions, the pMTG responded more strongly to the rigid, unarticulated motion vectors characterizing dynamic depictions of tool motions. Thus, in the same way that activity in ventral temporal cortex differentiates along category boundaries, presumably due to different visual form characteristics for animate objects and manipulable artifacts, so activity in lateral temporal cortex similarly differentiates the distinctive motion properties of the two categories.

As reviewed earlier, behavioral (Cree and McRae, 2003) and imaging (see Martin, 2007) evidence demonstrate that an object concept's property profile (e.g., its form, motion, taste, sound) predicts the conglomeration of sensorimotor regions underlying that object concept's storage and representation in the brain. In light of this, it should come as no surprise that in addition to the temporal regions representing their form and motion properties, tasks involving manipulable artifacts also recruit posterior parietal and ventral premotor regions supporting the representation of

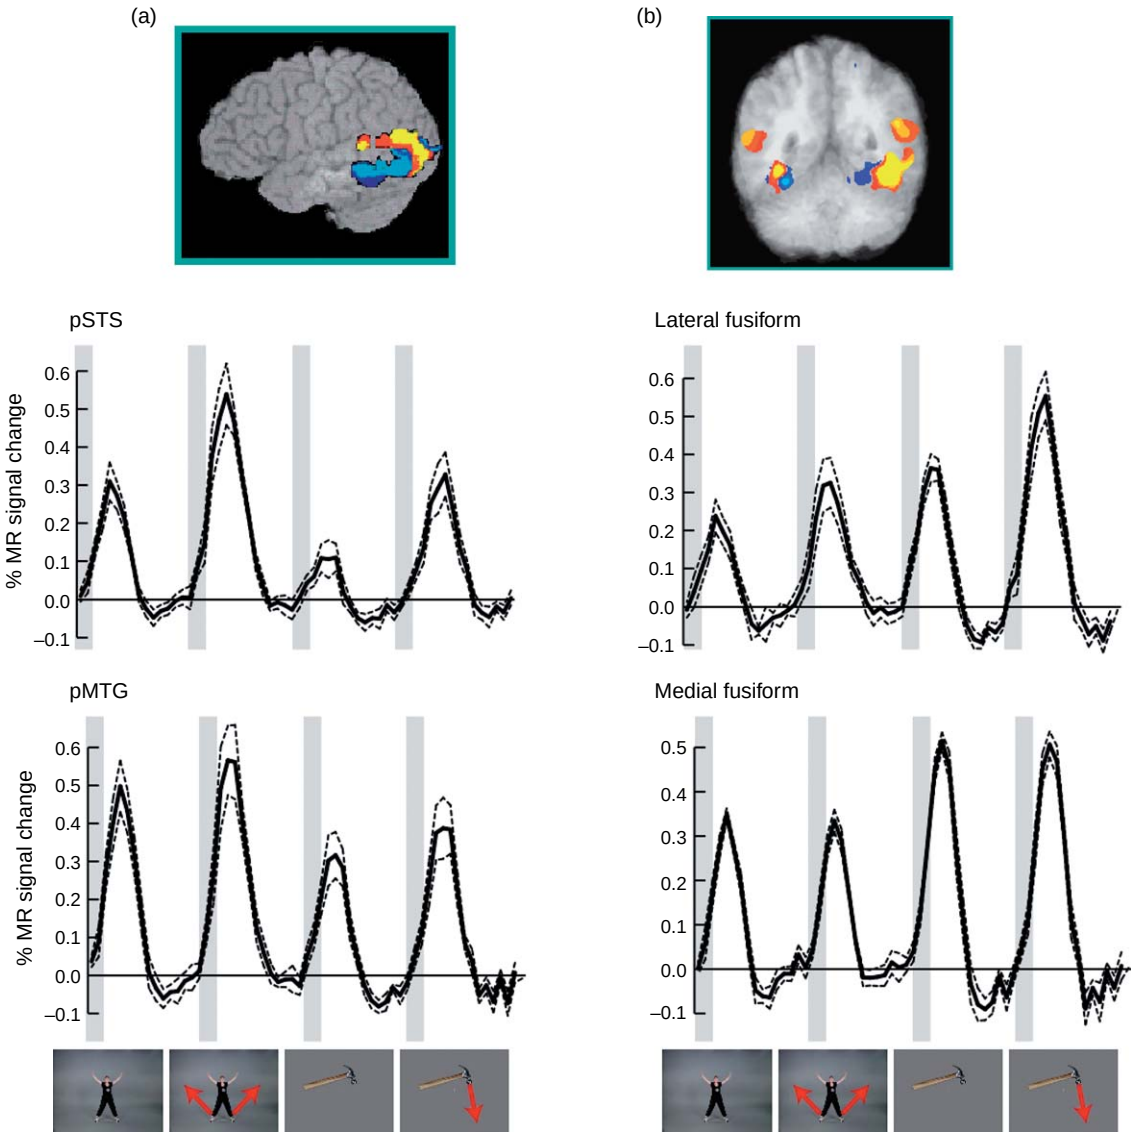

Figure 4 (a) Lateral view of the left hemisphere showing MTG regions that are more responsive when subjects identify static and moving images of tools than people (blue), and pSTS regions that are more responsive for identifying people than tools (yellow). (b) Coronal section illustrating medial fusiform regions that are more responsive when subjects identify static and moving images of tools than people (blue), and the lateral fusiform region that is more active for identifying people (yellow). Below each brain are group-averaged bold response functions depicting activity for static and moving images in each region shown in (a) and (b). The lateral cortical areas in (a) exhibit category and motion effects, where as ventral areas depicted in (b) exhibit only category effects. Vertical gray bars indicate stimulus presentation periods. Dashed lines indicate ±1 SEM. Adapted from Beauchamp MS, Lee KE, Haxby JV, and Martin A (2002) Parallel visual motion processing streams for manipulable objects and human movements. *Neuron* 34: 149–159.

object-associated actions (Chao and Martin, 2000). This finding is consistent with monkey neurophysiology evidence demonstrating that neurons in the ventral premotor and parietal cortices respond when monkeys grasp objects, as well as when they merely see objects they have previously manipulated (Jeannerod et al., 1995; Rizzolatti and Fadiga, 1998).

3.07.4.5 Category-Related Activations in Property Regions Are the Bases of Conceptual Representations of Objects

Processing various object categories elicits activity in sensorimotor property regions. But how do we know that the activity in property regions represents

conceptual information? Three findings in particular from the literature on animate and manipulable artifact object concepts strengthen the case that property regions are involved in conceptual-level processing.

3.07.4.5.1 Reason #1 to think that property regions are involved in conceptual-level processing: Activity in category regions transcends stimulus features

For both animate and manipulable artifact categories, substantial evidence demonstrates that activity in the categories' property regions is not stimulus specific. For example, differential responses are observed in the lateral fusiform to animate entities in response to pictures and written names of animals (Chao et al., 1999; Okada et al., 2000; Price et al., 2003; Devlin et al., 2005; Rogers et al., 2005; Wheatley et al., 2005; Mechelli et al., 2006), human voices (von Kriegstein et al., 2005), and when simply imagining faces (O'Craven and Kanwisher, 2000). In addition, lateral fusiform activity is also observed in response to stimuli depicting point-light displays of human bodies in motion (Grossman and Blake, 2001, 2002; Beauchamp et al., 2003; Peelen et al., 2006) and degraded and abstract visual stimuli such as human-like stick figures (Peelen and Downing, 2005). These findings are important because they demonstrate that this region is responsive to representations of animate entities, even after most form and color information has been stripped from the stimuli.

Perhaps most significantly, lateral fusiform activity has even been observed when participants view abstract representations of social situations depicted in interactions among simple geometric shapes (Heider and Simmel, 1944). For example, the lateral fusiform gyrus responds to animations suggesting social interactions such as hide-and-seek (Schultz et al., 2003), mocking and bluffing (Castelli et al., 2000, 2002), and sharing (Martin and Weisberg, 2003).

Similarly, differential responses in the medial fusiform to manipulable objects are observed in response to both pictures and written names of tools (Chao et al., 1999, 2002; Whatmough et al., 2002; Devlin et al., 2005; Mechelli et al., 2006), the spoken names of tools (Noppeney et al., 2006), and point-light displays depicting tools in motion (Beauchamp et al., 2003). Medial fusiform activity has even been observed when participants view simple geometric shapes that move and interact in ways that suggest mechanical interactions such as a bowling ball knocking down pins or billiards (Martin and Weisberg, 2003). Clearly, activation in these category-related property areas is not due to particular stimulus features but, rather, appears to be related to high-level conceptual representations.

3.07.4.5.2 Reason #2 to think that property regions are involved in conceptual-level processing: Activations in property areas occur as property inferences

Further evidence that property regions for animate and manipulable objects are involved in conceptual processing comes from studies in which property inferences manifest as activations in property areas; in other words, when a response occurs within a property area even though that particular property is not, in fact, present in the stimulus. For example, perceiving pictures of animals or people or reading animal names activates the region of the pSTS sensitive to biological motion, even when the stimuli presented are static photographs (Chao and Martin, 1999; Beauchamp et al., 2002). Similarly, perceiving static pictures of tools or reading tool names activates the region of the pMTG known to represent nonbiological motion (Chao and Martin, 1999; Beauchamp et al., 2002; Chao et al., 2002; Phillips et al., 2002; Kellenbach et al., 2003; Creem-Regehr and Lee, 2005; Devlin et al., 2005; Kable et al., 2005; Tranel et al., 2005a, b; Mechelli et al., 2006; Noppeney et al., 2006). In addition to the motion property inferences, however, motor property inferences are also observed in response to tool photographs, with subjects exhibiting activations in premotor cortex, even though they are not physically manipulating the tools (Chao and Martin, 2000; Chao et al., 2002; Creem-Regehr and Lee, 2005; Kan et al., 2006).

These findings are in the same vein as the observations described earlier when subjects viewed appetizing foods. Upon viewing pictures of appetizing foods, activations were observed in insula/operculum and OFC regions known to represent the tastes and taste rewards of foods, even though subjects were not receiving any gustatory stimulation (Simmons et al., 2005).

The ability to make inferences about an entity's properties is at the very core of what most cognitive scientists call conceptual knowledge. Across various categories, human subjects frequently exhibit activations in property regions that correspond to salient object concept information, often when that information is not present in the immediate stimulus. Given

its great utility, and likely survival value, we might expect that the ability to infer properties would be preserved across primate species, and recent evidence demonstrates that it is.

In a study demonstrating evolutionary continuity in the neural mechanisms for representing conceptual information, Gil-da-Costa et al. (2004) presented both species-specific calls and nonbiological sounds to awake rhesus macaques undergoing PET imaging. Although both the species-specific calls and nonbiological sounds were attended by activity in auditory cortex, the conspecific calls also elicited activation in area TE/TEO, the presumed monkey homologue of human fusiform gyrus, and in the STS (**Figure 5**). Note that these ventral and lateral temporal activations in visual form and motion property regions occurred to auditory stimuli. As with humans, when monkeys process information about animate entities, in this case other monkeys, activation occurs across a distributed network of property regions to represent those entities' salient features, namely, what they look like and how they move, even when those properties are not immediately present in the stimulus.

3.07.4.5.3 Reason #3 to think that property regions are involved in conceptual-level processing: Retrieving information from memory depends on reactivating property regions engaged while learning that information

A recent finding using fMRI brain state classification provides yet more evidence that property regions are involved in conceptual processing *per se*, rather than simply responding to features present in experimental stimuli. Polyn et al. (2005) demonstrated that

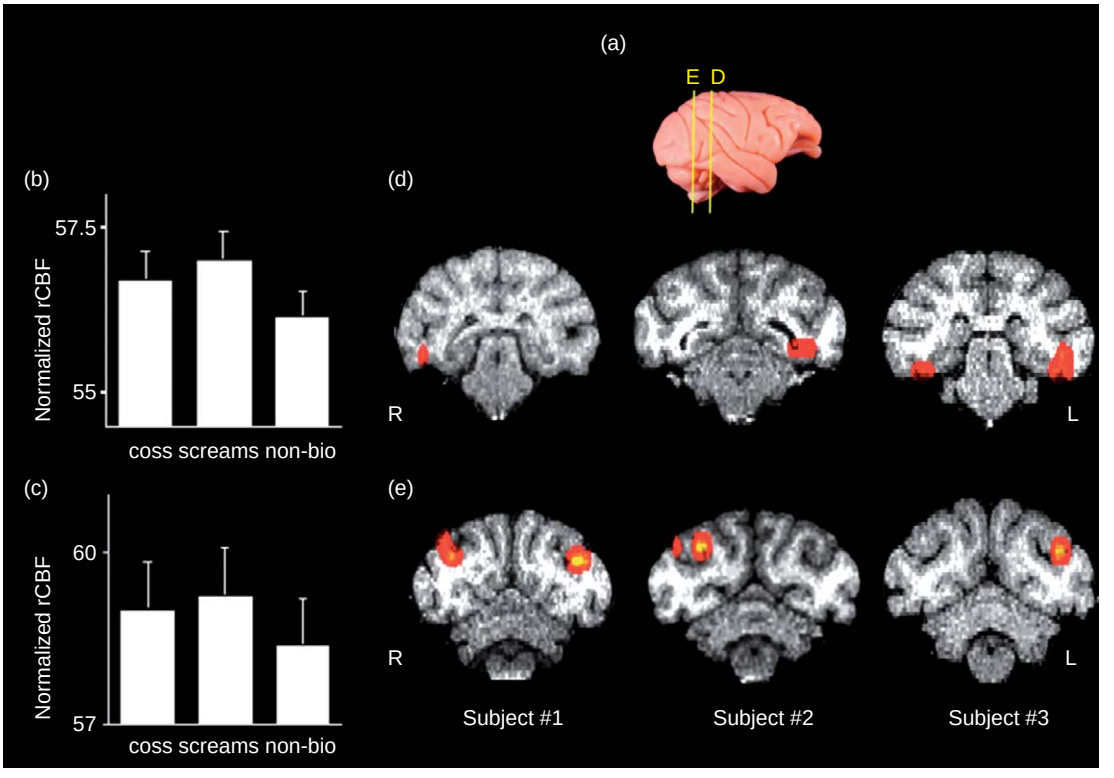

Figure 5 Activation of visual cortical areas in response to species-specific vocalizations in the rhesus macaque. (a) Lateral view of a rhesus monkey brain demonstrating the approximate locations of the coronal sections in (d) and (e). Both (b) and (c) show the mean (± SEM) normalized rCBF for the activations in TE/TEO and MT/MST/STS, respectively. In both regions, coos and screams exhibited reliably greater activation than nonbiological sounds. The coronal slices in (d) and (e) illustrate regions in each monkey that were more responsive to conspecific vocalizations (coos and screams) than to nonbiological sounds. Adapted from Gil-da-Costa R, Braun A, Lopes M, et al. (2004) Toward an evolutionary perspective on conceptual representation: Species-specific calls activate visual and affective processing systems in the macaque. *Proc. Natl. Acad. Sci. USA* 101: 17516–17521.

machine-learning algorithms are capable of detecting activity across the property regions underlying faces, places, and manipulable objects immediately prior to the free recall of information about each of these categories. During the classifier training phase of the study, subjects learned associations between labels and photographs of famous people, places, and common manipulable objects while undergoing fMRI. Later, while still undergoing fMRI, subjects were instructed to recall the items they had learned during the training phase. Brain state classifiers that were trained on data collected during encoding were able to detect distinct patterns of category-related activity that occurred several seconds prior to recall. Importantly, lateral fusiform activity served as the best predictor of famous face recall, left pMTG and parietal cortex activity best predicted manipulable object recall, and parahippocampal activity best predicted recall of places. By demonstrating that retrieving an item from memory depends on reactivating the pattern of activity in property regions that occurred during learning, this finding further establishes the centrality of property-specific information systems in the memory encoding, storage, and retrieval of conceptual information.

3.07.4.6 Learning about Objects by Building Property Circuits

The close correspondence between brain regions underlying perception and action with an object, and its representation in memory, suggests that conceptual property circuits develop out of experience with objects. A small but growing body of literature demonstrates that this is indeed the case. For example, Weisberg et al. (2007) asked subjects to perform a simple visual matching task on photographs of novel objects while undergoing fMRI. After scanning, the subjects were then given extensive training interacting with the objects, each of which was designed to perform a specific tool-like function. After training, the subjects were once again scanned while performing the visual matching task. Comparing the data from the two imaging sessions revealed that physical experience using the objects in a tool-like manner led to significant changes in the objects' neural representation. Whereas the novel objects elicited only diffuse ventral temporal activation in the first scan session, ventral temporal activity after training was largely restricted to the medial aspect of the fusiform gyrus, the same region previously implicated in representing the visual shape or form of tools. Similarly, new activations emerged after training in other regions observed in studies of tool knowledge, namely, the left pMTG (nonbiological motion) and left intraparietal sulcus and premotor cortex (physical manipulation).

Learning effects have also been observed for animate entities. As described earlier, viewing point-light displays of human forms in motion elicits activity in lateral fusiform and pSTS. Grossman et al. (2004) trained subjects to perceive human forms in point-light displays embedded within visual noise. After training, the subjects were not only better at indicating when a human form was present in a noisy visual display, but they also exhibited greater fusiform and pSTS activity in response to detecting those forms. Interestingly, the amount of activity in both regions was positively correlated with a subject's behavioral performance.

Yet further evidence for the development of property circuits with learning comes from James and Gauthier (2003), who demonstrated that property circuits can develop even through verbal learning. Prior to scanning, subjects learned verbally presented facts about families of novel animate-like entities called greebles. For example, subjects were trained that a particular family of greebles were associated with an auditory property (e.g., roars or squeaks), whereas other types of greebles had action properties (e.g., hops or jumps). After training, subjects underwent fMRI while performing a visual matching task that did not require retrieval of the learned associations. James and Gauthier found that viewing greebles associated with auditory properties produced activity in auditory cortex (as defined by an auditory functional localizer) and viewing greebles associated with action properties produced activity in the biological motion-sensitive region of the pSTS (as localized by moving point-light displays).

James and Gauthier's findings are important for at least two reasons. First, along with the findings of Weisberg et al. (2007), they illustrate how experience with category exemplars leads to the development of property circuits, which can later activate as property inferences. In both studies, simply seeing a particular object from the training set elicited activation in either premotor (for tools) or auditory and motion-sensitive cortex (for greebles), even though that information was unnecessary for successfully performing the task and not present in the stimuli. Second, it illustrates that this process can occur even when experience is verbally mediated. This finding is important precisely because so much of

our knowledge is acquired verbally, rather than through direct sensorimotor experience with objects and their properties.

3.07.5 Summary

The neuropsychological and functional neuroimaging findings presented here tell us much about the organization of conceptual knowledge in the brain. Surveying these studies, it appears that information about any particular object concept is distributed across a discrete network of cortical regions, rather than being represented in a single brain region. In addition, the particular neural circuit for a given object concept includes property regions that are most commonly engaged during perceptual experience with, or functional use of, the object, as demonstrated by training studies that documented the development of property circuits as subjects gained experience with an object.

One reason for suspecting that these property regions are not strictly perceptual but, rather, support conceptual representations is that some property regions activate automatically when an object is identified, regardless of whether their respective properties are immediately present in the stimulus. As such, these activations constitute property inferences about the object. At present, the extant findings suggest that for any given object, properties such as form, motion, and function-associated motor actions are particularly likely to be retrieved automatically. As such, these three property types may form a core set of information that is necessary and sufficient for representing object concepts in memory. There is good reason to believe, however, that future research using a wider array of object categories will reveal important roles for other property types as well (e.g., taste properties may be particularly important for food concepts). Finally, a close physical proximity exists between the neural systems underlying perception and knowledge representation for objects. Indeed, for color and motor properties, the neural bases underlying perceptual and conceptual property representation may partially overlap. Taken together, these findings strongly support so-called embodied cognition accounts of knowledge representation, which claim that conceptual property information is stored in the perceptual and motor systems active when that property information is learned.

3.08 The Neurobiological Basis of Recognition Memory

C. E. Stern and M. E. Hasselmo, Boston University, Boston, MA, USA

3.08.1 Introduction to the Concept of Recognition Memory

Recognition memory refers to the capacity to accurately identify a particular item or stimulus as having been previously encountered. An everyday example is our ability to recognize a person we have met once as someone that we have seen before. This ability to accurately recognize a person or an item requires that an individual encode the person or stimulus into memory at the time of encoding. After a delay, the subject must be able to then subsequently discriminate between a novel or new stimulus and a previously encountered stimulus. In the example in which a subject recognizes a person as someone whom they have met before, the subject would first need to have accurately encoded the person's face at an earlier time, and then at a later time would need to be able to accurately identify the person or select the person from a group of other subjects that the individual had not previously met. In research on memory function, recognition is often tested by having subjects distinguish between previously presented stimuli and stimuli that were not previously presented (termed lures). In the preceding example, we encounter novel and familiar stimuli all the time. Sometimes we are able to recognize with certainty a person or object: "That is my dog's vet" or "That is my coat." Other times the face or object looks familiar, but one is less certain about where the person or object was encountered before; "That person looks familiar, but I can't think of their name," or "I have seen that hat before, but I don't know who it belongs to."

Until the 1960s, memory was described as being a solitary process (Tulving, 2001), but in research over the last 50 years, memory researchers have moved toward describing memory as being comprised of multiple memory systems (Tulving, 1972; Eichenbaum and Cohen, 2001; Tulving, 2001). Within the framework of recognition memory, in the 1970s, Atkinson and Juola described two processes as being important for recognition (Atkinson and Juola, 1974). They proposed that an initial fast familiarity process was followed by a secondary slower process necessary for retrieving specific detailed information. In the recognition example given above, if you pass someone on the street, you may initially recognize that person as being someone who is familiar to you. This initial fast familiarity signal is then followed by a slower secondary search process in which you are able to retrieve detailed information about who that person is, their name, their relationship to you, and where you last saw them. We can all recall episodes in which this retrieval attempt is successful, and we remember the person's name and their relationship to us. In other cases, our retrieval attempt is unsuccessful, and while we still have our initial reaction of knowing that the person is familiar, we cannot recollect their name or recall where you last met this person.

In 1983, Endel Tulving suggested that long-term recognition memory could be could be divided into two separate components. He termed these components recollection (or remembering) and familiarity (or knowing). In keeping with the example given above, when you meet someone in the street, you can recognize that you simply know the individual, or you can clearly remember the individual encountered. The recollection process is proposed to involve the retrieval of the prior episodic experience, that is, you remember the contextual details associated with the last time you saw that individual. In contrast, familiarity is thought to represent a process that

does not rely on any explicit remembering of the details of the spatial or temporal context of the prior event, that is, you recognize the person as familiar but cannot place where or when you met them.

In addition to dissociating the processes of recollection and familiarity, another useful distinction that memory researchers make is the distinction between the processes of recognition and recall. Both recognition and recall require that stimuli be encoded, stored, and retrieved from memory. However, the process of recall places a much greater demand on the retrieval system, whereas recognition tests can assess whether information was encoded while placing less demand on memory retrieval systems by simply requiring that the subject distinguish previously learned information from new information. One analogy is that recognition memory tests resemble multiple-choice exams, where the answer is present but must be identified from false lures, whereas a recall test resembles a fill-in-the-blank exam, where the subject must retrieve the learned information from long-term memory in order to generate the answer. When memory declines, such as during aging and in diseases such as Alzheimer's disease, recall performance declines earlier and faster than recognition performance. A person may therefore be unable to recall someone's name, but if they are provided with multiple choices, they can recognize the correct one.

Recall can be divided into two types, free recall and cued recall. Both free recall and cued recall involve the retrieval or recall of a previously presented stimulus without the stimulus being presented during the test period. In a free-recall task, stimuli are presented during the sample period, and during the test period the subject is requested to generate as many stimuli as possible. Usually answers are provided verbally. In a cued recall test, the experimenter provides a cue, such as "name the animals that were on the list," that assists the subject in recalling the stimuli. In one specific type of cued recall task, known as a paired associates test, stimulus pairs are presented during the sample period; during the test period only a single stimulus in a pair is presented, and the subject must generate the previously paired stimulus. Free recall and cued recall can only be performed for stimuli that can be generated by the subject and therefore usually require the use of verbal stimuli in humans. Because recognition can be tested without requiring the subject to generate the previously presented stimulus, it proves very important in neuroscience studies of memory function in animals.

In the following sections, work on the neuroscience of recognition memory in humans and in animals is described in greater detail. First, an overview of recognition memory tests is provided, followed by sections describing lesion studies of recognition memory in humans and animals, electrophysiological studies of recognition memory in animals, imaging studies of recognition memory in humans, and computational studies of recognition. The human and animal studies indicate an important role for medial temporal lobe structures in the encoding of stimuli for subsequent recognition.

3.08.2 Experimental Tests of Recognition Memory

Recognition memory has been studied extensively in human subjects using a number of different paradigms. In one classic recognition memory task, the experimenter first presents subjects with a series of stimuli to be learned. After a variable delay period, the experimenter then presents the subject with a list of previously presented stimuli mixed with new ones (lures). The subject simply responds yes or no to each stimulus. This recognition paradigm is known as a simple yes–no recognition test. In another common recognition test, a single stimulus or set of stimuli are presented during a sample period, followed by a delay period of different durations, after which recognition is tested by presenting both a previously viewed sample stimulus and a novel lure at the same time during the test period. The subject must generate a response indicating which stimuli (target stimuli) were previously presented and which stimuli (lures) were not previously presented. This method is known as a forced-choice recognition memory test. The simple yes–no recognition test cannot be used effectively with patients with memory disorders, as they will often respond no to all stimuli. The method is not often used because of this response bias. The forced choice recognition memory test is less sensitive to response bias and can more sensitively assess recognition memory impairments, and measurements of response bias can be generated. There are a number of variations of these two basic behavioral designs that have been created and are described here.

More recent studies have elaborated on the simple yes or no response to more accurately characterize the two processes that combine to support recognition

memory, recollection, and familiarity. Both recollection and familiarity would generate a yes response in a yes–no or forced-choice recognition memory paradigm. By modifying the task, the experimenter can distinguish between recollective and familiarity responses. The distinction between a strong feeling of recollection and a weaker sense of familiarity is sometimes referred to as the remember versus know distinction. In experimental tests of these processes, a subject may be requested to identify whether they have a distinct recollection of the event of observing the stimulus (recollection) or whether they only have a general feeling of familiarity about the stimulus (familiarity). They may also be asked to retrieve information about contextual information related to the stimulus. Alternatively, in another twist on the yes–no recognition test, subjects may be requested to use an arbitrary scale to provide information about the strength of their memory or their level of confidence in remembering an item or event. Some behavioral and imaging studies have used a simple 3-point scale, corresponding to high-confidence yes (recollection), low-confidence yes (familiarity), and new (for the lures). Others have used 5- or 6-point scales ranging from a high-confidence yes (identify target) response (numerical value 5 or 6) to a high-confidence no (reject lure) response (numerical value 1). Studies of behavioral confidence rankings have been used to support a two-process theory of recognition memory in work by Yonelinas (2001). This work uses signal detection theory-based receiver-operator-characteristics (ROC) curves to analyze the nature of recognition memory. This work used the distribution of proportions of responses to argue that recognition memory includes a graded mechanism of familiarity recognition and a high-threshold process of recollection-based recognition. The Yonelinas model assumes that previously presented items give rise to a range of confidence ratings based on their familiarity, whereas new items (lures) give rise to some familiarity but not as much as the previously presented items. In contrast, when recollection is triggered for an individual item, the recollection process is assumed to provide sufficient confidence for subjects to respond with certainty in the highest yes category (allowing the responses to cross a high-threshold criterion). In the dual-process model, familiarity is a variable phenomenon, and recollection is an all or nothing response. There have been studies that suggest distinct medial temporal lobe regions support recollection and familiarity-based recognition. However, the studies remain controversial. Some researchers support the idea that the hippocampus is required for recollection, whereas parahippocampal structures support familiarity; however, other data suggest that recollection and familiarity are part of a unified single process, supported by the same neuroanatomical structures within the medial temporal lobe. Similar controversy surrounds efforts to make distinctions between regions supporting encoding during the sample period versus separate regions mediating recognition during the testing period.

Another common recognition memory task is known as the delayed match-to-sample task, or DMS task. The DMS task involves presentation of a single sample stimulus followed by a delay period, followed by a pair of test stimuli, where one stimulus matches the presentation stimulus and one does not match the sample stimulus. The subject must select the stimulus that matches the sample stimulus. In a variant of this task known as a delayed non-match-to-sample or DNMS task, the subject (human or animal) must select the nonmatching novel stimulus. A further variation involves continuous presentation of stimuli, in which the subject must respond on the basis of whether the current stimulus matches the stimulus presented n trials previously (an N-back task), which can be extended to longer intertrial intervals. Since it typically uses very short delays, the N-back task is considered to be a working memory task.

The DMS or DNMS task designs have been used most extensively in studies of the neural basis of recognition memory in animals. In these paradigms, the animal encounters the sample stimulus and, after a delay period, is presented with a pair of stimuli and must respond to either the match (target) or nonmatch (lure). Alternatively, the sample stimulus could be followed sequentially by single lure stimuli (during which the animal withholds its response) until the target stimulus appears and the animal must generate a response. Performance of these tasks requires recognition memory, but the process of recognition could be interpreted as involving either short-term active maintenance of the stimulus (working memory) or long-term synaptic encoding of the stimulus, depending on the length of the delay.

Other paradigms used in animals include presentation of a longer list of sample stimuli, which could include a series of visual stimuli presented to monkeys, or a set of odor stimuli presented to rats. After a delay period, the animals are then tested with a forced-choice design, in which the animal encounters pairs of stimuli, each of which includes one sample

stimulus and one lure stimulus. In rats, recognition memory is commonly tested using the non-match-to-sample paradigm, to capitalize on the natural tendency of rats to explore novel stimuli more extensively than familiar ones. The rat can be presented with a sample stimulus, and subsequently when presented with an identical sample stimulus and a novel lure, it will spend more time exploring the novel lure.

3.08.3 Lesion Studies of Recognition Memory

There is extensive lesion evidence supporting the idea that the medial temporal lobe structures, including the hippocampus and neighboring parahippocampal regions, are critical for encoding information into long-term memory. Research on the neuroanatomical structures critical for memory function focused on the medial temporal lobe, following the case of patient HM, first described by Scoville and Milner (Scoville and Milner, 1957) and studied extensively in further work by Milner and Corkin (Corkin, 1984). Patient HM showed a striking impairment of episodic memory encoding following bilateral removal of his medial temporal lobes in an attempt to control epileptic seizures. Initial descriptions of patient HM's impairment focused on his almost total loss of free recall and severe impairment of cued recall performance. Similarly, other hippocampal amnesic patients show strong impairments of free recall and cued recall. Hippocampal amnesics also show moderate impairment on tests of recognition memory (Manns et al., 2003), and the amount of impairment appears to be associated with the magnitude of damage to the parahippocampal structures including the entorhinal cortex, perirhinal cortex, and parahippocampal gyrus (Rempel-Clower et al., 1996).

Lesion studies in humans have also addressed the question of whether the processes of recollection and familiarity are subserved by different regions within the medial temporal lobes. However, the results continue to be controversial. Researchers including Yonelinas have argued that hippocampal lesions cause a greater impairment of recollection-based recognition than familiarity-based recognition (Yonelinas et al., 2001, 2005). On the other hand, studies by Manns and Squire have demonstrated impairments of both recollection- and familiarity-based recognition associated with medial temporal lesions (Manns et al., 2003).

In primates, lesions of medial temporal lobe structures cause impairments on the recognition of individual trial unique stimuli in a range of different studies on delayed matching function (Gaffan, 1974; Zola-Morgan and Squire, 1985, 1989, 1993; Alvarez et al., 1994; Leonard et al., 1995). Selective hippocampal lesions alone cause impairments in DNMS tasks (Zola-Morgan and Squire, 1985), but the impairment is much more severe if lesions include damage to surrounding cortical areas such as the perirhinal cortex and parahippocampal gyrus (Meunier et al., 1993, 1996; Zola-Morgan et al., 1993). Entorhinal and perirhinal cortex ablations also impair performance in DMS tasks (Gaffan and Murray, 1992). The impairments in these studies appear at longer delays (e.g., 1 min, 10 min) but not short delays (0.5, 1, or 3 s) (Gaffan and Murray, 1992; Alvarez et al., 1994), consistent with the notion that entorhinal cortex and perirhinal cortex are important for recognition memory function that is distinct from short-term active maintenance for working memory.

Impairments of performance in object- or odor-recognition tasks have also been shown with inactivation or lesions of the perirhinal cortex in rats (Otto and Eichenbaum, 1992; Ennaceur et al., 1996; Bussey et al., 2000). These studies show that object recognition is not impaired with lesions of the fornix or the orbitofrontal cortex, again suggesting an important role of the perirhinal cortex beyond its interactions with the hippocampal formation. The tasks designed for human studies of recollection and familiarity have been modified for odor recognition to examine these processes in rats (Fortin et al., 2004). The yes–no response used in human visual recognition memory was altered to a delayed nonmatching paradigm for odor recognition, in which a rat was exposed to a set of sample odors and then subsequently had to respond to individual test odors presented in cups filled with sand. If the odor did not match a previous sample odor (new), the rat could dig in the cup for a food reward. If the odor did match a previous sample odor (old), the rat would return to the back of the experimental chamber to dig in a separate cup for food reward. In these studies, the signal detection approach used in humans was applied to rats by manipulating the selectivity criterion for recognition responses from conservative to liberal. This was achieved by changing the relative cost and benefit of a positive recognition response by changing the

amount of reward given for an old response and by increasing the height of the cup containing the test odor. In this paradigm, rats show a threshold response for a conservative criterion, demonstrating a significant number of hits even when the false alarms are near zero. This resembles the threshold response proposed to result from the use of recollection-based memory in humans. Lesions of the hippocampal formation in rats appear to selectively remove this recollection-based response property, causing the response properties to resemble those proposed to indicate use of familiarity-based recognition alone.

Pharmacological manipulations can also affect recognition memory function, indicating a role for cellular neuromodulatory effects in this process. Systemic injections of muscarinic cholinergic antagonists has been shown to impair performance on recognition memory tasks at longer delays in monkeys, while sparing performance at 0-s delay; this occurs with both the antagonists scopolamine (Bartus and Johnson, 1976) and atropine (Penetar and McDonough, 1983). Injections of scopolamine appear to impair the encoding of new stimuli for recognition but not retrieval of stimuli learned before scopolamine injection (Aigner and Mishkin, 1986; Aigner et al., 1991; Tang et al., 1997). Scopolamine also impairs recognition memory in humans (Sherman et al., 2003; Schon et al., 2005) but has a stronger effect on free recall and cued recall (Atri et al., 2004). Systemic injections of scopolamine also impair arm choice behavior in an eight-arm radial maze in rats when there is a delay between the individual choices (Bolhuis et al., 1988). The locus of the cholinergic effect has been tested with localized injection of cholinergic antagonists in monkeys. Tang et al. (1997) demonstrated that infusion of scopolamine into perirhinal cortex before encoding impairs performance on a recognition memory task, whereas infusion into adjacent structures did not cause impaired performance. Microdialysis shows a 41% increase in acetylcholine levels in perirhinal cortex during encoding in this visual recognition task (Tang and Aigner, 1996). Selective impairments of the encoding of stimuli for subsequent recognition have also been induced with manipulations that remove the cholinergic innervation of cortical structures. Recent experiments used the selective agent IgG 192 saporin to lesion the cholinergic innervation of the entorhinal cortex in rats (McGaughy et al., 2005). These selective lesions caused a significant and selective impairment of DNMS function for novel odors (McGaughy et al., 2003, 2005). Similarly, DMS function for novel visual stimuli was also impaired by selective lesions of entorhinal cholinergic innervation in monkeys (Turchi et al., 2005).

3.08.4 Electrophysiological Studies of Recognition Memory

As noted, most studies of memory function in animals use tasks that test recognition memory, since it is not feasible to have animals perform recall tasks. Thus, most studies of electrophysiological activity associated with memory function have been conducted during short- or long-term recognition memory paradigms. In both monkeys and rats, unit recording studies analyze the generation of action potentials by individual neurons during performance of such tasks. The activity associated with recognition can be evaluated by comparing the response to a previously presented target stimulus during the test period with the response to a nonpresented lure or by comparing the response to the target stimulus with the response to the same stimulus during the sample period. A number of studies have shown changes in neural activity for a previously presented target stimulus in comparison to nonpresented lures. Many studies suggest that recognition memory for an item involves a reduction of neurophysiological activity, not more activity, as shown by recordings of single-neuron spiking activity during performance of a serial recognition task by monkeys (Brown et al., 1987; Wilson et al., 1990; Riches et al., 1991; Fahy et al., 1993). In those experiments, monkeys see a series of novel stimuli, with occasional repeat presentations of familiar stimuli. The familiar stimuli cause a reduced level of spiking activity in single neurons recorded from parahippocampal cortices (Brown et al., 1987; Wilson et al., 1990; Riches et al., 1991). A similar reduction of neuronal spiking activity to familiar stimuli was observed in recordings in the prefrontal cortex, inferotemporal cortex, and entorhinal cortex of monkeys during repeated presentation of stimuli in a DNMS task (Miller et al., 1991, 1993, 1996; Suzuki et al., 1997). Miller demonstrated that repetition suppression occurs even for repeated distractor stimuli presented during a delay period, whereas enhancement of the target test stimulus relative to the sample stimulus (match enhancement) only occurs for the target stimulus and not for distractor stimuli (Miller et al., 1993, 1996). Increased responses to matching stimuli were

shown in the anterior thalamus in studies of a serial recognition task (Rolls et al., 1982). Computational modeling indicates that the delay activity and match enhancement over short periods could be due to intrinsic currents, but the longer-term match suppression effects have been modeled as dependent upon synaptic long-term depression (Sohal and Hasselmo, 2000; Bogacz and Brown, 2003).

The process of recognition could be supported either by synaptic modification or by active maintenance of information during the delay period. In support of active maintenance, a number of unit recording studies during DMS tasks (Fuster, 1973; Fuster and Jervey, 1982; Fuster, 1995, 2000) have demonstrated that some neurons activated by the sample stimulus will maintain their activity during the delay period until the test stimulus is presented. This delay period activity could reflect active maintenance of the stimulus for performance of the recognition task. Much of this research has focused on the prefrontal cortex (Fuster, 1973, 1995; Miller et al., 1996; Fuster, 2000), but delay activity has also been shown for neurons in the inferotemporal cortex (Fuster and Jervey, 1982; Miller and Desimone, 1994) and in parahippocampal regions including the entorhinal cortex (Suzuki et al., 1997). The prefrontal cortex activity shows greater resistance to the effect of distractors, whereas the medial temporal delay activity is more likely to be terminated by a distractor (Miller et al., 1996). Persistent activity has also been shown for entorhinal neurons in the rat during the delay period of a continuous DNMS task using odors (Young et al., 1997). Neurons in the entorhinal cortex of the rat also show increases or decreases of activity associated with match or mismatch between sample and test (i.e., match enhancement or match suppression). The persistent activity could arise from intrinsic mechanisms within individual neurons or from excitatory feedback between neurons in a population. For example, network simulations demonstrate how the patterns of unit firing during DMS and DNMS tasks could arise from cholinergic activation of intrinsic persistent spiking mechanisms (Fransén et al., 2002; Hasselmo and Stern, 2006). However, most models of persistent spiking activity have focused on the hypothesis that persistent spiking activity during delay periods occurs due to attractor dynamics caused by excitatory recurrent synapses (Amit, 1988; Lansner and Fransen, 1992; Amit and Brunel, 1997; Lisman et al., 1998). This type of persistent spiking activity could contribute to the increase in cerebral blood flow measures seen during the delay period of DMS tasks or two-back tasks in human subjects.

The role of cholinergic receptors in recognition memory function described above could be due to involvement in either persistent spiking for active maintenance or synaptic depression for repetition suppression. These mechanisms may coexist in single neurons of perirhinal cortex. In the rat, the perirhinal cortex shows reduced levels of activity in response to repeated stimuli, and this effect has been proposed to arise from cholinergic activation of long-term depression (Warburton et al., 2003), because scopolamine blocked the induction of synaptic long-term depression in that study. However, scopolamine did not block repetition suppression in a study in monkeys, though it did cause a behavioral impairment (Miller and Desimone, 1993). This latter result suggests that cholinergic modulation may also play a role in persistent activity or match enhancement mechanisms important for recognition memory.

3.08.5 Functional Imaging Studies of Recognition Memory

Despite considerable evidence from human and animal lesion studies regarding the importance of the hippocampus and medial temporal lobes for encoding and recognition, early imaging studies using positron emission tomography (PET) primarily identified changes in activity in cortical structures outside of the medial temporal lobe, most notably within the prefrontal cortex (for review, see Schacter and Wagner, 1999). The tasks used in these earlier studies focused on priming and on recognition memory for verbal stimuli learned prior to scanning. Using functional magnetic resonance imaging (fMRI) and a task design that focused on examining functional changes during the encoding period, as opposed to examining the recognition period, Stern and colleagues (Stern et al., 1996) identified robust activation of the hippocampus and parahippocampal structures when subjects viewed sets of novel visual items with the goal of being able to identify them later. This simple block-designed paradigm contrasting blocks of stimuli that were novel with blocks of repeating stimuli provided clear evidence that the hippocampus and neighboring parahippocampal regions were necessary for encoding complex visual stimuli into memory. With the development of event-related fMRI methods (Rosen et al., 1998), it became possible to examine fMRI activity

during individual trials as opposed to blocks of stimuli. Researchers designed studies to focus on how the event-related fMRI activity during presentation of single stimuli during the encoding period would correlate with recognition performance for those individual stimuli during a subsequent recognition memory task. Two of the earliest event-related studies (Brewer et al., 1998; Wagner et al., 1998) demonstrated a subsequent memory effect, in which increases in fMRI activity in medial temporal lobe structures were noted for stimuli that were remembered with high confidence, but not for stimuli that were subsequently forgotten. Since the first block-designed studies (Stern et al., 1996; Gabrieli et al., 1997), these event-related studies have examined subsequent memory effects for individual words and pictures (Brewer et al., 1998; Wagner et al., 1998; Henson et al., 1999; Kirchhoff et al., 2000).

More recently, functional imaging studies have extended these subsequent memory studies to address the hypothesis that recollection and familiarity are dependent on different regions within the medial temporal cortex. Based on animal studies (see Brown and Aggleton, 2001, for review) and anatomical differences between the hippocampus and parahippocampal regions, neuroimaging researchers have examined the hypothesis that the hippocampus is critical for the process of recollection, whereas the parahippocampal gyrus is sufficient and necessary for supporting familiarity-based recognition. Ranganath et al. (2003) conducted an event-related fMRI study in which activity at the time of encoding within the rhinal cortex supported familiarity-based recognition, whereas encoding related activity within the hippocampus and posterior parahippocampal cortex predicted recollection. Proponents of this account suggest that the parahippocampal regions are associated with successful item recognition, whereas hippocampal activity is necessary for successful source memory, which includes information about contextual details. It should be noted that while there are several studies supporting the idea that separate neuroanatomical regions support recollection and familiarity (Ranganath et al., 2003; Daselaar et al., 2006), the issue remains controversial, as there is also research supporting the idea that the hippocampus and parahippocampal regions support both recollection and familiarity (Manns et al., 2003; Squire et al., 2004), supporting the idea that the strength of recognition varies along a single continuum as opposed to the dual-process model (Wixted and Stretch, 2004).

In addition to activity within medial temporal lobe regions, functional neuroimaging studies have provided data that support the idea that encoding and subsequent recognition require widespread activity outside the medial temporal lobe, including areas within the ventrolateral prefrontal cortex and parietal lobe (Schacter et al., 1997; Kirchhoff et al., 2000; Yonelinas et al., 2005). Current research is ongoing to determine whether this prefrontal and parietal activity is related to the successful retrieval of information from memory or is attributable to control mechanisms driving recollection attempts (Kahn et al., 2004).

In addition to the long-term recognition studies described above, another area of research has examined the recognition of stimuli that were observed only a short time previously. In neuroimaging research, these studies have primarily employed working memory N-back tasks as well as DMS tasks with short delays. It should be noted that at a cellular level, these tasks most likely require active maintenance rather than modification of synapses. At a systems level, the N-back task and other working memory tasks typically cause extensive activity in prefrontal cortex and parietal cortex, which increases when the memory load is increased by increasing the value of N to require matching with a stimulus presented two or three stimuli previously. When familiar stimuli are used in a delayed matching task, it does not cause significant medial temporal lobe activity, but when novel stimuli are used, it causes a significant increase in medial temporal lobe activity (Stern et al., 2001). This could reflect a greater role for medial temporal lobe structures in active maintenance and encoding of novel stimuli (Ranganath and D'Esposito, 2001; Stern et al., 2001). Recently, Schon et al. (2004) demonstrated that delay-related activity in the medial temporal lobe during a DMS task with novel stimuli correlated with subsequent recognition memory for the stimuli.

Primate neurophysiological studies have suggested that repetition suppression is involved in recognition memory function (Miller and Desimone, 1994; Suzuki et al., 1997; Brown and Aggleton, 2001). However, these previous studies were not able to answer the question of whether the reduction in spiking activity correlated with the parametric graded strength of recognition memory performance. A recent article by Gonsalves et al. (2005) provides crucial data to answer this question. This study demonstrated a correlation between reduced activity (as measured using fMRI and MEG) and higher confidence recognition

of stimuli. This study builds on extensive cognitive research using the remember versus know recognition memory paradigm, described earlier. Stimuli given the highest confidence recognition rating (recollected–R-hit) showed the least activity in the perirhinal and parahippocampal cortices, while stimuli showed somewhat more activity when the subject was less confident and merely had a feeling of knowing the stimulus (K-hit). Even greater activity was seen for the incorrect responses (miss) and correct rejections (CR). These data clearly demonstrated that the reduction of activity for familiar stimuli is correlated with stronger recognition of the stimuli as measured behaviorally. This study provides a crucial extension of previous neuroimaging studies showing a reduction in activation associated with novel stimuli becoming familiar. The earliest demonstration of changes in medial temporal lobe fMRI activity during a memory task showed less activity during repeated presentation of a single stimulus versus substantial activity during sequential presentation of different novel stimuli being encoded for subsequent recognition (Stern et al., 1996), and studies have demonstrated that the repetition reduction occurs for both visual and verbal stimuli and that greater activity for novel stimuli in hippocampal and parahippocampal regions is associated with the encoding of information into long-term memory (Brewer et al., 1998; Kirchhoff et al., 2000; van Turennout et al., 2003). Though these and other studies have shown correlations between increased medial temporal lobe activity during encoding and subsequent performance on recognition tasks, and others have shown reduced activity associated with recognition of old stimuli (Weis et al., 2004), the study by Gonsalves et al. (2005) evaluated correlations between reduced activity during recognition testing and the concurrent graded levels of performance on recognition tasks.

3.08.6 Computational Modeling of Recognition Memory

The processes involved in recognition memory have been modeled on a number of different levels. Many modeling studies have focused on the mechanisms of active maintenance, in which persistent spiking activity of a population of neurons during the delay period is proposed to form the basis for retaining information about the stimulus presented during the sample stimulus. Most models of active maintenance focus on the role of excitatory recurrent connections within cortical structures such as the prefrontal cortex (Amit, 1988; Lansner and Fransen, 1992; Amit and Brunel, 1997; Lisman et al., 1998). These excitatory recurrent connections can cause a population activated by the sample stimulus to continue to reactivate its component neurons, allowing the population to maintain activity for the full delay period and retaining the information until the test period, when a comparison can be made. In contrast, other recent models of active maintenance focus on intrinsic single-cell mechanisms, in which a single neuron can maintain persistent spiking activity without requiring excitatory synaptic feedback between neurons (Fransén et al., 2002; Hasselmo and Stern, 2006). This mechanism would be particularly appropriate for novel stimuli for which a representation has not previously been formed (Hasselmo and Stern, 2006). The persistent spiking of single cortical neurons stemming from intrinsic properties can persist for many minutes, allowing this mechanism to contribute directly to performance of DMS tasks with delays of several minutes.

For recognition over longer periods, it is not possible to maintain persistent spiking representing all previously viewed stimuli. In this case, some representation of stimuli based on changes in synaptic connections between neurons would be more appropriate. Computational models have demonstrated how presentation of a sample stimulus could induce Hebbian synaptic potentiation, in which synapses are strengthened dependent upon presynaptic activity coupled with postsynaptic activity (Hasselmo and Schnell, 1994; Hasselmo and Wyble, 1997; Sohal and Hasselmo, 2000). This synaptic modification results in greater activity of neurons during the test period if they were previously active during the sample period (match enhancement). In addition to nonselective match enhancement, recognition can also be modeled as the capacity to retrieve a context given a specific item (Hasselmo and Wyble, 1997). In contrast, match suppression or repetition suppression can be obtained by competitive long-term depression of synapses for nonactivated neurons (Sohal and Hasselmo, 2000). Alternately, researchers have proposed that repetition suppression might arise from Hebbian long-term depression, which provides a mechanism for recognition memory with higher capacity than Hebbian long-term potentiation (Bogacz and Brown, 2003). The above processes focus on responses to the item alone and could be seen as reflecting familiarity processes. The separate

theoretical processes of recollection- versus familiarity-based recognition have been modeled as different processes in different structures (Norman and O'Reilly, 2003). In contrast to familiarity, which could involve an increase or decrease in activity of the neurons representing the sample stimulus, recollection may involve a test item reactivating a full representation of contextual features associated with a specific episode (Hasselmo and Wyble, 1997; Norman and O'Reilly, 2003). This recollection process could involve more complex neuroanatomical circuits required for reactivation of the temporal or spatial context of the item being recognized.

3.09 Animal Models of Amnesia

M. C. Alvarado and J. Bachevalier, Emory University, Atlanta, GA, USA

3.09.1 Introduction

Our understanding of the nature of the human amnesic syndrome has expanded enormously in the last 60 years. This increased knowledge stems not only from the detailed description of memory disorders in patients with more circumscribed brain lesions and from more recent neuroimaging studies in both patients with memory disorders and normal subjects, but also from a growing number of animal models of different species. These animal models have been used to refine our understanding of the specific brain regions involved in human amnesic syndromes and the critical memory processes mediated by each region. Because the field is so broad and covers a number of brain systems whose contribution to memory is certain, but less well understood (e.g., diencephalic structures), this chapter will focus on research centered on the medial temporal lobe structures and their participation in memory processes. After a brief review of the early work in humans leading to the description of the temporal lobe amnesia syndrome, we will discuss the importance of developing animal models for the study of this syndrome. We then describe several classes of behavioral paradigm and their analogs that have been used in both rats and monkeys to more specifically determine the memory processes mediated by different medial temporal lobe structures, and their recent use to study both human amnesic patients and normal human subjects will be discussed. Finally, we will briefly review some of the conclusions derived from the use of animal models of amnesia and how they have contributed to our understanding of the neural substrates of both human and animal memory.

3.09.2 The Neural Substrates of Memory: Earlier Studies

The concept that memory can be localized in the brain dates back at least several hundred years when Descartes proposed that experience left traces in the

brain which could then be retrieved through the actions of the pineal gland (Descartes, 1662/1972). However, it wasn't until the beginning of the twentieth century that systematic searches for these traces were made. In a decades-long search to discover where in the brain memory traces, or 'engrams,' resided, Karl Lashley trained rats on mazes and then systematically disconnecting cortical areas using knife cuts, or ablating areas of cortical tissue, to assess their effects on performance. In spite of his efforts, a specific locus where memory resided could not be identified. The ability of knife cuts or ablations to affect memory was directly related to the amount of tissue damaged. In 1950, he published the results of 30 years of research in his landmark paper, 'In search of the engram,' in which he concluded that:

> It is not possible to demonstrate the isolated localization of a memory trace anywhere within the nervous system. Limited regions may be essential for learning or retention of a particular activity, but within such regions the parts are functionally equivalent. The engram is represented throughout the region. (Lashley, 1950: 478)

These conclusions were summarized in two principles of brain function: (1) principle of mass action, which states memory is distributed throughout the brain (no centralized loci), and (2) the principle of equipotentiality, which proposes that if one area of the brain is damaged, another is able to assume the functions of the damaged region. These two principles explained why only large lesions produced deficits and why recovery of function was possible from discrete lesions. Thus, it appeared that the theory of localized memory traces had been laid to rest. At about this same time, quite different results were discovered in the brain mapping work of neurologist Wilder Penfield. In preparing epileptic patients for removal of epileptic foci, he would stimulate areas of cortex to pinpoint the critical tissue. During some of these stimulations deep in the temporal lobe, he discovered that the patient would suddenly describe detailed memories depending upon the location of the stimulation. Furthermore, stimulating the same locus elicited the same memory (Penfield, 1958), and mild memory impairments were observed in some patients with unilateral temporal lobe resections. However, the landmark case that to this day drives the study of memory and the brain was that of patient H. M.

This patient was treated for intractable epilepsy by the bilateral removal of the temporal lobes, which included parts of the amygdala, hippocampus, and subjacent temporal cortex (See **Figure 1**). The result of this surgery was a profound anterograde amnesia that persists to this day, and a somewhat milder retrograde amnesia for events closer to the time of his operation, although childhood memories were intact (Scoville and Milner, 1957). What was

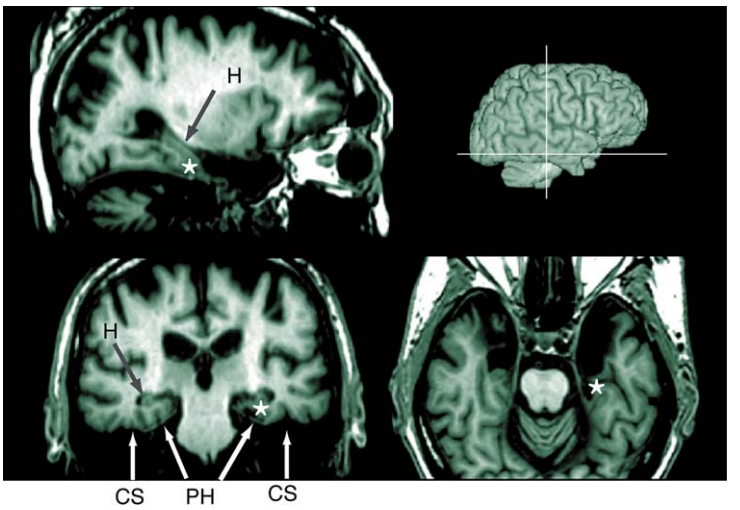

Figure 1 Multiplanar views of 18 averaged T1-weighted magnetic resonance imaging volumes showing preserved structures in H. M.'s left medial temporal lobe (MTL). The asterisk marks the intersection of the three viewing planes, just caudal to the left MTL resection, seen best in the transaxial view. Abbreviations: CS, collateral sulcus; H, hippocampus; PH, parahippocampal gyrus. Reprinted from Corkin S (2002) What's new with the amnesic patient H. M.? *Nat. Rev. Neurosci.* 3(2):153–160, with permission from Macmillan Magazines Ltd.

particularly interesting about this patient was that, in spite of this devastating memory impairment, some learning capabilities survived (Corkin, 1968). The evidence from H. M. and other patients with milder impairments seemed to point to the hippocampus as the structure commonly damaged in patients with memory impairments (Penfield and Milner, 1958). Several important points came from this research: (1) the hippocampus and possibly other structures in the human medial temporal lobe (MTL) was required to encode some new memories, but some memory functions remained intact after MTL damage; (2) because some past memories survived, the hippocampus or related MTL structures were not the permanent storage site of long-term memory; and (3) to the extent it was involved in retrieval, this role must be time limited as well. The study of H. M. and other amnesic patients in the subsequent years revealed much about the neural basis of human memory. As is discussed elsewhere in these volumes, the idea of multiple memory systems, some of which are spared even in global amnesics, came directly from patients like H. M. What was not immediately forthcoming was similar evidence from the animal literature.

In spite of the effects of MTL damage on human memory, damage to the hippocampus in animals initially appeared to have very limited (Douglas, 1967; Weiskrantz and Warrington, 1975) and somewhat specific effects in rat or monkey memory (e.g., Mahut, 1971; Olton, 1977). For some time it appeared that there was no comparison even between humans and monkeys, in spite of the high degree of anatomical homology between human and nonhuman primates, and even rodents, with respect to the medial temporal lobe structures (see **Figure 2**). However, in 1975, Mishkin and Delacour described a modification to the matching-to-sample memory task developed by Gaffan (1974) that could be readily learned in monkeys and that was closer to tests of human recognition memory, known as trial unique, delayed *non*matching-to-sample (**Figure 3**). Earlier versions of this task (Gaffan, 1974) used small stimulus pools and were very difficult for monkeys to learn and served more as tests of *recency* rather than recognition. To better approximate the recognition tasks used in humans, Mishkin and Delacour (1975) used large pools of stimuli, creating a 'trial-unique' version of the task. That is, rather than one which required the subject to remember which stimulus had been seen most recently (i.e., recency memory), the new version required the subject to indicate which stimulus was novel (presumably known because the other stimulus was remembered, i.e., recognition memory). Combining this task with damage to the medial temporal lobe similar to that sustained by H. M. yielded at last an impairment in monkeys apparently equivalent to the memory deficits suffered by human amnesic patients. Mishkin (1978) demonstrated for the first time that, whereas amygdalectomy or hippocampectomy alone produced mild impairments at best, combined lesions, effectively replicating H. M.'s damage, not only produce a severe impairment on relearning the task postoperatively, but even once relearned, memory for an individual stimulus rapidly decayed across brief delays (**Figure 4**). Continued work in human amnesic patients further characterized the nature of the deficit as being limited to particular long-term memory processes, termed 'declarative' or 'episodic/semantic' or 'explicit' memory (Cohen and Squire, 1981; Cohen, 1984; Tulving, 1972), and those processes that are spared in human amnesics termed, for example, 'nondeclarative' or 'implicit' memory were also shown to be spared in the operated monkeys (Zola-Morgan and Squire, 1984). The pattern of impairment and sparing of memory functions in both humans and monkeys with medial temporal lobe damage led to the idea that there are multiple memory systems in the brain, which has been a major guiding force in the research of the last 30 years. This research has vastly increased our knowledge about the neural bases of memory and generated model systems in monkeys, rodents, and at the cellular level in invertebrates.

3.09.3 Animal Models

3.09.3.1 Why Animal Models?

From the outset, the goal in the creation of models of human amnesia has been to better understand the neural circuits that contribute to human memory. The underlying assumption, which is supported by detailed anatomical studies, is that there is conservation of structure and function among mammalian systems, that is, the organization of the infrahuman brain is sufficiently similar to that of the human brain to permit such comparisons. In spite of great differences in size and complexity, the basic organizational principles in the brain apply up the evolutionary scale (see **Figure 2**). The benefit is that animal studies can provide a degree of experimental control that

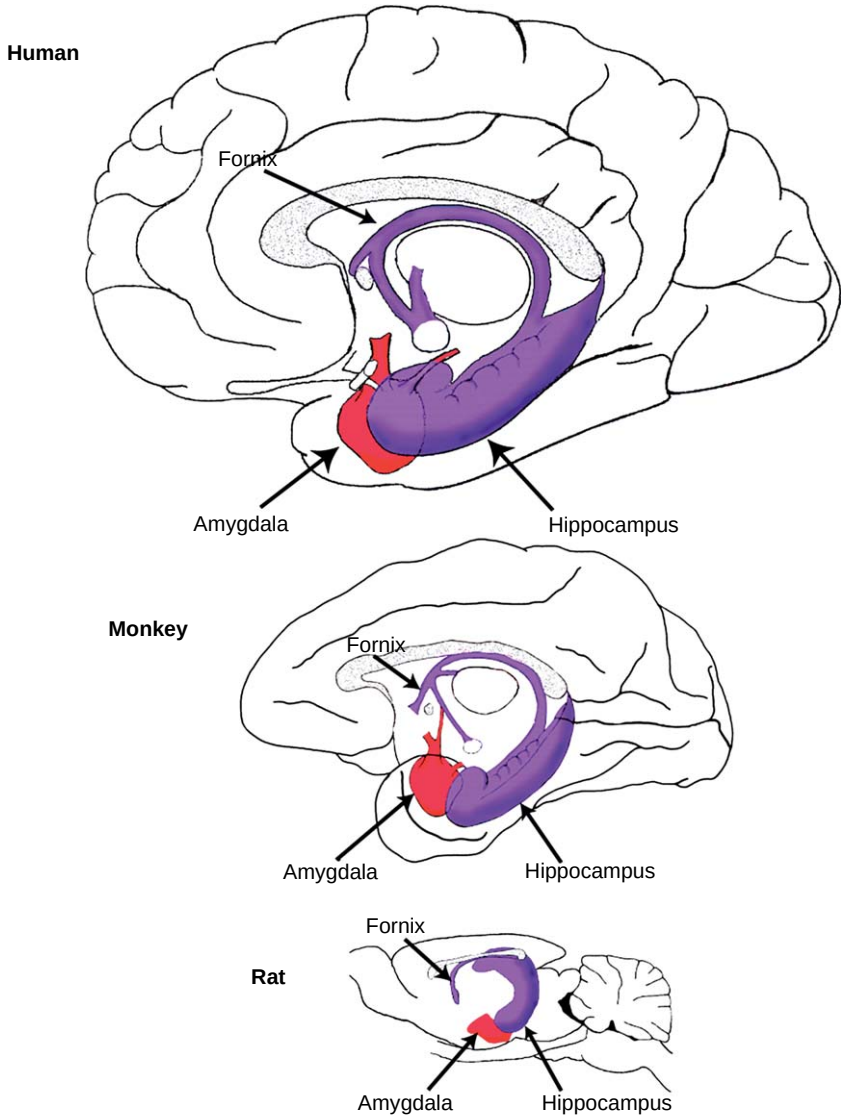

Figure 2 Midsagittal view of the human, monkey, and rat brains illustrating some components of the medial temporal lobe important for memory function: the amygdaloid complex, hippocampus, and fornix. Relative sizes are not to scale. *See also* Chapter 3.03.

is almost impossible to achieve with human studies. With very few exceptions, the neural damage associated with human amnesia has been fairly extensive, and not always determinable. Furthermore, though physical damage can be detected and mapped out, it is not always clear whether 'spared' tissue is functioning normally (a caveat for all lesion studies). The methods available to animal researchers improve selectivity in the assessment and manipulation of brain function, which allows not only for the revelation of the individual contributions of brain structures to memory, but also for the assessment of how different circuits interact with each other in the service of normal memory. As described earlier, initial studies suggested that only when damage approximated that sustained by H. M. was a clear memory impairment observed in monkeys. Although smaller lesions do impact memory, either with greater specificity (e.g., memory for objects vs. memory for space) or degree (e.g., only at long delays), these restricted lesions do not produce dense amnesia in animal or human subjects. Nevertheless, the investigation of how individual structures contribute to memory will better enable the understanding of amnesic symptoms and, in the case of organic causes of amnesia, the development of treatments.

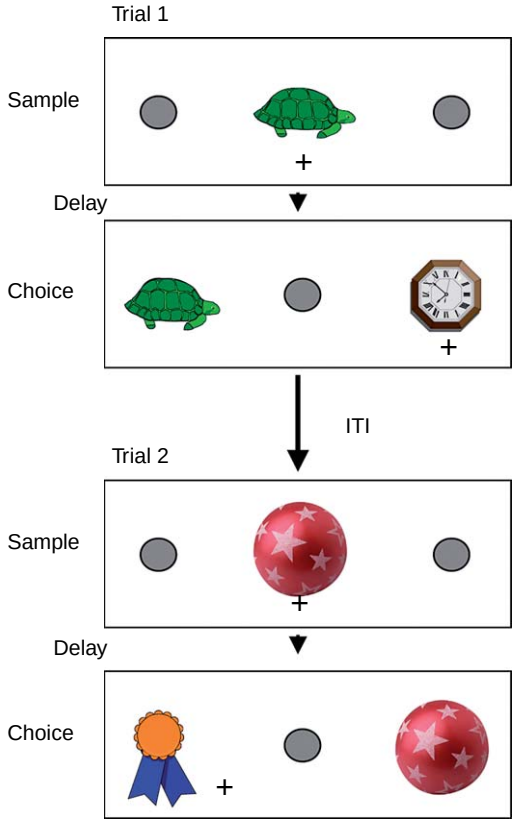

Figure 3 Delayed nonmatching-to-sample (DNMS) task. Trial 1: The monkey is presented with a sample object covering a food reward (+) in the central well of the testing tray. After a delay, during which the test tray is obscured, the sample object and a novel choice object are presented simultaneously covering the lateral wells, but the novel object is now rewarded (i.e., nonmatch-to-sample). After a brief intertrial interval (ITI), the next trial begins. Trial 2: For this and all subsequent trials, a new pair of objects serves as the sample and choice (i.e., trial unique).

3.09.3.2 What Is Being Modeled?

The focus thus far has been on the history of human amnesia resulting from damage to the MTL. It should be noted, however, that there is a wide literature for human Korsakoff patients, whose prolonged alcoholism has produced damage to the diencephalic structures of the brain, as well as anterograde declarative amnesia (*See* Chapter 3.04; Squire, 1982; Squire et al., 1990). Although animal studies have demonstrated a role for the diencephalic structures in memory (e.g., Aggleton and Brown, 1999; Vann and Aggleton, 2004), the research has been more extensive for structures in the MTL, and so we will focus on research in these structures of the brain in the remainder of this chapter. Nevertheless, the question must be raised: what exactly is it that is being modeled? Human memory has been defined as comprising two main systems: a declarative, or explicit system, containing rich memory representations that can be recalled at will, and a nondeclarative, or implicit system such as skill learning (for which there is not always a particular recollection of having acquired the skill). Whereas such divisions have a clear basis and intuitive appeal when applied to humans, how are we to ask a nonverbal animal to 'declare' what is in its memory store? Thus in animal models, there is an ongoing debate as to how best to define the animal equivalents of declarative and nondeclarative memory systems (*See* Chapter 1.04).

In humans, it can be verified that someone has a memory of an event, because they can recall and describe the event in detail at a later time. It is not possible to measure recall in the same way in animals; however, we can use several means to determine whether an animal can demonstrate that it has experienced an event and remembers it on some level. In this instance we infer memory by observing a change in the animal's behavior. To this end, there are some clear consistencies in the human amnesic syndrome that may be taken as core deficits that can be assessed with animal models. These include global (i.e., multiple modality) anterograde amnesia for facts and events, in the presence of intact skill learning or conditioning; spared memory for remote events, but possible temporally graded retrograde amnesia for information closer to the onset of amnesia; and intact short-term memory, with a forgetting curve that is steeper in amnesic patients than in normal subjects. Thus, although we cannot determine whether an animal can *recall* a specific memory, we can determine whether an animal can *recognize* a previously seen memorandum and use that information to guide behavior. We can then assess whether animals forget newly learned information more rapidly as a result of particular brain damage than controls. Finally, we can determine whether only information learned in a specific context (i.e., episode) is forgotten, or if the processes that allow encoding of context are somehow impaired.

In addition to the development of specific tests of animal memory, a number of theories of memory formation have been developed that are, to a greater or lesser degree, tied to specific neural structures. These 'memory systems' are reviewed elsewhere in these volumes, so discussion will be limited to pointing out where different theories make specific

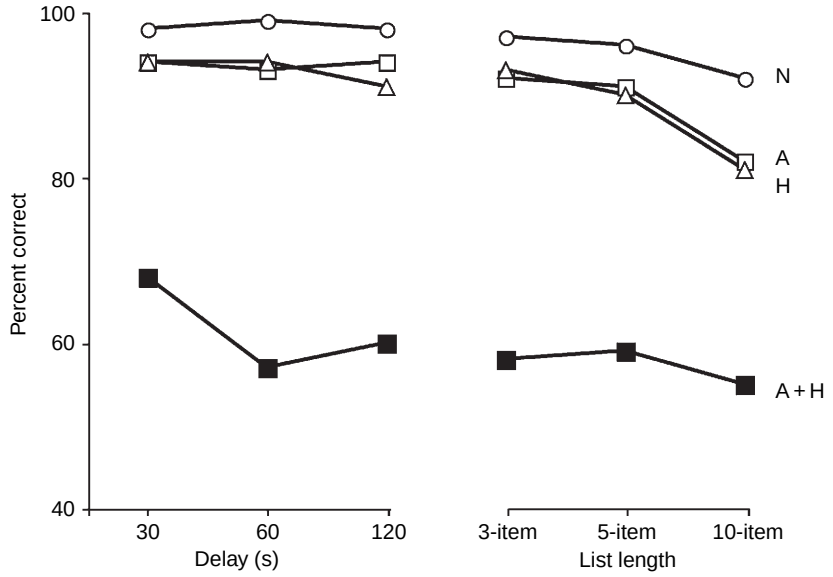

Figure 4 Performance of monkeys with damage to the medial temporal lobe on DNMS, when delays are increased from 30 to 120 s or the number of to-be-remembered objects is increased from three to ten. N, unoperated controls; A, animals with aspiration lesions of the amygdala; H, animals with aspiration lesions of the hippocampal formation; A + H, animals with combined amygdala and hippocampal lesions. predictions about a given task and to group the discussion of particular memory tasks into theoretical categories. In particular, we will focus on tasks requiring recognition memory, conjunctive/relational memory, or spatial memory. This is a loose distinction, as recognition memory tasks, for example, can be used to assess spatial or relational information and vice versa.

3.09.4 Recognition Memory

Two paradigms in particular have been used to assess recognition memory in rodents and monkeys: the delayed nonmatching-to-sample task (DNMS) and the visual paired comparison (VPC) task (also known as preferential looking, or spontaneous recognition). Like some tests of human recognition or recall, each task assesses whether subjects demonstrate that a given stimulus has been previously seen (judgment of prior occurrence; Brown, 1996). However, substantial differences in the task requirements may alter both the demands made on memory processes and, potentially, the specific brain regions necessary for successful performance of each. In particular, these tasks may be seen as testing memory for 'facts' as well as the duration of the memory trace, but with slight parametric modification.

3.09.4.1 Delayed Nonmatch to Sample

This task was the first to successfully demonstrate a deficit in recognition memory consequent to the same neural damage that produces human amnesia. The task is simple in that monkeys learn to displace junk objects to obtain a hidden food reward. However, food is only located under objects that have not been seen recently. That is, animals are trained to associate novelty with reward. In the basic paradigm, the monkey is seated in a sound-attenuated chamber (Wisconsin General Testing Apparatus, or WGTA) behind an opaque screen (see **Figure 3**). When the screen is raised, the monkey views a testing tray containing three equidistant food wells, which can be covered with junk objects, hiding either a baited or an empty well. Training takes place in two phases for each trial: sample and choice. During the sample phase, a single object covers the central food well, and when displaced, a food reward can be retrieved. The screen is then lowered and the now-familiar sample object is moved to cover a lateral well (empty), while a novel object covers the opposite lateral well (baited). After a brief period, typically

ranging from 10 s to 10 min, the screen is raised, and the monkey must choose one of the objects. If the animal remembers the sample object and correctly applies the nonmatching rule 'choose the unfamiliar item,' then the novel item is chosen and the food reward can be retrieved. When the animal reliably masters the rule governing the task, memory can be further manipulated by changing the length of the delay between the sample and choice phases, by changing the number of items to be remembered (i.e., list learning), or by changing the nature of the information to be remembered (i.e., stimulus location, or nonvisual modalities, such as tactual or olfactory).

The early work by Mishkin and others on this task confirmed that large lesions to the MTL dramatically impaired performance (Mahut et al., 1982; Mishkin, 1978; Squire and Zola-Morgan, 1983) while sparing performance on tasks such as visual discrimination learning in which monkeys learn a set of 20 concurrent discrimination problems that are presented only once per day, thus with 24-h delays (Malamut et al., 1984). These results seemed to match the spared and impaired performance capabilities of amnesic patients such as H. M., who could not retain new information for more than a few seconds without active rehearsal, but could improve over many trials to perform tasks such as mirror drawing or the incomplete figures task (Gollin, 1960; see Milner, 2005). However, as a measure of *hippocampal* memory function, the results from the DNMS task have been called into question.

Using more selective lesion techniques, it has become possible to parse out the individual contributions of MTL structures to recognition memory. For example, Zola-Morgan et al. (1989) showed that the addition of cortical-sparing amygdala damage to animals with hippocampal damage did not exacerbate their memory impairment, suggesting that Mishkin's (1978) initial findings were due in part to the cortical damage sustained by the animals with combined lesions. Indeed, further studies demonstrated that damage to the subjacent perirhinal and entorhinal cortices, removed along with the hippocampus and amygdala in the initial Mishkin studies, devastates performance of this task in monkeys (**Figure 5**; Zola-Morgan et al., 1989; Meunier et al., 1993, 1996). However, damage to these cortical areas (collectively referred to as 'rhinal' cortex) that spares the hippocampus and amygdala produced as large an impairment as the combined lesion (Murray and Mishkin, 1998; Baxter and Murray, 2001).

The use of neurotoxic lesions of the hippocampus has not entirely solved the question. Murray and Mishkin (1998) showed that monkeys with selective neurotoxic damage to the hippocampus and amygdala showed normal DNMS performance out to 2-min delays. Nor were they impaired on lists of 40 items, which were then tested in reverse order, resulting in delays ranging from 30 s to 40 min. Zola and colleagues (2000) found that regardless of lesion method, hippocampal damage impaired DNMS performance at delays of 10 min and beyond (see also Beason-Held et al., 1999, for similar findings). However, a meta-analysis of the results across several laboratories suggested that there was a negative correlation, even within studies, with the amount of damage on performance of the task (Baxter and Murray, 2001; see Zola and Squire, 2001, for reply). By contrast, one study has suggested a positive correlation between lesion size and memory deficit at delays of 10 min (Nemanic et al., 2004). Indeed, those results suggested that the lack of impairment in monkeys with hippocampal damage might be due in part to alternate performance strategies that allow the animal to bridge the longest delays. When a distraction is inserted into the delay period (opening the screen at short delays, having the animal perform a motor task at longer delays, or removing it from the apparatus during 10-min delays) an impairment is revealed in animals with selective neurotoxic hippocampal damage at the longest delay, which correlates positively with the amount of hippocampal damage (Nemanic et al., 2004). However, in this same study, damage to the perirhinal cortex produced an even greater impairment on performance of DNMS, with or without distraction, even after short delays.

Taken in context with what we now know of the anatomy of the region, it is clear that the perirhinal cortex is important for object memory, in particular for object identity (Ungerleider and Mishkin, 1982), and that damage limited to this region produces a severe impairment in visual recognition memory (Suzuki et al., 1993; Eacott et al., 1994; Buffalo et al., 1999). Indeed, it is currently being argued that the perirhinal cortex may be important for visual perception as well as memory (e.g., Murray and Bussey, 1999; Buckley et al., 2001; but see also Hampton, 2005, for a different interpretation of the data). Hippocampal damage, by contrast, leaves short-term memory intact on this task, which is maintained both by the temporal cortical region and also by active mechanisms when necessary, possibly controlled by the prefrontal cortex.

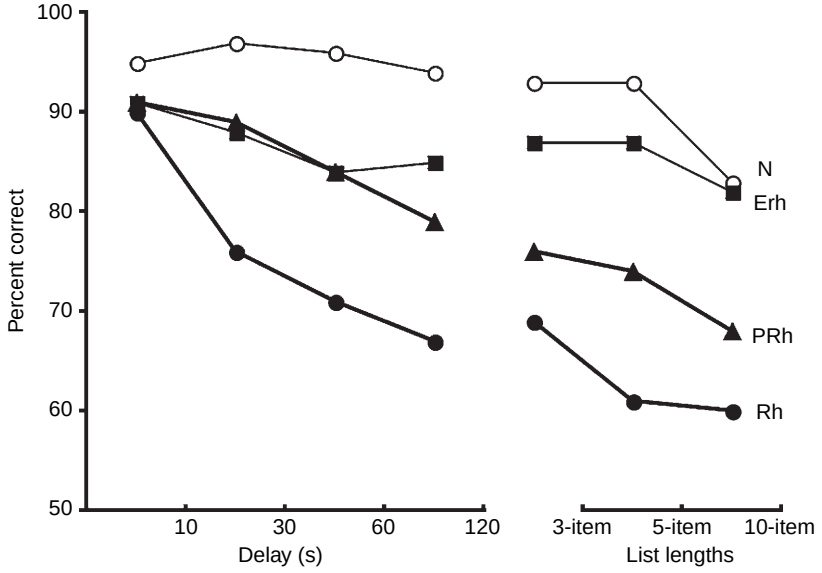

Figure 5 Effects of entorhinal (Erh), perirhinal (PRh), and rhinal (Rh; Erh + PRh) lesions on DNMS performance as compared to unoperated (N) animals. Adapted from Meunier M, Bachevalier J, Mishkin M, and Murray EA (1993) Effects on visual recognition of combined and separate ablations of the entorhinal and perirhinal cortex in rhesus monkeys. *J. Neurosci.* 13: 5418–5432, with permission from the Society for Neuroscience.

Several rodent versions of the DNMS task for objects have been developed (e.g., Aggleton, 1985; Kesner et al., 1993; Mumby and Pinel, 1994; Rothblat and Hayes, 1987); however, results from rodent studies have also questioned the view that the hippocampus is necessary for object memory. As recently reviewed by Mumby (2001), the majority of studies assessing the effects of hippocampal damage on DNMS or delayed matching-to-sample (DMS) have shown no effect on recognition memory in rodents, except in instances where cortical damage was also present (e.g., Clark et al., 2001) or in those studies where hippocampal damage was produced by forebrain ischemia. The hippocampus is extremely sensitive to ischemia, and as has been shown in humans, ischemic events produce quite profound memory deficits in monkeys (Zola-Morgan et al., 1986; Rempel-Clower et al., 1996). However, although ischemia was thought to have damaged only a single hippocampal cell field (CA1) in human patients (Squire and Zola, 1996), there is evidence to suggest that the damage is more widespread, and particularly detectable through the use of specific histological methods (Bachevalier and Meunier, 1996). Furthermore, although ischemic damage in human amnesic patients impaired performance on a DNMS-like task, thus seemingly providing a direct link between the hippocampus and recognition memory, later work in rats by Mumby and colleagues (1996) showed that ischemia-related memory impairments were likely due to either extra-hippocampal damage or to abnormal discharges in the remaining cortical tissue. They showed that producing ischemia, followed by removal of the entire hippocampus, actually spared learning on DNMS. Thus, at best, the effect of hippocampal damage on DNMS for objects is mild and restricted to long delays and lists.

Finally, it is worth noting recent developments in the nature of recognition memory. It has been suggested that two processes support recognition memory performance: recollection and familiarity. These two processes are in play when an animal or human must determine whether or not a given item was previously seen (see Aggleton and Brown, 1999, for review). In the absence of strong recollection, familiarity processes will determine whether they recognize the item or not. These two processes can be measured by the use of receiver operating characteristic (ROC) (see **Figure 6**) curves in which the shape of the curve determines the degree to which recollection or familiarity contributes to performance (Yonelinas, 1994, 1997). For normal memory, the shape of the ROC curve reflects the contribution of both recollection and familiarity, showing an asymmetrical and curvilinear shape (**Figure 6(a)**). It has been proposed that the familiarity component has a symmetrical and curvilinear shape, whereas the recollection component is

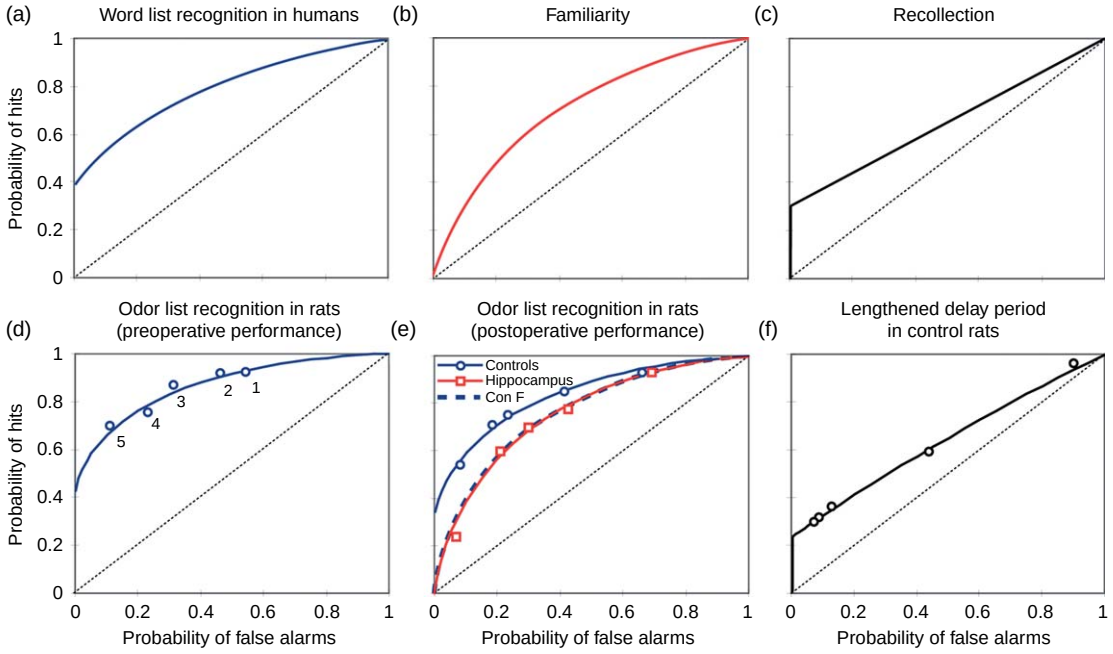

Figure 6 Example of receiver operator characteristic (ROC) curves for normal human performance (a) and the portions of the curves contributing to (b) familiarity and (c) recollection. (d) Performance of normal rats on odor discrimination tasks. (e) Performance of normals vs. hippocampectomized rats illustrating characteristic familiarity curve in the hippocampal group. (f) Performance of control rats after 75-min delay, illustrating the recollection component of the curve. From Fortin NJ, Wright SP, and Eichenbaum H (2004) Recollection-like memory retrieval in rats is dependent on the hippocampus. *Nature* 431(7005): 188–191; reprinted with permission from Macmillan Publishers Ltd.

asymmetrical and linear. In an odor recognition task, Fortin et al. (2004) showed that rats demonstrated both the asymmetrical and curvilinear components of the ROC curve by manipulating the rat's 'bias' level. By changing the amount of reward and the effort required to retrieve it, rats shifted their response criterion to more or less strict levels, shifting their tendency to correctly identify previously encountered odors ('hits') or incorrectly identify new odors as old ('false-alarm'), suggesting that both recollection and familiarity play roles in normal rodent recognition memory performance (**Figure 6(d)**). By contrast, selective hippocampal damage produced symmetrical and curvilinear ROC curves (**Figure 6(e)**), indicating that only familiarity was contributing to their performance (Fortin et al., 2004). Finally, after very long delays, the ROC curve for control rats was asymmetrical and linear, suggesting that only recollection contributed to performance after long delays (**Figure 6(f)**). Thus, these results suggest that the hippocampal formation in rodents is necessary for recall, but not recognition. Although these results remain to be replicated, studies in humans with selective hippocampal damage also show similar shifts in the ROC characteristics (e.g., Yonelinas et al., 1998; Aggleton et al., 2005; Cipilotti et al., 2006), although there is active debate about the interpretation of the results (e.g., Wixted and Squire, 2004; Wais et al., 2006).

3.09.4.2 Visual Paired Comparison/ Spontaneous Recognition

Similar to DNMS, the VPC task utilizes a familiarization phase and a choice phase, but the task demands are quite different. This task takes advantage of monkeys' natural preference for looking at novel things in their environment, and in contrast to the DNMS, it in fact requires no specific learning and no forced choices between two objects to obtain rewards. For VPC, monkeys passively view a visual stimulus, typically a black/white image, and are allowed to look at it for a sufficient period to show habituation (i.e., they cease visual exploration). This familiarization period may range from 15 to 30 s of looking time. At this point, the image disappears, and after some delay period (as brief as 1 s) the image reappears on the screen, side by side with a novel image. Monkeys, rats, and humans

naturally prefer to look at (explore) the stimulus they have not yet seen (novelty preference); thus we infer that they remember the familiar stimulus. Given that the subject is not actively performing a task, it should not be surprising that performance levels on VPC are much lower than on DNMS, where animals are trained to a 90% correct criterion. With VPC, typical novelty preference is in the range of 65–70% preference for novelty, but this effect is reliable. Unlike the DNMS task, VPC has proven to be very sensitive to hippocampal damage at delays as short as 1 min (Pascalis and Bachevalier, 1999; Zola et al., 2000; Clark et al., 2001; Nemanic et al, 2004). Similar to DNMS, however, damage to the temporal cortex produces impairments at shorter delays (~30 s for parahippocampal gyrus, and ~10 s for perirhinal cortex). Thus, though the sensitivity may be greater in detecting recognition memory deficits in the VPC task, the contributions of at least three regions of the MTL maintain a similar relationship to each other; that is, perirhinal contributes in the initial encoding and short-term retention of visual stimuli, whereas parahippocampal area TH/TF and hippocampus are required for longer retention. Similar to the DNMS task, the role of the hippocampus and area TH/TF in VPC becomes more prominent when arrays or locations of objects are used as stimuli (see **Figure 7**), making the task more spatial in nature, but the role of perirhinal cortex is evident in all object conditions, regardless of their spatial relations (Nemanic and Bachevalier, 2002).

Studies in rodents initially employed what was termed the spontaneous recognition paradigm (Ennaceur and Delacour, 1988). In this task, rodents are allowed to examine a junk object using vision, olfaction, and touch during a sample phase, and then after some delay during which the object is not present, an identical old object and a novel one are placed equidistant from the rat. Rats preferentially spend time exploring the novel object. Variants of the task have been used to explore recognition of single items, locations, or item configurations as well as the effects of specific neural damage on performance. Initial studies failed to find effects of fornix damage on object recognition, but did find an effect on recognition for location (Ennaceur and Aggleton, 1994; Ennaceur et al., 1997). By contrast, using methodology similar to the monkey visual VPC experiments, Clark and colleagues showed deficits as early as 1 min in rodent visual preference (Clark et al., 2000) after neurotoxic damage to the hippocampus. Later studies have also been equivocal. Spared novelty preference has been reported in rats with selective hippocampal damage at delays of 48 h (Forwood et al., 2005; Winters et al., 2004) and recently as long as 3 weeks (Mumby et al., 2005), although the latter study used five daily familiarization sessions. By contrast, damage to the peri-postrhinal region

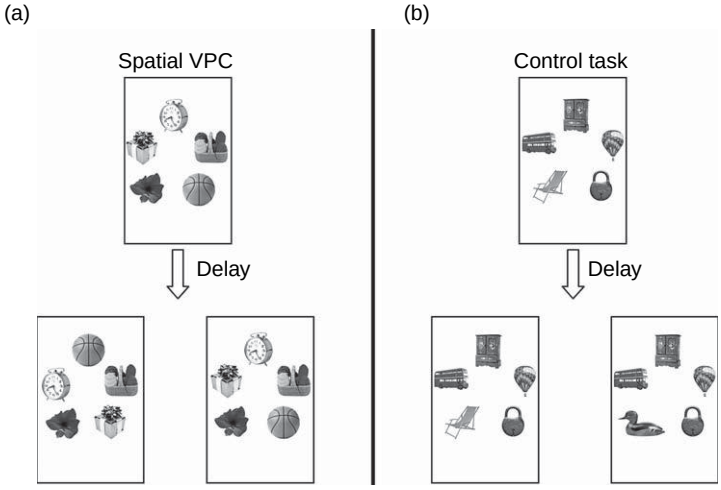

Figure 7 Spatial variant of the visual paired comparison (VPC) task using arrays of objects. (a) Spatial VPC: Five objects are presented in a visual array. Following a brief delay, the sample array and a novel arrangement (in which three objects are repositioned) are presented to the monkey. (b) Control task: A similar spatial array is presented in the sample phase, but the novel array has one object replaced with a new one.

showed impaired novelty preference (Ennaceur et al., 1996; Winters et al., 2004). It is possible that this difference between rodent and monkey results in part from the methods used. With the exception of the Clark et al. (2000) study, most rodent paradigms allow the rat to physically explore the object, using any or all of three sensory systems: vision, touch, smell. The primate studies were limited to visual recognition (see Mumby, 2001).

In sum, these two measures of recognition memory show very different sensitivity to selective damage to hippocampus or temporal cortex. As noted, however, in both tasks, each region contributes to recognition memory in the same relative manner, but the absolute delay for which impairment occurred differs for each region damaged.

3.09.4.3 Performance of Human Amnesics on Animal Tests of Recognition

Human amnesia has, by and large, been tested with numerous tasks that are quite different from those used with animals (*See* Chapter 3.04). Thus differences in the nature or extent of impairments between animal models and the human impairment may be due to task differences, to lesion differences, or to evolutionary forces, in addition to the lack of language capabilities. Thus, it is important to test humans on animal memory tasks both to validate the behavioral assays and to better understand specific impairments in human patients. Regarding the lesion differences, the recent reports of patients with selective damage to individual components of the MTL provides an opportunity to test specific memory functions in humans with similarly selective damage and to compare the results with those from other species, and eventually may inform the assessment of human patients.

Tests of human amnesic patients on animal tests of recognition, while relatively few, are largely in agreement with the animal findings when large temporal lobe lesions were used. For example, Squire et al. (1988) reported that a group of patients whose presumed damage was either diencephalic (Korsakoff's patients) or hippocampal (ischemic/anoxic patients) were severely impaired on the DNMS task, similar to the initial monkey studies (Mishkin, 1978). Similarly, Reed and Squire (1999) reported marked impairments on DNMS in patients with damage to the hippocampal formation. Unlike the monkey studies, however, they were also impaired on a concurrent discrimination task that is routinely spared in monkey studies and that presumably is a model of procedural memory. Based on the finding that performance levels on the task were directly related to declarative knowledge of the solution, Squire et al. (1988) suggested that, unlike monkeys, humans normally learn this task declaratively. By contrast, patients with damage restricted to the hippocampus have shown spared performance even on DMS at delays up to 30 s (Holdstock et al., 2000a), which follows more closely the results in monkeys and rodents and suggests that the impairment seen in the early studies of Squire may have resulted from damage to the adjacent MTL structures (*See* Chapter 3.08).

Similarly, recognition memory impairments have been demonstrated on the VPC task, and as in animals, these impairments are often larger than those obtained from matching or nonmatching tasks. For example, McKee and Squire (1993) reported novelty preference in human amnesic patients when the delays were short (0.5 s) but not when delays were extended to 2 min or 2 h. Direct comparisons of VPC and DMS performance in human amnesic patient Y. R., who became amnesic after a possible ischemic infarct, resulting in reduced hippocampal volume and no other obvious pathology as measured by magnetic resonance imaging (MRI) (Holdstock et al., 2000b). This patient had previously shown impaired recall, but intact recognition on standard human memory tests (Holdstock et al., 2000b). She also demonstrated severe impairments in memory on VPC (Pascalis et al., 2004), demonstrating preference for novelty at the 0-s delay only. At the longer delays of 5 and 10 s, her performance fell to chance. By contrast, as described above, her performance was as good as controls on the DMS task with delays up to 30 s (Holdstock et al., 2000a). Unfortunately, she was not tested at longer delays on DMS, but the reported results map onto those reported in rats and monkeys in that hippocampal damage impairs VPC performance at much shorter delays than on DNMS (Clark et al., 2000; Zola et al., 2000; Nemanic et al., 2004). As for the animal studies, it is possible that the difference between VPC and DMS/DNMS performance is related to the forced choice required by the matching tasks that may encourage the subjects to rely on familiarity in the absence of recall to support good performance.

3.09.5 Conjunctive/Relational Memory

As is described in detail elsewhere in these volumes (*See* Chapter 1.04), a number of memory systems have been proposed to uniquely account for the

types of deficits observed in animals with selective hippocampal damage. Within the animal literature, this discussion has often centered around theories proposing that the hippocampal formation is predisposed toward spatial or contextual memory processing, and those which contend that this is too narrow a view and does not account for deficits on nonspatial memory tasks except by invoking 'context.' Two of these viewpoints, the conjunctive account (Sutherland and Rudy, 1989; O'Reilly and Rudy 2001) and the relational account (Eichenbaum et al., 1989), have generated much attention in the search for hippocampal function. Both of these viewpoints address the way in which the hippocampus forms associations among individual elements in the environment, with Rudy, Sutherland, and O'Reilly taking the conjunctive viewpoint and Eichenbaum and colleagues taking the relational viewpoint. The distinctions between these accounts will be addressed in detail in the relevant chapters of this book; for the purposes of this chapter, we will focus on two tasks that are representative of the two viewpoints. These two tasks have been selected because they have been tested in a variety of species, including humans, and have provided evidence for nonspatial deficits in animals and humans with hippocampal or MTL damage.

3.09.5.1 Transverse Patterning

The transverse patterning task was first described by Spence (1952) as an example of a task that cannot be solved on the basis of individual stimulus representations. It is formed of three concurrent discrimination problems that are presented as follows: A+ versus B–, B+ versus C−, and C+ versus A−, where A, B, and C are individual stimuli, and + or − indicates the rewarded or unrewarded member of the pair, respectively. Because the individual elements (A, B, and C) are inconsistently associated with reward, a representation of the three conjunctions <AB>, <BC>, and <CA> allows for the disambiguation of the individual elements. By contrast, it has also been suggested that this task requires a relational solution, in that the subject must learn that A, B, and C stand in unique relationships to each other (Dusek and Eichenbaum, 1998).

Using a swim-maze version of the Lashley jump stand, Alvarado and Rudy (1992) trained normal rats on a visual discrimination version of the transverse patterning task. By adding problems incrementally, they were able to determine that learning two problems at once (e.g., A+ vs. B− and B+ vs. C−) produced configural learning in normal rats, in spite of the possible elemental solution (pick A, avoid C) the animals could have used. However, there is a clear point in training beyond which configural representations are needed, which is the addition of the third discrimination (C+ vs. A−). It is at this point that hippocampal damage was predicted to impair performance, a prediction that has been empirically proven in further rodent studies using neurotoxic lesions of the hippocampal formation (Alvarado and Rudy, 1995a,b). Rats with hippocampal lesions were able to perform the task only when an elemental solution was possible (i.e., when two problems had to be simultaneously resolved), but not when the third was added. Furthermore, they were unimpaired at learning three elemental discriminations (A+ vs. B−, C+ vs. D−, and E+ vs. F−). In another swim version of the task, Driscoll et al. (2005) replicated Alvarado and Rudy's (1995a,b) basic findings, but further found a retrograde impairment for *both* elemental and configural information learned presurgically. Thus, the elemental impairment was in the retrograde direction only (i.e., remembering previously learned elemental problems was impaired, but learning new elemental problems was intact). The impairment for conjunctive information, however, was both anterograde and retrograde (Driscoll et al., 2005).

In a related study, Dusek and Eichenbaum (1998) used an olfactory digging version of the task in which three scented sand-filled cups served as stimuli, and a food reward was buried in the correct cup. Using a slightly different training paradigm, they found that animals with fornix transection or damage to the temporal cortex were impaired when stimulus presentation was random, although they could manage to perform when the problems were presented in blocks. Similarly, these authors showed that NR1-knockout mice, which have been genetically modified such that they have no *N*-methyl-D-aspartate (NMDA) receptors in hippocampal cell field CA1, were also impaired on the odor version of transverse patterning, but were unimpaired at learning a set of concurrent odor discriminations (Rondi-Reig et al., 2001).

More recently, monkeys with neonatal damage to the hippocampus and subjacent cortex (but not those with damage to the amygdala and subjacent cortex; Alvarado et al., 2002) and adult macaques with neurotoxic hippocampal damage (Alvarado and Bachevalier, 2005b) were impaired in an object

version of the transverse patterning task. These operated animals were unimpaired in performing a linear sequence of discriminations A+ versus B−, B+ versus C−, C+ versus X−, confirming that the impairment was only for the use of conjunctive representations.

By contrast, neither fornix transection nor selective hippocampal damage was able to impair a touch screen version of the task in either rats or monkeys (Bussey et al., 1998; Brasted et al., 2003; Saksida et al., 2007). The reason for the differences between the findings on the effects of hippocampal damage on the transverse patterning task are not yet clear, but methodological differences between the studies could be responsible. For example, it is noteworthy that, in the touch screen version of the transverse patterning task, control rats and monkeys required more trials to learn the task and reached lower performance levels (performing at 60–70% correct after several thousand trials when the three problems are intermixed) as compared to control rats trained on the swim or digging versions of the task and monkeys in an object version of the task (performing at 90% correct within 90–300 trials for rats and 300–500 trials for monkeys). It will be informative to assess in future studies whether the different versions of the task encourage the use of specific strategies that determine the success or failure of control subjects. Such information will likely reveal the types of memory processes engaged for task performance and have implications for the degree to which the hippocampus or cortical structures are preferentially engaged.

3.09.5.2 Transitive Inference

This task specifically tests predictions from the relational memory view of hippocampal function. In particular, it assesses a proposed property of declarative memory that allows for the inferential or flexible use of memories in new situations (Cohen, 1984; Eichenbaum, 1992). The logical structure of the task takes the form of A+ versus B−, B+ versus C−, C+ versus D−, and D+ versus E− (Dusek and Eichenbaum, 1997). Note that, with the exception of the endpoints A and E, all other stimuli are equally often rewarded or nonrewarded. It has been suggested that humans and animals form an orderly series of representations, such that A > B > C > D > E. The crucial test of this hypothesis is a novel test between B and D. Although these two stimuli have never before been paired together, if the subject has learned a set of hierarchical relationships, it should be able to *infer* that B is greater than D (i.e., if John is taller than Bill and Bill is taller than Peter, who is taller, John or Peter?). Eichenbaum and colleagues have suggested that the hippocampus allows for the formation of these orderly representations, and importantly, that these relational representations permit the flexible use of memory, so that in novel situations, animals and humans can respond correctly. In support of this hypothesis, they have shown that, whereas some 88% of normal animals correctly choose B over D on the probe, animals with hippocampal damage were at chance (Dusek and Eichenbaum, 1997; but see Frank et al., 2003; van Elzakker et al., 2003, for alternative interpretations).

3.09.5.3 Role of the Temporal Cortex

Finally, it should be noted that a number of recent studies have implicated the perirhinal, entorhinal, or parahippocampal cortices in conjunctive or relational tasks. For example, damage to the perirhinal cortex (Alvarado and Bachevalier, 2005a; Saksida et al., 2007) or parahippocampal areas TH/TF in monkeys (Alvarado and Bachevalier, 2005a) impaired performance on transverse patterning, but not elemental discriminations. Similarly, combined perirhinal-entorhinal lesions in rodents impaired transverse patterning performance (Dusek and Eichenbaum, 1998). Variants of purely configural tasks, such as the biconditional discrimination (e.g., AB+, CD+, AD−, CB−), have been shown to be sensitive to perirhinal damage but not fornix damage (Whishaw and Tomie, 1995; Buckley and Gaffan, 1998; Bussey et al., 1998) or hippocampal damage (Saunders and Weiskrantz, 1989; Killiany et al., 2005; Saksida et al., 2006). Finally, monkeys with entorhinal lesions (Buckmaster et al., 2004) and rodents with combined perirhinal and entorhinal lesions (Dusek and Eichenbaum, 1997) are impaired on transitive inference. The fact that perirhinal and parahippocampal lesions do impair performance on several relational tasks certainly suggests a role for the cortex in the use or formation of configural or relational cues (e.g., Eichenbaum et al., 1994; O'Reilly and Rudy, 2001; Bussey and Saksida, 2002; Saksida et al., 2007), but the precise nature of this role is yet to be determined.

3.09.5.4 Performance of Human Amnesics on Animal Tests of Conjunctive/Relational Memory

The use of conjunctive and relational tasks to tap human memory processes has flourished in the last few years, in particular in the service of functional neuroimaging studies. With respect to configural tasks, such as transverse patterning, recent reports have confirmed hippocampal activation while control subjects perform the tasks (Hanlon et al., 2003; Astur and Constable, 2004) and impaired performance in schizophrenic patients who also showed abnormal hippocampal activity while performing the task (Hanlon et al., 2005). By contrast, these same patients were unimpaired and showed normal hippocampal activation when performing the uniquely human version of this task (i.e., the children's Rock-Paper-Scissors hand game). This game, however, can be solved verbally as well as on the basis of the inherent properties of the stimuli (e.g., Rock crushes, Paper wraps, Scissors cut), which can be compared at the time of presentation without further reference to the other discriminations. Thus, it provides an interesting control mechanism for studies of transverse patterning in humans. Importantly, these same patients were also unimpaired in elemental discriminations or a feature-neutral task that have also been shown in animals not to depend upon an intact hippocampus (Gallagher and Holland, 1992; Alvarado and Rudy, 1995a,b). Activation in the temporal cortical areas, though present, did not differ between controls and patients.

Several behavioral studies of human amnesic patients also reported deficits on transverse patterning. Rickard and Grafman (1998) compared performance of four patients with ischemic, anoxic, or hypoglycemic (insulin overdose)-related amnesia on transverse patterning and elemental discriminations. Similar to animal results, these patients performed like controls on elemental discriminations and two problems of transverse patterning. Only when all three problems were trained and a configural solution was required did their performance drop. This report contrasts somewhat with another by Reed and Squire (1999) who not only found impaired performance on transverse patterning in human amnesic patients, but also reported that these patients were impaired on six-pair elemental, concurrent discriminations as well, which suggested that amnesic patients had a more general deficit in solving multiple discrimination problems, of which transverse patterning was a particularly difficult example. However, as suggested by Rickard et al. (2006), when comparing performance *per problem*, those patients required the same number of trials to criterion whether solving three or six elemental discriminations, but required twice as many to perform the transverse patterning problem (Rickard et al., 2006). This hypothesis was confirmed with additional amnesic subjects; however, because their damage was not quantified, it remains to be answered whether damage to the hippocampus or temporal cortical areas played a greater role in the observed impairments. One indication of specific hippocampal involvement is provided by Driscoll and colleagues (2003), who showed that aged human subjects who were impaired on transverse patterning (but not elemental discriminations) showed correspondingly reduced hippocampal volumes (Driscoll et al., 2003).

In a study that supports both the relational and conjunctive accounts, Davachi and Wagner (2002) asked human subjects to memorize triplets for which, at the time of encoding, they were required to either simply repeat, or process elaborately by mentally ordering them along the lines of subjective desirability. This elaborate processing was thought to encourage encoding of the relationships between items, or the conjunction of the members as a unique triplet. Not surprisingly, elaborate processing improved memory of the triplets over simple repetition. Furthermore, elaborate processing was associated with greater hippocampal activity (which also correlated with memory), whereas item-based processing increased activity in the entorhinal and parahippocampal cortices (Davachi and Wagner, 2002).

Human studies of transitivity have also suggested a role for the hippocampus in relational learning tasks. Performance of relational memory tasks is associated with changes in hippocampal activation in humans (Heckers et al., 2004; Preston et al., 2004; Titone et al., 2004), and in the anterior hippocampus in particular for humans performing the transitive inference task (Heckers et al., 2004; Preston et al., 2004). By contrast, spatial relational memory in humans activates posterior hippocampus (e.g., Pihlajamaki et al., 2004), and studies in primates have suggested that damage to the posterior hippocampus was particularly correlated with impairment on transverse patterning (Alvarado and Bachevalier, 2005b). It is possible that these discrepancies reflect differences in task demands, encoding versus retrieval

effects, or even enhanced anterior signals in the human studies as a result of novelty detection for the new pairs during the test phase in humans.

3.09.6 Spatial Memory

The initial research into the role of the hippocampus in spatial memory was conducted for the most part in rodents. In the years following the first description of H. M.'s amnesia, work in the rodent fared little better than that in the monkey with respect to finding a link between the hippocampus and memory. The discovery of hippocampal place cells by O'Keefe and Dostrovsky (1976) firmly linked the hippocampus with spatial mapping. In 1978, O'Keefe and Nadel published their landmark work that laid the foundation for studies of the hippocampus in spatial memory. In their book (O'Keefe and Nadel, 1978) they suggested that the unique contribution of hippocampus to memory was the formation and storage of cognitive maps (*See* Chapter 1.04). In the following decades, lesion and electrophysiological studies have clearly shown the key role played by the hippocampus in place learning. Indeed, the litmus test for functional damage to the hippocampal formation has been whether or not spatial memory is impaired. Damage to the hippocampus proper, in the absence of extrahippocampal damage, impairs performance on a variety of spatial tasks, be they contextual, navigational, or locational, although disconnection of the hippocampus from its diencephalic targets via fornix transection has given less clear results.

3.09.6.1 Radial Arm Maze

Originally developed by Olton and Samuelson (1976), the radial arm maze was a departure from previous maze tasks, as it was designed to test whether the hippocampus was required for working memory, which in this case refers to memory of information that changes, or is updated from trial to trial, as opposed to reference memory, which refers to information that is consistent over trials. In this case, the information was whether the rat had recently foraged for food in a specific location. This task differed from most maze tasks, which were more concerned with some aspect of navigation. While the radial arm maze does require animals to discriminate locations, the routes are predefined. In its original form, eight arms projected out radially from a central location. For each trial, a food reward was placed at the end of each arm; then the rats were placed onto the central platform of the maze and allowed to enter the different arms repeatedly until all the food was retrieved. Thus, rats had to learn not to reenter arms already visited on a given trial to achieve the optimum foraging strategy. A reentry counts as an error. This version of the task contrasted with a reference memory version in which four of the arms were consistently baited. In this version, both working and reference memory errors are possible, in the first case by reentering an arm that was already visited on that trial, and in the case of reference memory, by entering a never-baited arm (Olton et al., 1979). The addition of a delay imposed after a certain number of choices permits the assessment of retrograde and anterograde working memory as the remaining choices are completed. Reentry of an arm visited prior to the delay constitutes a retrograde error, whereas repeatedly entering an arm not visited prior to the delay constitutes an anterograde error (Olton, 1983).

Rats with lesions to the hippocampal formation are quite impaired on the spatial working memory variants of the task (Olton et al., 1979; Olton and Papas, 1979; Olton, 1983) and somewhat on the spatial reference memory version (Jarrard, 1983). Pretraining prior to receiving hippocampal lesions selectively disrupts working memory, but not reference memory. If a delay is imposed, more retrograde working memory errors than anterograde working memory errors will be generated (Olton et al., 1979; Olton, 1983).

3.09.6.2 Morris Water Maze

In contrast to the radial maze, which measures working memory for location, the swim task developed by Morris (1981) is generally a reference memory task (though one can test working memory) that tests spatial navigation based on extramaze cues. In this task, the rat swims in a large round tank full of opaque water. Submerged somewhere in the tank is a platform onto which the rat can climb to escape from the water. On each trial, the rat is randomly released into the water at one of four cardinal starting points. The rat then swims until it locates the platform, or is guided to it by the experimenter if it fails to find it. To solve this task, the rat must form a spatial representation of the cues in the room, and the position of the invisible platform in relationship to those cues, and on each trial find the quickest trajectory to navigate to the platform. Normal rats learn this task quickly, learning to navigate to the platform in a few seconds and taking fairly accurate direct headings in order to get there. The final performance test entails the removal of the

platform and the release of the rat from a novel starting position. Normal rats quickly orient then take a heading toward the platform location. Upon reaching the spot, they concentrate their search over where the platform had been. Hippocampal damage produces a severe impairment in rats' ability to locate the hidden platform (Morris et al., 1982). For these operated animals, the swim path may be concentrated toward the side of the maze that contained the platform, but with a less concentrated search pattern and fewer platform location crossings, or adopting a strategy, i.e., swimming at a certain distance from the wall, which will eventually bring them in contact with the platform. On the probe trials, these operated rats circle the tank many times, crossing all potential platform locations.

3.09.6.3 Spatial Tasks in Monkeys

Unlike the various spatial navigation studies conducted in rodents, spatial memory in monkeys has more frequently used the DNMS paradigm to test for nonmatching to location on the test tray, or to test for recognition of a previously seen item in the location where it was previously viewed (object-in-place). The results of these studies have been equivocal, with some reporting impairment after hippocampal damage on place recognition (Angeli et al, 1993; Málková et al., 1995; Beason-Held et al., 1999; Alvarado and Bachevalier, 2005b), object-in-place/scene (Parkinson et al., 1988; Doré et al., 1998), or spatial scene learning (Murray et al., 1998), whereas others have found spared performance on place or object-in-place memory (Murray and Mishkin, 1998; Málková and Mishkin, 2003) and have suggested that the temporal cortical areas may be equally or more important in monkey spatial learning (Murray et al., 1998; Málková and Mishkin, 2003; Alvarado and Bachevalier, 2005a). One large difference between these nonhuman primate studies and the rodent studies discussed earlier is the lack of movement through space to reach a goal and the potential for the use of egocentric information to solve the tasks.

Recently, however, several foraging studies have been published in which freely moving monkeys forage for food in large enclosures akin to the radial or Morris mazes. For example, Hampton and colleagues (2004) trained monkeys on a match-to-location task that took place in an open room containing three visually identical foraging containers placed in three different locations. Although hippocampal monkeys were impaired on a match-to-location task as compared to controls, both groups of monkeys were impaired when they reentered the room from the opposite side, suggesting that neither group was consistently using allocentric cues to locate the correct site, nor were cues in the room manipulated to assess which ones were controlling behavior (Hampton et al., 2004). By contrast, Lavenex et al. (2006) used a large hexagonal foraging board placed in an open room that contained 18 foraging sites (**Figure 8**). Identical local cues (colored cups) distinguished sets of foraging sites that were either potentially baited or never baited. The tendency to use egocentric strategies was controlled by using four different entry points to the foraging array. Controls and monkeys with hippocampal damage were able to forage correctly based on local cues. In addition, control monkeys also demonstrated the ability to use spatial relations to solve the task when the local cues were removed, but hippocampal-damaged animals were impaired in this condition. Thus, consistent with studies in rodents, the primate hippocampus is required for the allocentric use of environmental cues.

3.09.6.4 Performance of Human Amnesics on Animal Tests of Spatial Memory

Consistent with reports in rats, and now monkeys, reports of human amnesic patients have indicated impaired recent or anterograde spatial memory, although remote spatial memory may be preserved. For example, H. M. never learned the location of his home at the time of his surgery, although he could navigate to his previous home (Milner, 1966) and could draw a map of the layout of his present home (Corkin, 2002). Similarly, patient E. P., with extensive MTL damage due to herpes encephalitis (Teng and Squire, 1999), and K. C., with MTL damage in addition to widespread damage due to closed-head injury (Rosenbaum et al., 2000), both demonstrated remote, but not recent, topographic knowledge of neighborhoods lived in prior to the onset of amnesia. By contrast, neither demonstrated acquisition of new spatial knowledge. Similarly, Astur and colleagues (2002) trained patients with unilateral temporal lobe resection in a virtual reality version of the Morris water maze. Regardless of the side of resection, and in a manner similar to that reported in rodent studies, these patients showed longer latencies to locate the platform and failed to prefer the platform quadrant on probe trials (Astur et al, 2002). These results contrast with those reported by Bohbot and colleagues

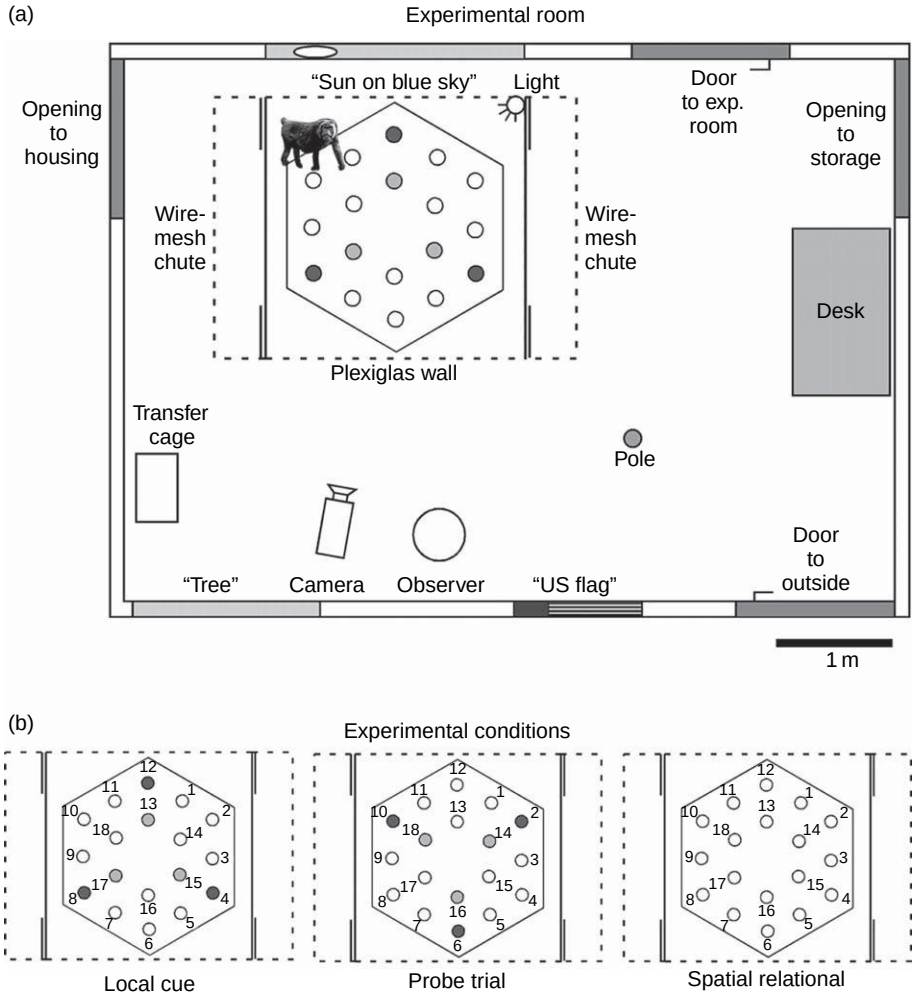

Figure 8 Open field spatial foraging task for monkeys. (a) Animals foraged under plastic cups for food in several of 18 possibly baited locations. (b) Food could be indicated by local cues (red or blue cup color) or by distal cues alone (all beige cups). Reproduced from Lavenex PB, Amaral DG, and Lavenex P (2006) Hippocampal lesion prevents spatial relational learning in adult macaque monkeys. *J. Neurosci.* 26(17): 4546–4558, with permission from the Society for Neuroscience.

(1998), who showed spared performance in patients given one-trial learning to locate a hidden sensor in the floor of a large room, but impaired performance when required to relocate the sensor after 30 min (Bohbot et al., 1998, 2002). Procedural differences among the studies may clarify the differences, but in general, the results from the task closest to the rodent version of the Morris maze were quite similar in rats and humans. Finally, a case of developmental amnesia with restricted damage to the hippocampal formation associated with impaired episodic, but some spared semantic, memory also demonstrated impairment in recognizing object locations when tested from a viewpoint different from that used during training (King et al., 2002).

3.09.7 Episodic Memory

The deficit in autobiographical, or episodic, memory has been a hallmark of human amnesia and a point of contention between human and animal researchers. As defined by Tulving (1983), a requirement of episodic memory is that it be available to conscious recollection, which makes it difficult to assess in nonverbal species. However, Tulving also suggested that episodes can be distinguished by the storage of temporal and spatial relations between events. Using this definition, Clayton and Dickinson (1998) suggested that animals do demonstrate episodic-like memory by encoding 'what,' 'when,' and 'where' specific experiences occur. Thus, scrub-jays do indeed

express knowledge of what, when, and where with respect to food caching (*See* Chapter 1.23). Episodic-like memory has also been reported in rats (Clayton and Griffiths, 2002; Bird et al, 2003; Eacott et al., 2005; Babb and Crystal, 2006) and apes (Schwartz and Evans, 2001), and monkeys have demonstrated 'what' and 'where' knowledge (but not 'when') within the same paradigm (Hampton et al., 2005). Although no studies have assessed the effects of hippocampal lesions of these episodic-like memory tasks, to the degree that they have a spatial or contextual component, damage to the hippocampus would be predicted to have an effect. However, other evidence of how the hippocampus might contribute to episodic-like memory comes from electrophysiological studies which have shown differential firing patterns of hippocampal place cells depending upon context (see Smith and Mizumori, 2006, for review) or differentiating where the animal has been and where it has to go next (Frank et al., 2000; Wood et al., 2000; Ferbinteanu and Shapiro, 2003) or differentiating sequences of actions (see de Hoz and Wood, 2006, for review), and these correlates of behavior may provide better insight into the workings of episodic-like memory than lesion studies (*See* Chapter 1.21).

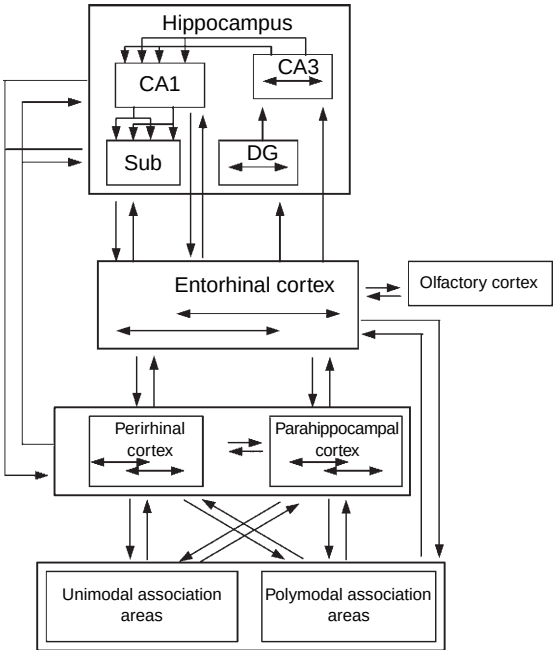

Figure 9 Suggested hierarchical organization of medial temporal lobe structures contributing to memory functions. CA, hippocampal cell field; DG, dentate gyrus; Sub, subiculum. Adapted from Lavenex P and Amaral DG (2000) Hippocampal-neocortical interaction: A hierarchy of associativity. *Hippocampus* 10(4): 420–430, with permission from Wiley-Liss.

3.09.8 What We Have Learned from Animal Models

A particularly important contribution of the animal modeling research is a richer appreciation of how the MTL structures contribute individually to memory. Anatomical and physiological evidence from animal studies certainly suggests that there is a hierarchy of function within the MTL, with increasing convergence of information as one proceeds from the neocortex toward the hippocampus (**Figure 9**; e.g., Mishkin et al., 1998; Lavenex and Amaral, 2000; *See* Chapter 3.03). Thus, projections from association cortex to the perirhinal and parahippocampal cortices are a first level of integration; projections from these areas to the entorhinal cortex are a second level of integration, and finally projections to the hippocampus from all three areas provide a final level of integration (Lavenex and Amaral, 2000). However, as reviewed, the animal models also suggest that those individual MTL structures likely contribute to normal behavioral processes in addition to simply passing sensory information to the hippocampal formation. Indeed, not only have the animal models suggested that the cortical areas are functionally heterogeneous, but there is increasing evidence to suggest that the hippocampus may also demonstrate a degree of heterogeneity.

Anatomically, connections between the hippocampus and its afferents suggest that visuospatial information projects primarily to the dorsal hippocampus in rats and the posterior hippocampus in monkeys, whereas visual information about object identity reaches the ventral or anterior hippocampus, respectively (e.g., Witter et al., 2000; Burwell et al., 2002; Lavenex et al., 2006). Thus, damage to the hippocampal formation may have different consequences for memory function depending upon where the damage occurs. For example, rats with lesions of the dorsal hippocampus were impaired in spatial learning as measured by the Morris water maze task (Duva et al., 1997), the radial arm maze (Ferbinteanu and McDonald, 2001; Lee and Kesner, 2003; Pothuizen et al., 2004), or T-maze (Hock and Bunsey, 1998). By contrast, rats with ventral lesions, with the dorsal half intact, were able to successfully learn the water maze task (Moser et al., 1993, 1995; Moser and Moser, 1998), suggesting that spatial information processing takes place predominantly in the dorsal hippocampus.

Similar findings have been reported in primates, although the distinction in the primate is between anterior and posterior hippocampus (Witter et al., 1989; van Groen and Wyss, 1990; Witter, 1993). For example, Jackson (1984) showed that damage to the middle hippocampus, but not the anterior or posterior hippocampus, impaired acquisition of matching-to-sample. One study recorded differential patterns of activity in the hippocampus of monkeys performing either a spatial or a nonspatial delayed matching-to-sample task and revealed greater spatial delay-dependent activity in cells within the posterior than the anterior hippocampus, whereas nonspatial delay-dependent activity was found along the entire length of the hippocampus (Colombo et al., 1998). Although not specifically discussed in this context, recent findings by Rolls et al. show a gradient from anterior to posterior of object, place, and object-place cells recorded from the hippocampus of awake macaques (Rolls et al., 2005).

Some research in humans also supports a heterogeneous view of temporal lobe function. For example, damage to the right temporal lobe in patients is associated with deficits in detecting changes in the spatial location of objects (Smith and Milner, 1981, 1989; Pigott and Milner, 1993), in maze learning (Milner, 1965), and in spatial memory (Abrahams et al., 1997), whereas those with left temporal lobe damage were not. Functional MRI studies have shown that activation in the hippocampus and posterior parahippocampal cortex versus perirhinal cortex during encoding differentially predicts successful source or item recognition, respectively (Davachi et al., 2003). Similarly, encoding activity in these same regions predicts recollection (hippocampus and posterior parahippocampal gyrus) or familiarity (rhinal cortex) in humans (Ranganath et al., 2004). Activation of the right hippocampus was shown to occur when control subjects used spatial landmarks to navigate within a virtual environment during early training (Iarai et al., 2003). Human amnesic patients with predominantly hippocampal or medial temporal cortical damage were differentially impaired on tasks adapted from the nonhuman primate literature such that hippocampal damage was associated with impairments on scenes (Graham et al., 2006; Lee et al., 2006), but spared performance on object memory and feature ambiguity (Barense et al., 2005), whereas damage to the cortical areas was associated with deficits in object memory or perception (Lee et al., 2006; Barense et al., 2005, respectively).

With respect to the anterior/posterior distinction in hippocampal functions, the posterior hippocampus appears to be more involved in spatial/episodic memory processing than the anterior hippocampus in humans (Hartley et al., 2003; Pihlajämaki et al., 2004; Ranganath et al., 2004). Furthermore, the distinction between the left and right hippocampus in spatial memory processing has received additional support from case studies in humans. Finally, human imaging studies have suggested an anterior/posterior distinction with respect to encoding versus retrieval processes in hippocampus (Lepage et al., 1998; Schacter and Wagner, 1999).

There is also evidence of behaviorally relevant circuits between hippocampal subfields and cortex. For example, Kesner and colleagues found a double dissociation between the dentate gyrus and CA1 with respect to spatial or temporal pattern separation (Gilbert et al., 2001), and between perforant path and dentate gyrus inputs to CA3 on retrieval versus encoding of spatial memory (Lee and Kesner, 2004). Finally, evidence for the functionality of the direct Erh-to-CA1 pathway was provided by a 2-deoxyglucose analysis of hippocampal activity while adult monkeys were performing a DNMS task (Sybirska et al. 2000). Performance of this task activates CA1, subiculum, and entorhinal cortex, but not dentate gyrus or CA3.

3.09.9 Summary

We began by highlighting the key deficits in human amnesia and then by describing some of the behavioral tasks being used to tap into these memory deficits. In spite of initial difficulties that delayed the development of animal models, the choice of appropriate tasks provided the means to assess memory processes in animals similar to those impaired in human amnesic patients. However, the animal literature quickly diverged from modeling human amnesia to modeling the function of the individual brain structures, whose collective damage were the putative cause of human amnesia. Consequently, each particular animal paradigm only models a subset of the observed impairments in human amnesic patients (e.g., spatial, relational, recognition, encoding, retrieval, etc.). Nevertheless, given the increasing reports of patients with more selective memory deficits and lesions (e.g., Baddeley et al., 2001; Aggleton et al., 2005; Barbeau et al., 2005), almost as restricted as those used in animals, the fields of animal and human memory have now begun to draw from each other in ways that promise to advance our understanding of human amnesia. Testing human amnesic patients using the animal paradigms has

strengthened the validity of several models and will further our understanding of how the brain contributes to normal memory, and of how memory-impaired animal and human subjects express that impairment. By mapping out the contributions of individual brain regions to learning and memory, we may produce even better assays of the milder impairment seen in these patients. Lastly, the use of functional imaging in humans will illuminate which areas of the brain are working together to solve a given task, and thus point the way for new studies in animals using either electrophysiological measures or imaging to further our understanding of memory processes at the systems level (i.e., the entire network of structures that support memory processes) as well as at the level of individual structures.

Acknowledgments

Preparation of this chapter was supported in part by grants from the National Institute of Mental Health, MH58846, the Yerkes Base Grant NIH RR00165, and the CBN grant NSF IBN-9876754.

3.10 Perirhinal Cortex: Neural Representations

M. W. Brown and M. Eldridge, University of Bristol, Bristol, UK

3.10.1 Introduction

3.10.1.1 Scope of Chapter

Perirhinal cortex is importantly involved in a number of different memory functions. For elements of recognition memory, paired associate learning, and reward sequence learning, there is evidence of the direct involvement of perirhinal neurons in the learning process per se. However, perirhinal cortex also has perceptual functions, and through these functions, it can also be indirectly involved in other learning processes.

This chapter primarily concerns what is known of neural representations in perirhinal cortex and how these may relate to its roles in learning and memory. After some background anatomical information, a summary is given of the results of ablation experiments that indicate the functions of perirhinal cortex. These functions include roles in perception, particularly for object-related information, and in memory, notably but not exclusively, recognition memory and paired associate learning. A brief overview of recent attempts to find synaptic plastic substrates for the memory functions of perirhinal cortex is also included. The chapter does not include the results of human brain imaging except by passing mention where of particular pertinence.

3.10.1.2 Location of Perirhinal Cortex

In the last 20 years, perirhinal cortex (**Figure 1**) has received increasing scientific attention because of its important roles in perception and learning. Perirhinal cortex is located in the anterior and medial portion of the inferior aspect of the medial temporal lobe of primates. While in the past there has been considerable variation in the definition of the

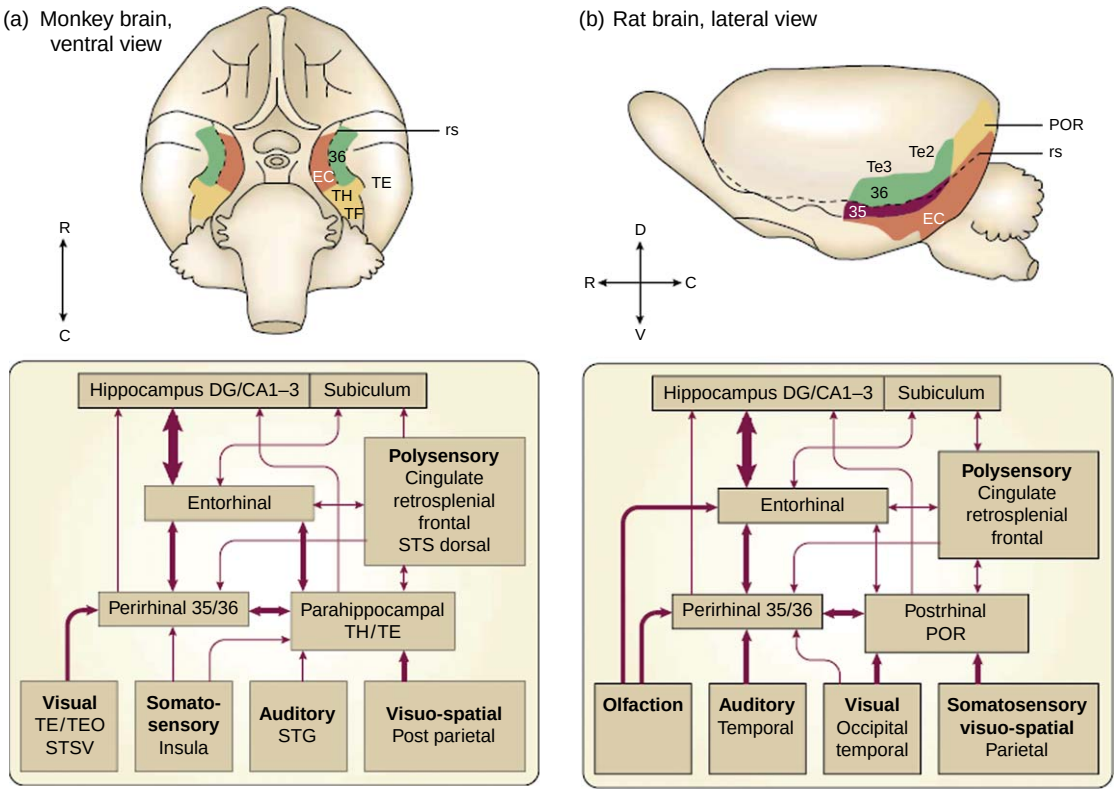

Figure 1 Position and some major connections of the perirhinal and neighboring cortices in the monkey (a) and rat (b). Routes are shown by which sensory information may reach perirhinal cortex and the connections from perirhinal cortex to the hippocampus, again in the monkey and the rat. The arrow thickness indicates the relative size of the projections. Perirhinal cortex: areas 35 and 36; dentate gyrus, DG; entorhinal cortex, EC; postrhinal cortex, POR; parahippocampal cortex, TH and TH; rhinal sulcus, rs; superior temporal gyrus, STG; superior temporal sulcus, STS; subicular complex, SUBIC; visual association cortex, TE and Te2. Reproduced with permission from Brown MW and Aggleton JP (2001) Recognition memory: what are the roles of the perirhinal cortex and hippocampus? *Nat. Rev. Neurosci.* 2: 51–61. As adapted from Witter MP, Groenewegen HJ, Lopes da Silva FH, and Lohman AHM (1989) Functional organization of the extrinsic and intrinsic circuitry of the parahippocampal region *Progr. Neurobiol.* 33: 161–253.

boundaries of perirhinal cortex (Suzuki and Amaral, 2003), there is now broad agreement that in the monkey it extends immediately lateral to the full extent of the rhinal sulcus and includes cortex corresponding to both areas 35 and 36 of Brodmann. In the rat, perirhinal cortex (areas 35 and 36) is located on either side of the caudal part of the rhinal sulcus. The precise extent of the corresponding region in the human brain remains uncertain.

3.10.1.3 Overview of Connections

Perirhinal cortex is highly interconnected with many other brain regions (for reviews, see Suzuki and Amaral, 1994; Burwell et al., 1995; Suzuki, 1996; Witter et al., 2000). It receives highly processed sensory information of all modalities and provides an important route for transferring information to and from the hippocampus (**Figure 1**). Its position at the top of the sensory processing hierarchy and at the gateway to the limbic system means that it is ideally placed to play important roles in sensory perception and memory. Once a stimulus may be identified, it is appropriate to be able to process aspects of its past history and associations.

In the monkey, the most prominent input arises from inferior temporal cortex (unimodal visual areas TE and TEO), although it also receives input from auditory, olfactory, and somatosensory association areas of cortex. Further substantial inputs arise from polymodal association areas including prefrontal and cingulate cortex, entorhinal cortex (and thereby, indirectly from the hippocampus), parahippocampal cortex (areas TH and TF), and cortex of the dorsal bank of the superior temporal sulcus. Perirhinal outputs largely mirror its inputs, with

strong connections to entorhinal cortex (again, therefore, indirectly connecting to the hippocampus), the parahippocampal gyrus, prefrontal cortex, and unimodal and polymodal sensory association areas. Perirhinal cortex also has reciprocal connections with the amygdala and thalamus (mediodorsal and midline nuclei) and sends outputs to the tail of the caudate nucleus and ventral putamen. It additionally receives input from brainstem monaminergic cell groups and cholinergic input from the basal forebrain. A parallel, similarly widespread pattern of connectivity is found in the rat.

Perirhinal cortex is juxtallocortex, cortex of a type that is transitional between the neocortex and the archicortex and paleocortex of the hippocampal and entorhinal regions. Unlike neocortex, area 35 lacks an inner granular layer (layer 4), and this layer is very narrow in area 36. Again, in contrast to neocortex, perirhinal cortex does not have an obviously columnar organization.

3.10.1.4 Overview of Functions

There is a very large body of evidence indicating that perirhinal cortex plays a central role in certain aspects of recognition memory. The evidence is most clear for familiarity discrimination for single items (Brown and Xiang, 1998; Brown and Aggleton, 2001). There is also much evidence of a role in perceptual functions (Buckley and Gaffan, 2006), though this role is not universally accepted (Squire et al., 2004; Hampton, 2005). Additionally, perirhinal cortex is involved in other types of memory linked to learned associations made with items (notably including reinforcement learning and paired associate learning). More detailed discussions of the findings of ablation studies may be found in several reviews (Murray and Bussey, 1999; Brown and Aggleton, 2001; Murray and Richmond, 2001; Murray and Wise, 2004; Squire et al., 2004; Eacott and Gaffan, 2005).

Overall, ablation studies provide strong evidence for a role for perirhinal cortex in object identification (Buckley and Gaffan, 2006), though some findings have challenged this role (Squire et al., 2004; Hampton, 2005). Monkeys with perirhinal lesions have been shown to be impaired in a series of tasks designed to test object identification. Thus there is impairment in perceptual oddity tasks in which the odd one of a set of images must be chosen, tasks requiring object identification from different views or partial views of the same object (Buckley et al., 2001; Buckley and Gaffan, 2006), and tasks in which an object only previously experienced by touch must be selected using vision (Goulet and Murray, 2001). Additionally, monkeys with perirhinal lesions are particularly impaired on tasks requiring discrimination between visual stimuli with a high level of feature ambiguity (Bussey et al., 2005). It has been argued that, where perceptual deficits have not been found, the tasks may have been solved using discrimination based on individual features rather than whole objects as entities in themselves. Where test has been made, the evidence indicates that it is possible to dissociate the mnemonic and perceptual functions of perirhinal cortex (Buckley and Gaffan, 1998b, 2006; Saksida et al., 2006).

The ability to recognize the novelty or familiarity of individual items is an important aspect of recognition memory. Such recognition memory relies not only on identification (perception) but also on judgment of prior occurrence (memory). The involvement of perirhinal cortex in the judgment of prior occurrence for individual items is widely agreed. Although in one view it forms part of a unified medial temporal lobe memory system (Squire et al., 2004), an alternative view is that its role is differentiable from that of the hippocampus (the hippocampus being concerned with recollective, complex associational and spatial aspects of recognition memory, while perirhinal cortex is concerned with single-item familiarity discrimination and simple associations) (*See* Chapters 2.23, 3.08; Brown and Aggleton, 2001). The pattern of impairments after perirhinal cortex lesions has been doubly dissociated from neighboring areas such as the middle temporal gyrus, which corresponds to the dorsal part of visual area TE, the hippocampus, and the amygdala. Thus, whereas lesions of the middle temporal gyrus impair color discrimination but spare recognition memory, lesions of perirhinal cortex impair object recognition memory but not color discrimination (Buckley et al., 1997). Further, in both monkeys and rats, hippocampal or fornix lesions lead to marked impairment in spatial tasks with relatively mild or no effect upon recognition memory, whereas perirhinal cortex lesions result in a reversed pattern of deficits (Gaffan, 1994). Amygdala lesions impair food preference learning but not delayed matching to sample with infrequently repeated stimuli, whereas perirhinal lesions result in the opposite pattern of impairment (Gaffan, 1994). These double dissociations demonstrate that perirhinal cortex is necessary for visual recognition memory even when functionally isolated from structures to which it is connected both in the ventral visual processing stream and in

the medial temporal lobe. In addition to the above results for visual tasks, perirhinal lesions impair tactile recognition memory in monkeys (Goulet and Murray, 2001) and olfactory recognition memory in rats (Petrulis and Eichenbaum, 2003), though auditory recognition memory seems to be spared (Kowalska et al., 2001; Fritz et al., 2005).

Ablation studies also indicate that perirhinal cortex is necessary for making certain (though not all) associations involving objects (Murray and Bussey, 1999; Murray and Richmond, 2001). Such work has shown that perirhinal lesions impair tasks involving associations of objects with other objects (Murray et al., 1993; Higuchi and Miyashita, 1996; Buckley and Gaffan, 1998a), odors (Petrulis and Eichenbaum, 2003), tastes (Parker and Gaffan, 1998), and tactile information (Goulet and Murray, 2001). Such associations may also be abstract. Monkeys with perirhinal lesions are impaired in a task where they must respond to a sequence of discriminations to obtain reward; the results suggest a role of perirhinal cortex in forming associations between objects and position in a series, or proximity to reward in a sequence (Liu et al., 2000). Additionally, perirhinal lesions in rats produce impairments in conditioned avoidance tasks, notably contextual fear conditioning. The impairment relates to processing of the conditioned stimulus rather than the spatial context of the task (Corodimas and LeDoux, 1995).

3.10.2 Neural Responses Related to Judgment of Prior Occurrence

The responses of a subset of neurons in perirhinal and neighboring cortex signal information concerning the previous occurrence of infrequently encountered stimuli (Brown et al., 1987; Brown and Xiang, 1998). Most strikingly, responses of such neurons are strong for stimuli that have not been seen previously and weak once these stimuli appear again. Such responses will here be termed repetition sensitive and have characteristics necessary for making judgments of prior occurrence. They have been related to the recency and familiarity discrimination aspects of recognition memory. These response changes have also been called stimulus-specific adaptation (Ringo, 1996) and response suppression (Desimone, 1996); however, these phrases carry implications concerning the underlying mechanisms or functionality of the changes that cannot currently be justified. In particular, to date no evidence has been found that the response reductions (decrements) are dependent upon an active suppressive or inhibitory mechanism. Moreover, the term 'response suppression' is used in relation to attentional processes; the use of the same term for a different process involved in familiarity discrimination is inappropriate. It is important to note that as perirhinal neurons with repetition-sensitive responses typically respond only weakly to stimuli that have been presented multiple times, they are likely to form a different subset of perirhinal neurons to those whose responses are discussed in sections 3.10.3 and 3.10.4.

Most information on these responses comes from monkeys and visual stimulation. The information in sections 3.10.2.1, 3.10.2.2 and 3.10.2.3 is based on this information. Those sections are followed by comments concerning generalizations across modalities and species. The characteristics of these neuronal responses is presented here.

3.10.2.1 Response Characteristics

Up to 25% of perirhinal neurons have a reduced response to familiar compared with novel visual stimuli, representing about 60% of the visually responsive neurons (**Figure 2**) (Riches et al., 1991; Li et al., 1993; Miller et al., 1993; Sobotka and Ringo, 1993; Xiang and Brown, 1998). Thus, collectively, such perirhinal neurons give a strong signal on the occurrence of a novel stimulus but a weak signal when a stimulus is familiar. Note that such a response change divides perirhinal neurons into two classes: those that have repetition-sensitive responses signaling information concerning even a single prior occurrence of a stimulus, and the remainder, which do not. The overall tendency to response reduction on repetition is sufficiently large that it is readily seen in population measures of neuronal activity from this cortex. Except under specific circumstances (see section 3.10.2.2), response increases with stimulus repetition occur at a level below that expected by chance (Miller and Desimone, 1994; Brown and Xiang, 1998). Response reductions with repetition have been described for three-dimensional objects and two-dimensional pictures of objects, faces, patterns, and scenes. Repetition-sensitive responses also encode information concerning physical features of the stimuli, just as do responses that are not repetition sensitive. Thus, for example, some neurons respond only to novel faces and not novel objects, or only to novel stimuli of a certain color (Riches et al., 1991; Fahy et al., 1993). Similar response changes are found in

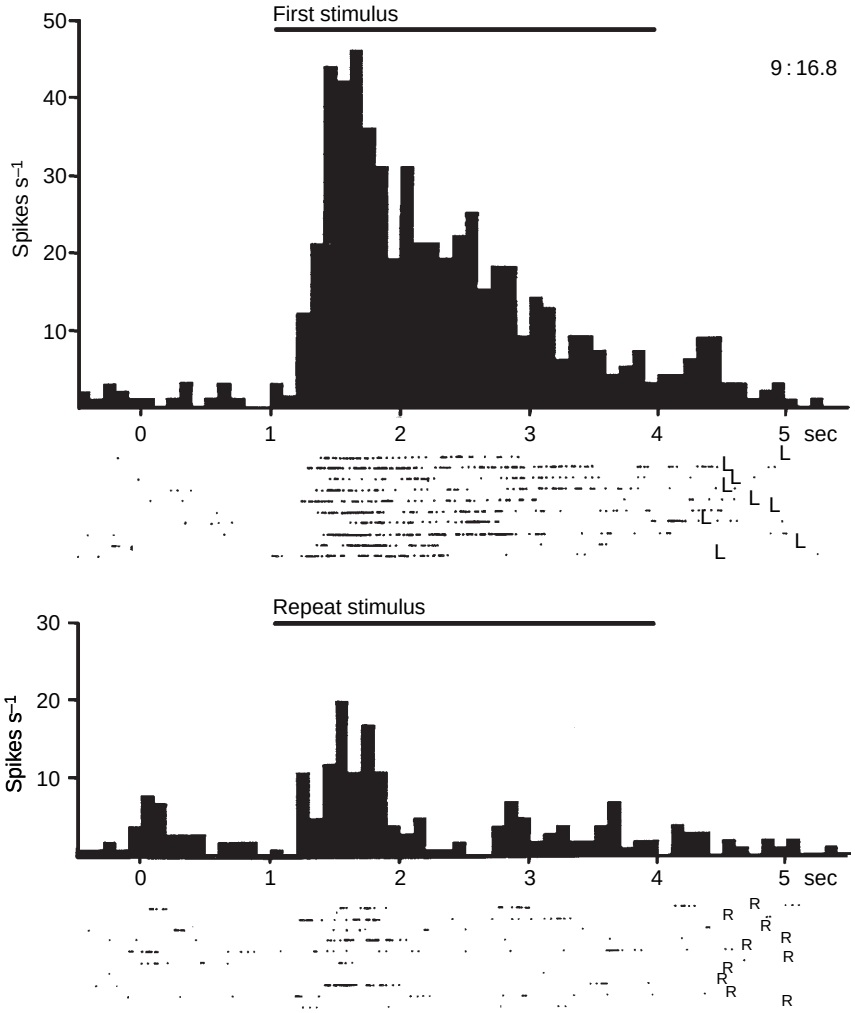

Figure 2 Example of repetition-sensitive monkey perirhinal neuronal response. Responses are stronger to first (upper peristimulus histogram and rasters) than repeat (lower peristimulus histogram and rasters) appearances of ten initially novel pictures. One stimulus was shown (bar above histogram) on each trial of a serial recognition memory task. To be rewarded, the monkey had to press left (L) for first and right (R) for repeat appearances of the stimulus. The first and repeat trials have been grouped in this display but were intermixed when presented. Controls (not shown) established that the difference in activity was not a result of the different behavioral responses. Note also that the neuron does not respond equally strongly to the first presentations of the ten different pictures; that is, its activity carries information about stimulus features as well as prior occurrence. Reproduced with permission from Brown MW (1990) Why does the cortex have a hippocampus? In: Gabriel M and Moore J (eds.) *Learning and Computational Neuroscience: Foundations of Adaptive Networks,* pp. 233–282. Cambridge, MA: MIT Press.

perirhinal cortex (areas 35 and 36), adjacent visual association cortex (anterior TE), and neighboring lateral entorhinal cortex (Brown and Xiang, 1998).

In experiments where both novel and highly familiar stimuli have been repeated, it has been possible to show that there is more than one pattern of response change on stimulus repetition (Fahy et al., 1993; Li et al., 1993; Zhu et al., 1995; Xiang and Brown, 1998). Under the conditions of the original experiments, these response types were termed 'novelty,' 'recency,' and 'familiarity' because that was the type of information signaled (Xiang and Brown, 1998). Novelty responses were strong to first presentations of novel stimuli and weak when these stimuli were repeated or already familiar stimuli were shown; the responses gave out a novelty signal. Recency responses were strong for novel stimuli and for highly familiar stimuli that had not been

seen for some time (e.g., 24 h) but weak when either type of stimulus had been seen recently; accordingly, such response changes contained information about the recency of presentation of stimuli. In contrast, familiarity responses were strong for novel stimuli even when they were seen for a second time after a brief interval (e.g., <5 min) but weak for highly familiar stimuli even if they had not been seen for a long time (e.g., 24 h): accordingly, such response changes contained information about the relative familiarity of stimuli. Importantly, these different patterns of response change indicated that information about recency of occurrence could be encoded separably from that about relative familiarity (Fahy et al., 1993; Xiang and Brown, 1998). Collectively, perirhinal neurons signaled information about both familiarity and recency. Further study of the properties of the response changes indicated that the term 'familiarity response' was potentially misleading. A better description is that they are slow-change responses, because such responses are reduced when an initially novel stimulus is shown for a second time if the interval between its presentations is sufficiently long (e.g., >10 min) (Xiang and Brown, 1998). They are not reduced if the interval is brief, and multiple repetitions of a stimulus in a short time do not result in reduction of the response. In contrast, the novelty and recency responses are reduced even when an initially novel stimulus is repeated after an interval of <1 s; correspondingly, such responses are fast change (**Figure 3**). This new designation does not alter the fact that more than one type of information is being signaled and that there must be more than one type of underlying synaptic change (see also section 3.10.5).

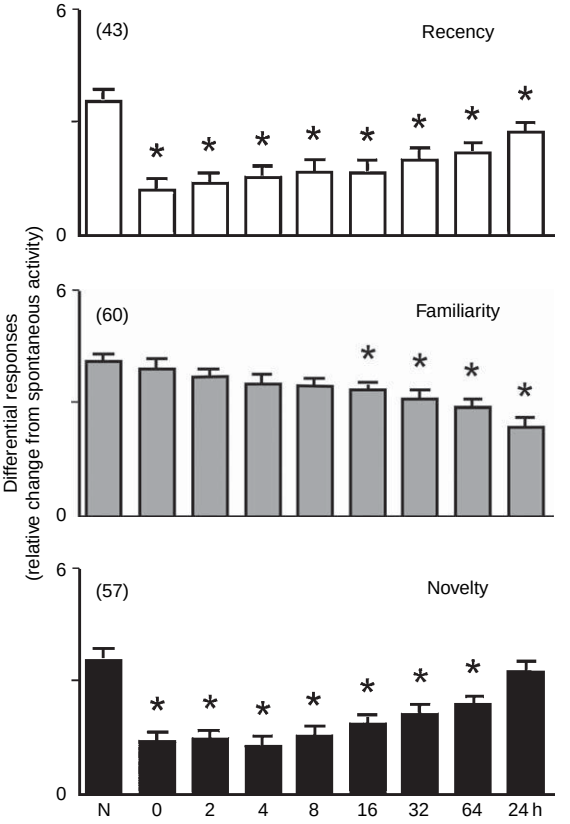

Figure 3 Population neuronal memory spans. Mean population responses (averaged within neurons and then across neurons) are shown for first presentations (N) and second presentations after different intervals (numbers of intervening trials in a serial recognition memory task or 24 h) for recency, familiarity, and novelty neurons in monkey anterior inferior temporal cortex. For these intervals, memory across the population increased with time elapsed for familiarity neurons but decreased for novelty and recency neurons. The decrement developed rapidly (<10 s) for recency and novelty neurons but took more than about 5 min to become significant for the population of familiarity neurons. $*p < .05$, difference in mean response to second presentations compared with first presentations. Reproduced with permission and adapted from Xiang JZ and Brown MW (1998) Differential neuronal encoding of novelty, familiarity, and recency in regions of the anterior temporal lobe. *Neuropharmacology* 37: 657–676.

3.10.2.2 Evidence of Relationship to Recognition Memory

The findings of a large number of ablation studies in both rats and monkeys are in agreement that lesions involving perirhinal cortex cause major impairment of recognition memory tasks that can be solved using familiarity discrimination for single items (see, for reviews, Murray and Bussey, 1999; Brown and Aggleton, 2001; Squire et al., 2004; Eacott and Gaffan, 2005). Perirhinal cortex is thus necessary for the solution of such tasks. Repetition-sensitive perirhinal responses provide sufficient information to solve such tasks (Brown and Xiang, 1998). *First,* they signal the information concerning stimulus novelty or familiarity and recency of occurrence. *Second,* the responses are changed by a single occurrence of a new stimulus. They therefore evidence single-exposure learning, as does animal and human recognition memory. *Third,* the system appears to have a very large capacity. Even after a monkey has been shown many hundreds of stimuli, the neurons still respond on the basis of whether or not an individual stimulus has been seen before. The responses are in this way

highly stimulus selective. This property also has an important corollary, namely, that the neurons do not respond weakly to a repeated stimulus because of response fatigue; they will again respond strongly to a subsequent new stimulus. *Fourth,* the response changes show access to information held in long-term memory. In particular, the response to the second appearance of a stimulus is reduced even when many other stimuli have been seen and a long time has elapsed since the stimulus was first seen. For many such perirhinal neurons (~70%, compared with ~45% in anterior TE), responses are reduced even when a stimulus has not been seen for 24 h (**Figure 3**). Neuronal memory spans (the length of time over which reduced responses are still found) of a few days have also been reported, but longer delays have not been tested. These properties establish that the underlying mechanism differs from that of simple habituation produced by a monotonously repeated stimulus. Moreover, the change is not a simple analogue of adaptation to prolonged sensory stimulation. Although the fast change responses might be related to priming mechanisms, evidence from human lesion and psychological studies makes this unlikely (*See* Chapters 2.23, 3.12; Brown and Xiang, 1998). Slow change responses do not have the characteristics necessary to explain priming. It should be noted that for many neurons, response reductions fade with the passage of time and that this provides information within the network concerning how recently a stimulus was presented. In addition, response reductions with stimulus repetition are found both when stimuli are presented within a recognition memory task, so that the animal must use their relative familiarity to gain reward, and when they are presented without the animal being trained in familiarity discrimination. The response changes are therefore automatic and endogenous and are not solely induced by training.

Three other types of perirhinal neuronal response change may also be observed during delayed matching to sample tasks in which judgments about the prior occurrence of a target stimulus have to be made in a choice phase following a delay. These other response changes are discussed in section 3.10.4. They signal information of importance to the solution of particular types of delayed matching to sample tasks but do not have the properties necessary to explain the behavioral features of general familiarity discrimination for infrequently repeated individual visual stimuli (Brown and Xiang, 1998; Brown and Aggleton, 2001). First, when only one stimulus need be held in mind at a time and a decision related to its prior occurrence made within a short period (seconds rather than many minutes), increased firing (delay activity) is found between the initial stimulus presentation and the subsequent presentation of the choice (match or nonmatch) stimulus (Fuster and Jervey, 1981; Miyashita and Chang, 1988; Riches et al., 1991; Miller et al., 1993). Such delay activity is not observed when more than one stimulus must be held in mind and the interval before the decision is long (Xiang and Brown, 1998), so that delay activity cannot provide the substrate for general familiarity discrimination. Second, if a monkey is trained to distinguish between a repeated unrewarded and a repeated rewarded stimulus, some perirhinal neurons show an increase in response to the repeated rewarded stimulus (Miller and Desimone, 1994); however, such increases have only been found when there is only a single repeated target stimulus and after training on the specific task. Thus, again, the mechanism appears to be specific to a particular type of task. Third, in delayed matching tasks using frequently repeating stimuli, many perirhinal neurons respond differently to the choice stimulus on match and nonmatch trials. However, it has been shown for many neurons (notably those outside perirhinal cortex in, e.g., the hippocampus) that these match/nonmatch differences are the same for novel as for familiar stimuli (Riches et al., 1991); hence, such differences do not signal the novelty or familiarity of a stimulus. Match/nonmatch differences therefore cannot provide a substrate for general familiarity discrimination, though they may provide information important to judging recency of occurrence of the stimulus.

One other aspect of perirhinal neuronal activity must also play an important role in familiarity discrimination: the correlated firing of action potentials of neurons within local and distal networks. There is still relatively little known about such interactions or the makeup of such networks in perirhinal cortex. Nevertheless, it has been established that, when the activity of synchronously recorded pairs of perirhinal neurons is studied, the firing of one neuron is quite commonly correlated with that of the other (Brown and Xiang, 1998; Erickson et al., 2000). So far, the evidence from such pairs indicates that synchronized firing, when the two neurons fire at approximately the same time, carries less information about the relative familiarity of stimuli than does the firing rate of the neurons.

3.10.2.3 Evidence for the Local Generation of the Response Changes

Neuronal response changes with the repetition of infrequently repeated stimuli are found in other areas than perirhinal and its neighboring cortex. For example, such changes are found in parts of prefrontal cortex and the striatum, and a small number (~1%) are found in the hippocampus (Brown and Xiang, 1998). (Note that neuronal response changes with frequently repeating stimuli are found in even more regions, including the many that demonstrate habituation.) Nevertheless, there is good evidence that response changes with the necessary properties to underlie the familiarity discrimination component of visual recognition memory are initially generated in perirhinal cortex, though possibly also in neighboring anterior inferior temporal cortex.

More posteriorly, and earlier in the visual processing pathway, repetition-sensitive response changes have memory spans that last at most for only a minute or so and are disrupted by one or two intervening stimuli. Such changes cannot explain those found in perirhinal cortex (Brown and Xiang, 1998). Therefore, perirhinal response changes are not merely passive reflections of responses earlier in the visual pathway. There is also evidence that the changes are not passive reflections of those occurring in subsequent processing areas. This evidence comes from the very fast latencies of the response changes found in monkey perirhinal cortex and neighboring area TE. In the fastest cases, the change between the response to a novel and that to a familiar stimulus occurs within milliseconds (measurements are accurate to only 10–20 ms) of the response to the visual stimulus itself (70–80 ms) (Miller et al., 1993; Xiang and Brown, 1998). Accordingly, there is no time for feedback from areas further on in the processing hierarchy. Indeed, where such latencies have been measured in the hippocampus, prefrontal cortex, and striatum, they are significantly longer than in perirhinal cortex (Brown and Xiang, 1998; Xiang and Brown, 2004). The conclusion is that at least the initial response change must be first generated in perirhinal cortex (and/or anterior TE) (Brown and Xiang, 1998). This conclusion receives support from experiments in which drugs have been infused locally into rat perirhinal cortex. Local infusions of different glutamate receptor antagonists block acquisition of longer- or shorter-term recognition memory, and no other brain region is able to substitute for perirhinal cortex for either type of delay period (see also section 3.10.5; Barker et al., 2006b).

The recording experiments where repetition-sensitive response changes have been found have employed many controls to establish that the changes are not explicable by behavioral or motivational changes, including changes in alertness, eye movements, and pupil diameter (see, for review, Brown and Xiang, 1998). The speed of the response changes further establishes that they are not artifactually generated, as they occur too soon to be explicable as secondary to ocular or attentional changes. It also establishes that these neurons provide a very rapid signal indicating the presence of a novel stimulus. It has been argued that the evolutionary advantage conveyed by the capacity to attend early to novelty provides a reason for the existence of such a network (Brown and Aggleton, 2001).

Thus, the available evidence strongly indicates that the occurrence of stimuli is registered (acquired) in perirhinal cortex. Moreover, if rat perirhinal cortex is reversibly inactivated (by a localized infusion of the AMPA/kainate glutamate receptor antagonist CNQX), retrieval of stimulus familiarity is blocked (Winters and Bussey, 2005a); the animals treat familiar stimuli as if they were novel. Hence, perirhinal cortex is either the information store or is necessary for access to the store. As modeling (see section 3.10.5.4) indicates that perirhinal cortex has ample storage capacity to allow familiarity discrimination, there is no good theoretical reason for the store being elsewhere. Indeed, in support of this contention, perirhinal lesions in rats produce retrograde amnesia for the prior occurrence of objects made familiar 4 weeks before the lesion (Mumby et al., 2002).

3.10.2.4 Generalization across Modalities and Species

Similar neuronal response changes on stimulus repetition have been described in both monkey (Brown and Xiang, 1998) and rat (Zhu et al., 1995) perirhinal cortex. Moreover, recent functional magnetic resonance imaging (fMRI) studies have also indicated that signals in the analogous human cortical region are also weaker for familiar than for novel stimuli (*See* Chapters 2.23, 3.08; Henson et al., 2003; Weis et al., 2004; Gonsalves et al., 2005; Henson et al., 2005; Fernandez and Tendolkar, 2006; Montaldi et al., 2006). Thus there is a strong indication that the same type of repetition-sensitive response reductions are likely to occur generally across mammalian species.

Such response changes have been largely studied using visual stimuli because of the availability of such

stimuli in the very large numbers necessary for such experiments. As the connections of perirhinal cortex indicate that it should be a multimodal area, it might be expected that similar results will be found whichever modality is used. Indeed, findings in the rat for olfactory stimuli are consistent with those for visual stimuli (Young et al., 1997). Neuronal activity measurements have not been made with somatosensory stimuli, though perirhinal lesions impair tactile familiarity discrimination (Suzuki et al., 1993). However, lesion experiments suggest that perirhinal cortex may not be necessary for auditory familiarity discrimination (Kowalska et al., 2001; Fritz et al., 2005). When neuronal activity is imaged using Fos (which has proved to be a useful marker for imaging activity changes related to visual recognition memory), activity is higher for novel than familiar sounds in auditory association cortex (as it is for visual stimuli in visual association cortex) adjacent to perirhinal cortex, but not in perirhinal cortex itself (Wan et al., 2001). The implication is either that another region performs the role of perirhinal cortex for auditory stimuli or that there is a difference in the nature/complexity of the auditory and visual stimuli being employed. The latter suggestion relates to the proposed role of perirhinal cortex in the perception of objects and the question as to whether the particular auditory stimuli employed are processed as objects; if they are not, this could explain the lack of differential activation of perirhinal cortex by the novel and familiar sounds (Wan et al., 2001).

3.10.3 Neuronal Responses Related to Paired Associate Learning

3.10.3.1 Correlates of the Sequential Pairing of Stimuli

Both recording and lesion experiments in monkeys have established the importance of perirhinal cortex for visual paired associate learning (see, for review, Miyashita, 2004). In the task used, the animal learns across many trials to associate arbitrarily assigned pairs of complex visual stimuli so that, after a delay following an initial (cue) stimulus presentation, the animal will select (e.g., by touching) the other stimulus of the pair (its paired associate). Two neural substrates of this form of multitrial associative learning have been identified in perirhinal cortex, namely (1) stimulus-specific delay activity (see section 3.10.4.2) and (2) the occurrence of neurons with strong responses to both of the stimuli that have been paired (Miyashita and Chang, 1988; Sakai and Miyashita, 1991; Naya et al., 2001; 2003; see also, Erickson and Desimone, 1999). Such paired responsiveness occurs more frequently than expected by chance (see **Figure 4**). Thus the learning results in single neurons that can code for both of a pair of stimuli, that is, information from both stimuli has come to converge on individual perirhinal neurons. Such 'pair-encoding' neurons occur far less frequently

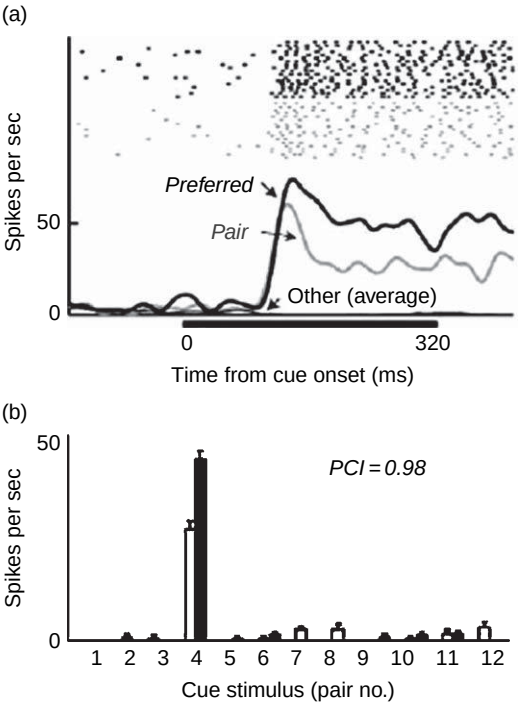

Figure 4 Example stimulus-selective neuronal response for learned paired associate stimuli. An example monkey perirhinal neuron that was strongly activated by both members of a particular pair of associated stimuli. In contrast, its responses were negligible when presented with members of any of the 11 other stimulus pairs. (a) Raster display and peristimulus time histogram for trials where the preferred stimulus (preferred, thick black) or its paired associate (pair, thick grey) were presented as the cue stimulus. The thin black line denotes the averaged responses in the trials where other stimuli were used as the cue (other). The horizontal gray bar indicates the cue presentation period. Note the continuing (delay) activity for the preferred stimuli after the cue stimulus is turned off. (b) Mean (+ SEM) discharge rates during the cue period (60–320 ms from the cue onset) for each of 12 learned pairs of stimuli. The responses to both members of pair 4 are much greater than the response to any member of the other 11 paired associates. Reproduced and adapted from Naya Y, Yoshida M, and Miyashita Y (2003) Forward processing of long-term associative memory in monkey inferotemporal cortex. *J. Neurosci.* 23: 2861–2871, with permission from Society for Neuroscience.

in TE than in Area 36 (5% cf. 33%). Thus perirhinal neurons can learn to encode new sensory constructs or contingencies, in this case the association between two stimuli.

Although sensory information is fed forward from TE to perirhinal cortex, memory retrieval is fed back from perirhinal cortex to TE (Naya et al., 2001; 2003). **Figure 5** illustrates the firing rate of a perirhinal neuron and that of a neuron from area TE in response to the stimulus to which they both respond preferentially. Memory-retrieval signals appear first in perirhinal cortex, after which TE neurons are gradually recruited to represent the sought target. For this paired associate learning, there is evidence that memory acquisition, storage, and retrieval are all perirhinal-dependent processes. Neurotoxic lesions involving the perirhinal and entorhinal cortices impair behavior and disrupt neuronal activity in TE related to paired coding (but not to individual stimuli) for paired associates learned either pre- or postoperatively (Higuchi and Miyashita, 1996; Miyashita et al., 1998).

It has been established that the perirhinal changes involve and are dependent upon the immediate early gene Zif268 (Tokuyama et al., 2002). Anatomical tracing indicates that paired associate learning is associated with changes in the pattern of axonal connectivity between TE and perirhinal cortex (Yoshida et al., 2003). Such alterations in the functional architecture of perirhinal cortex may facilitate the reactivation of newly formed object representations and, moreover, may form a neural basis for the process of memory retrieval (Miyashita, 2004).

3.10.3.2 Correlates of the Simultaneous Pairing of Stimuli

In contrast to findings for paired stimuli presented sequentially, when pairs of stimuli are shown simultaneously, inferior temporal (including perirhinal) neuronal responses to each of the individual stimuli appear to be unchanged even after many such pairings (Sobotka and Ringo, 1993; Erickson et al., 2000). However, responses to the stimuli shown as a pair are slowly changed by learning. In such experiments, the animal learns to respond (saccade) to whichever one of the two stimuli has been previously shown as a cue (Erickson et al., 2000). After training, when both stimuli are displayed simultaneously, the neuronal response is enhanced if the animal must saccade to the stimulus to which the neuron responds better but is reduced when the neuron must respond to the stimulus to which it responds more weakly. Thus the cortical representation of the pair appears to have become more differentiated. This differential responding develops across trials in which the two stimuli are paired when the pairing is repeated many times. The alteration of the representation of the pair

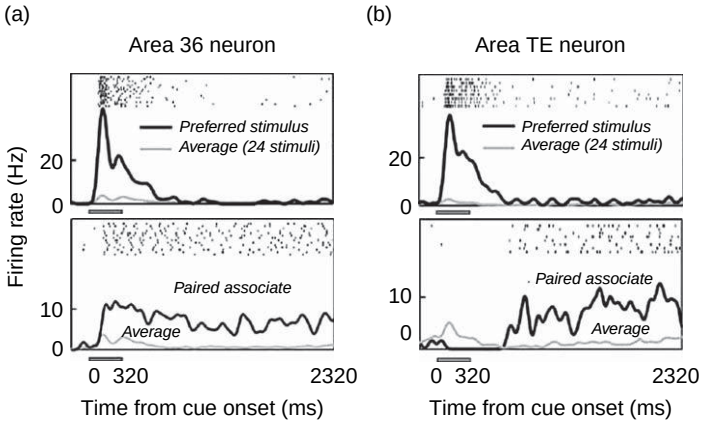

Figure 5 Neuronal activity during paired associate memory retrieval for a neuron in monkey: (a) perirhinal cortex (A36) and (b) area TE. For each neuron are shown raster displays and peristimulus time histograms for trials where the preferred stimulus (upper panel) or its paired associate (lower panel) was presented as the cue stimulus. The black lines indicate responses to the preferred cue stimulus (upper panel) or its paired associate (lower panel); the grey lines indicate mean responses to all 24 stimuli. Note that for the paired associate of the preferred stimulus (lower panel), the delay activity in perirhinal cortex is high from the time that stimulus presentation ends, whereas there is a delay before such activity appears in TE. The delay activity in TE is dependent upon a signal fed back from perirhinal cortex. Reproduced with permission and modified from Naya Y, Yoshida M, and Miyashita Y (2001) Backward spreading of memory retrieval signal in primate temporal cortex. *Science* 291: 661–664.

of stimuli in the cortex is presumably as a result of the altered effectiveness of interconnections within the cortex (Erickson et al., 2000). Moreover, measured across a range of stimuli, two neighboring perirhinal neurons tend to respond more similarly if the stimuli are familiar (presented many times on the previous day) than if they are relatively novel (not seen before the day of recording). This finding suggests that, as a result of repeated experience, neuronal responsiveness changes so that neighboring perirhinal neurons develop similar stimulus preferences (Erickson et al., 2000). It has not been established to what extent the learning occurs within perirhinal cortex itself.

3.10.4 Neural Responses Related to Stimulus Identification and Linked Associational Functions

3.10.4.1 Stimulus Identification

Visual information processing is largely divided between two pathways: a dorsal visual stream – primarily associated with spatial perception and sensorimotor output – and a ventral visual stream – primarily associated with object identification (Mishkin and Ungerleider, 1982). The latter pathway runs in the posterior–anterior direction through successive processing areas from primary visual cortex, via area V4, to inferior temporal cortex, including area TE, which supplies strong projections to perirhinal cortex. Electrophysiological evidence indicates that neurons in the anterior regions of the ventral visual stream code more complex visual representations than do neurons in the more caudal regions (Tanaka, 1996). Perirhinal cortex can be considered to be at the top of the hierarchy of processing regions (Felleman and Van Essen, 1991) and has been suggested to be necessary for the perception of objects as entities, as opposed to the identification of their individual features (Murray and Wise, 2004; Bussey et al., 2005). It is to be noted that the high-level perceptual categorization ascribed to perirhinal cortex is likely to be learned, presumably mainly during development. Thus, any such high-level discriminative properties of perirhinal neurons will represent the results of learned feature extraction and hence will be dependent upon long-term memory. Insofar as any such learning involves synapses on perirhinal neurons, these synapses must therefore be capable of long-term storage of information. To date there is only one published study of such potential perirhinal learning (Jo et al., 2006). However, as is discussed below, the responsiveness of perirhinal neurons to particular sensory stimuli can be changed as a result of training in the adult.

Most studies of neuronal response properties concerning stimulus identification in the anterior temporal lobe have concerned visual stimuli and inferior temporal cortex. While it is clear that some such studies have included perirhinal neurons, the sensory response properties of perirhinal neurons have rarely been distinguished from those of other anterior inferior temporal neurons. (Past uncertainties in the boundaries of perirhinal cortex have not assisted in making such distinctions.) Indeed, only a few distinctions have been described between the responses of neurons in anterior TE and in perirhinal cortex, and these chiefly relate to associative or mnemonic properties (specifically, neuronal responses in relation to judgment of prior occurrence, paired associate learning, and reward associations).

In conscious monkeys, typically more than half of recorded perirhinal neurons are reported as being visually responsive (Riches et al., 1991; Li et al., 1993; Miller et al., 1993; Sobotka and Ringo, 1993). Where reported, more than half of these visually responsive neurons respond to the majority of complex stimuli tested, though by no means with equal vigor to every stimulus. Nevertheless, some perirhinal neurons respond only to restricted classes of stimuli, such as faces or stimuli of a particular color (Riches et al., 1991; Fahy et al., 1993). Accordingly, the responses of perirhinal neurons signal information about the physical features of visual stimuli. It has been reported that a higher proportion of neurons are stimulus selective in perirhinal cortex than area TE (Brown et al., 1996). Unfortunately, in spite of the suggestion that perirhinal cortex is critical to object identification, no recordings examining this issue have included perirhinal cortex, and in particular, no recording studies have investigated whether learning to categorize stimuli or form an object percept involves changes at perirhinal synapses.

As in TE, when single stimuli are viewed, perirhinal receptive fields are large and may encompass a region extending into both visual hemifields (Desimone and Gross, 1979). There has been little study of perirhinal responses in relation to stimulus constancy, but again evidence indicates that it is similar to that found in TE, with similar responses being found when stimuli are shown across different positions or at different sizes (Lueschow et al., 1994). Although some tendency for clustering of similar perirhinal responses has been reported (Fahy et al., 1993;

Nakamura et al., 1994; Erickson et al., 2000), there is not strong anatomical or physiological evidence that perirhinal cortex has a columnar organization. Studies of neuronal responses in rats indicate that the responses of perirhinal neurons encode stimulus-specific visual (Zhu et al., 1995) and olfactory information (Young et al., 1997) but do not encode detailed spatial information (Burwell et al., 1998; Zironi et al., 2001).

Anatomical connectivity indicates that perirhinal cortex is a polymodal area, yet there is still no published major study of polymodal perirhinal responses (though, commonly, perirhinal neuronal activity in both monkeys and rats is found to vary with all aspects of the behavioral task during which recordings are made and not merely with the presentation of sensory stimuli). Again, there is no reported study of the establishment of a cross-modal perirhinal response through learning.

3.10.4.2 Correlates of Attention and Short-Term Memory

Two types of neuronal activity that occur in many brain regions in relation to attentional and short-term memory tasks are also found in perirhinal cortex, namely, response suppression and delay activity.

When monkeys are trained to select a target stimulus presented amongst nontarget stimuli, neural responses to the behaviorally irrelevant stimuli are suppressed, whereas the response to the behaviorally relevant target stimulus remains unchanged (Desimone, 1996); see **Figure 6**. This change in responsiveness reflects a neural mechanism encoding the learned salience of a given stimulus. The change may involve both bottom-up and top-down mechanisms (Pessoa et al., 2002), but the precise location of the learning remains to be determined. Any involvement of perirhinal neurons that is distinctive rather than typical of other sensory processing regions remains to be established.

Delay activity is found during the interval between stimulus presentations in short-term or working memory tasks such as delayed matching to sample (Fuster and Jervey, 1981; Miyashita and Chang, 1988; Riches et al., 1991; Sakai and Miyashita, 1991; Miller et al., 1993). In such tasks a stimulus is presented in an acquisition phase, and after a possibly variable but relatively brief (<1 min) delay interval, there follows a choice phase in which a decision must be made on the basis of the stimulus presented in the acquisition phase. For many perirhinal neurons, the activity in the delay period carries information concerning the stimulus presented during the acquisition phase, that is, it is stimulus specific. Such activity maintains a representation of that stimulus online and may be a correlate

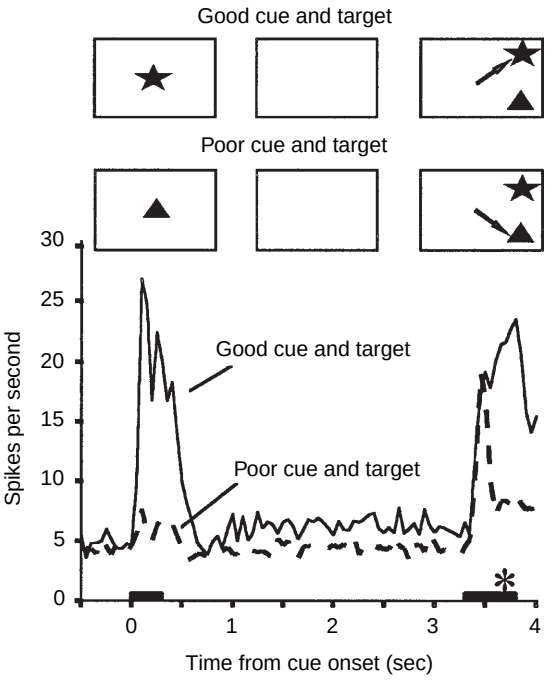

Figure 6 Differential delay activity and response suppression. For each neuron, one stimulus that evoked a strong response and one that evoked a weak response were chosen. Either stimulus was presented (bar on time scale) as the cue, and after a delay, the cue stimulus had to be selected (by making a saccadic eye movement to it) from a display of both stimuli in the choice phase. Thus, whichever stimulus was the cue, the display during the choice phase was of both stimuli. The activity was averaged for each neuron for trials using the good and poor stimuli and then across neurons to produce a population response. Shown is the population response for 22 monkey inferior temporal (including perirhinal) neurons for the good cues and targets (solid line) and the poor cues and targets (dashed line). Note that the delay activity occurring between the end of the cue stimulus presentation and the appearance of the choice stimuli is greater for the good than for the poor stimuli. Also note that the response to the display of both stimuli during the choice phase is rapidly suppressed when the poor stimulus is the target. Thus, across the population of neurons only those that respond strongly to the target are strongly active during the delay and the choice phases. The responses of other neurons are rapidly (~200 ms) suppressed in the choice phase. *Start of saccadic eye movement (NB later than start of suppression). Reproduced with permission from Desimone R (1996) Neural mechanisms for visual memory and their role in attention. *Proc. Natl. Acad. Sci. USA* 93: 13494–13499.

of the stimulus being 'held in mind' (Desimone, 1996; Naya et al., 1996). In certain cases the response of the neuron to the stimulus may then be enhanced when it is repeated on match trials (Miller and Desimone, 1994). Again, the activity change shows that perirhinal activity is modulated by attentive and mnemonic factors, but it has not been established that the delay activity is generated by learning mechanisms within perirhinal cortex itself, rather than being a reflection of activity generated elsewhere.

3.10.4.3 Correlates of Long-Term Memory and Learned Associations of Frequently Repeated Stimuli

A number of different types of long-term change have been reported in the responses of perirhinal neurons trained on different tasks where stimuli are seen many times and associated with reward. The findings emphasize the plasticity of perirhinal responses in relation to different processing demands. This plasticity and adaptation to specific learning situations may explain what are at first apparent inconsistencies in some reported findings. Information is now given about perirhinal neuronal responses related to four examples of such long-term changes and learned associations that are concerned with frequently presented stimuli.

First, the response change that has been most often reported is found in delayed matching tasks using small stimulus sets where the stimuli are frequently repeated (Gross et al., 1972; Riches et al., 1991; Nakamura and Kubota, 1995, 1996; Young et al., 1997). In such experiments the response to a stimulus changes (becoming variously either stronger or weaker for different neurons) according to whether it occurs as the choice stimulus on a match or mismatch trial. Such response changes establish that perirhinal neuronal responses can be determined by more than the physical characteristics of the presented stimulus: The responses can also reflect the behavioral context in which the stimulus is presented. In one description, such responses therefore contain information about learned associations of the stimulus and hence may be said to convey information concerning the behavioral meaning of the stimulus. In another description, the responses contain information about the recent occurrence or nonoccurrence of the stimulus and hence are related to temporal, rather than any more abstract, context, and therefore to judgment of prior occurrence. The same types of response change are found both in area TE and the hippocampus, so that they are not particular to perirhinal cortex (Gross et al., 1972; Mikami and Kubota, 1980; Riches et al., 1991; Otto and Eichenbaum, 1992). Once more, there is no evidence establishing that such changes are being generated in perirhinal cortex rather than passively reflecting changes generated elsewhere.

Second, sequence learning provides stronger evidence that perirhinal neurons can respond on the basis of the behavioral meaning of a stimulus (its abstract associations) rather than solely according to the physical characteristics of the stimulus (Murray and Richmond, 2001). Consider findings when a monkey has been trained in a task in which different-length sequences of stimulus presentations occur before the availability of reward (Liu and Richmond, 2000). The animal learns that certain stimuli signal the position in the sequence (e.g., first or last). Certain perirhinal neurons respond according to the position in the sequence leading to reward that is signaled by a stimulus, rather than to the physical attributes of the particular stimulus (Liu and Richmond, 2000). This type of responding to the implication of a stimulus rather than its physical characteristics was not observed for neurons in TE. Recent results have indicated that the development of such perirhinal responses can be blocked by local infusion of an oligonucleotide that interrupts dopaminergic transmission (Liu et al., 2004). Therefore, for such responses there is evidence that the learning (acquisition) is dependent upon perirhinal cortex, consistent with the results of ablation (Liu et al., 2000).

Third, after extensive training, perirhinal neuronal responses can be strongly modulated by the learned reward value of a stimulus (Mogami and Tanaka, 2006). Indeed, perirhinal responses are more strongly modulated than are responses in TE (Mogami and Tanaka, 2006). Again, while this establishes that learned reward-related information is present in perirhinal responses, previous ablation studies have indicated that perirhinal cortex is only necessary for stimulus–reward learning where the task requires discrimination of stimuli that is made difficult by feature ambiguity (Buckley et al., 2001; Bussey et al., 2005). Accordingly, this information might not be essential to task performance. Indeed, the modulation of the neuronal responses according to whether the stimulus signals reward or no reward has a mean latency that is >90 ms later than the onset of the visual response. Such a latency difference allows the modulation to be

transmitted from elsewhere rather than being generated locally (Mogami and Tanaka, 2006).

Fourth, when the same stimuli are used repeatedly for tens or hundreds of trials and the animal must attend to these stimuli to gain reward, the responses to these highly familiar stimuli show a gradual increase in magnitude (Holscher et al., 2003). This finding indicates that perirhinal neuronal representations of stimuli are plastic even in the adult. They adapt to experience, presumably to optimize the processing of behaviorally important information. Once more, although the changed activity reflects learning, the site of the learning remains to be established, and similar types of change with extensive training have been seen in other cortical areas (Buonomano and Merzenich, 1998; Kobatake et al., 1998).

In summary, after prolonged training perirhinal neuronal responses reflect task contingencies, signaling information potentially useful to task solution that is additional to the sensory properties of the stimuli. Such information may concern reward or more abstract associations of the stimuli and may involve tuning of the sensory responses. So far, in relation to the changes discussed in this section, there is published evidence suggesting that perirhinal cortex is the site of the learning-related change only in the case of sequence learning.

3.10.5 Synaptic Plasticity and Modeling of Perirhinal Neuronal Response Changes

The preceding sections describe several different types of perirhinal neuronal response changes related to learning. It is possible to list these under the following headings: (1) feature extraction (perceptual categorization), (2) familiarity/recency discrimination (potentially several different mechanisms), (3) paired associate learning, and (4) reward association learning. Yet other changes, thought to be related to attentional and/or short-term memory mechanisms, have also been described, such as delay activity and response suppression. It is already clear that there will also be developmental changes. The interrelationships and independencies of these different response changes and their underlying synaptic plastic mechanisms are largely unknown, but in the list above are at least eight types of activity change, all of which are observable in the activity of perirhinal neurons under different conditions. The changes observed are dependent on the particular conditions of the experiment and on the particular perirhinal neuron under study. Not all perirhinal neurons show all types of changes, though some may show more than one; again, information here is limited.

Perirhinal cortex provides a promising region for the investigation of neural substrates of memory. In recent years, increasing efforts have been made to relate perirhinal neuronal response changes to underlying synaptic plastic changes. As indicated above, this work has variously encompassed paired associate learning, reward learning, developmental changes, and familiarity discrimination. It has also involved the study of synaptic plasticity mechanisms in slices of perirhinal cortex.

3.10.5.1 Perirhinal Plasticity Studied in Brain Slices

In vitro studies have established that both long-term potentiation (LTP) and long-term depression (LTD) can be evoked in perirhinal cortex by suitable stimulation. The induction of both LTP and LTD are dependent on *N*-methyl-D-aspartate (NMDA) glutamate receptors in perirhinal cortex (Ziakopoulos et al., 1999; Cho et al., 2000) and elsewhere (Bliss and Collingridge, 1993). However, perirhinal LTD has been shown to have an unusual dependency on activation of metabotropic glutamate receptors (Cho et al., 2000). Moreover, in adult perirhinal cortex, LTP is dependent on activation of NMDA receptors containing NR2A subunits, whereas LTD (and depotentiation) is dependent on NMDA receptors containing NR2B subunits (Massey et al., 2004). Again, as in other regions (Kemp et al., 2000), there are differences between the adult and immature cortex in glutamate NMDA receptor composition and LTD induction mechanisms. Indeed, recently it has been shown that visual experience triggers such a change between immature and adult perirhinal LTD induction mechanisms (Jo et al., 2006).

3.10.5.2 Signaling Mechanisms Related to Paired Associate and Reward Sequence Learning

As mentioned above, studies of paired associate learning in the monkey have established that underlying perirhinal changes involve and are dependent upon the immediate early gene Zif268 (Tokuyama et al., 2002). Similarly, reward sequence learning in the monkey involves dopaminergic mechanisms, as

perirhinal neuronal response changes are blocked by local infusion of an oligonucleotide that down-regulates expression of D2 dopaminergic receptors (Liu et al., 2004). Interestingly, antagonism of NMDA receptors did not prevent development of the response changes in reward sequence learning.

3.10.5.3 Signaling Mechanisms Related to Recognition Memory

Several studies have been carried out looking at potential substrates of familiarity discrimination in the rat. This work has established that recognition memory is impaired following local infusions into perirhinal cortex of the muscarinic receptor antagonist scopolamine (Warburton et al., 2003; Winters and Bussey, 2005b) or selective antagonists of AMPA, NMDA, kainate, and metabotropic glutamate receptors (Winters and Bussey, 2005a; Barker et al., 2006a,b). When AMPA receptors are blocked, both acquisition and retrieval are impaired. Otherwise, all the studied drug actions are on acquisition and not retrieval. Interestingly, blockade of NMDA and metabotropic glutamate receptors produces recognition memory impairment only when the memory has to be held across a long (24-h) and not shorter (20-min) delay. In contrast, and most unusually, kainate receptor antagonism impairs recognition memory after a 20-min but not after a 24-h delay. These results parallel the evidence provided by perirhinal neuronal responses that there must be more than one substrate underlying familiarity discrimination (Fahy et al., 1993; Xiang and Brown, 1998). The indication is that there must be a rapidly induced shorter-term process that is dependent on kainate receptor activation and one or more longer-term processes more slowly induced and dependent on NMDA and/or metabotropic glutamate receptor activation (Barker et al., 2006b). In addition, viral transduction of perirhinal cortex has shown that phosphorylation of CREB (cyclic AMP responsive element binding protein) is necessary for both perirhinal LTP and long-term (24-h) recognition memory (Warburton et al., 2005), a dependency that parallels findings elsewhere (e.g., hippocampus).

3.10.5.4 Theoretical Models and Plasticity Mechanisms

There are now several theoretical neuronal models both of networks designed to extract features and thereby achieve stimulus categorizations leading to perception and of networks designed to achieve familiarity discrimination (*See* Chapter 3.08; Sohal and Hasselmo, 2000; Bogacz et al., 2001; Bogacz and Brown, 2003; Norman and O'Reilly, 2003). Such models have demonstrated that the relatively small number of neurons in perirhinal cortex (~0.1% of the total number of cortical neurons) potentially have the storage capacity to explain human visual recognition memory. Under the optimized conditions of such models, the occurrence can be stored, and hence the familiarity can be judged, of $\sim 10^9$ stimuli; that is, the capacity is sufficient to record an encounter with a new stimulus every several seconds for the whole of a human lifetime (Bogacz and Brown, 2003).

None of these models yet uses specific details of perirhinal circuitry (about which there is still relatively little information). Most of the models have employed synaptic enhancement (i.e., LTP-like mechanisms) as their primary synaptic plasticity mechanism. One way of achieving the reduced neuronal responses for familiar compared with novel stimuli in such models is by increasing inhibition, but experimental evidence of such increased inhibition is lacking. Recently, it has been argued that models that use separate (though interlinked) networks for feature extraction and familiarity discrimination are more economical (Bogacz and Brown, 2003). The idea of separate networks is consistent with the observation that perirhinal neurons have responses that are either repetition sensitive or not, rather than some mixture of the two. Moreover, the calculations indicate that the use of synaptic weakening as the primary mechanism is considerably more efficient than synaptic enhancement (Bogacz and Brown, 2003). Heuristically, this is because when features repeat across different stimuli, synaptic enhancement leads to certain synapses being successively strengthened, so that the neurons with these synapses come to fire selectively strongly for these features; that is, they signal the presence of such features. In contrast, synaptic weakening has the opposite effect; it emphasizes what is not common rather than what is common across stimuli – but this is what is required for novelty detection. Hence neuronal modeling has provided an explanation for why perirhinal responses are weaker for familiar than novel stimuli. Under this hypothesis the synapses that are most strongly activated by a novel stimulus are weakened; when the stimulus occurs again, that is, when it is familiar, the weakened synapses will give rise to a weaker response.

3.10.6 Summary

The position of perirhinal cortex at the top of the hierarchy of sensory processing areas and at the gateway to the limbic system means that it is ideally placed to play important roles in sensory perception and memory. Ablation evidence indicates that perirhinal cortex is indeed involved in both mnemonic and perceptual (stimulus categorization) functions. The results of recording studies establish that the responses of perirhinal cortical neurons carry information about complex stimuli and relate to stimulus identity, but they have yet to provide evidence for the categorization of objects as entities (as suggested by certain lesion studies). Recording studies have described perirhinal response changes indicating information processing related to short-term memory and multiple types of long-term memory – including recognition memory, paired associate learning, and stimulus–reward association learning. Perirhinal cortex is important in acquisition, storage, and retrieval of information related to such long-term memory. A variety of different neuronal response changes have been related to these different types of memory, and studies of their underlying synaptic plastic mechanisms are underway.

3.11 Cortical Plasticity in Associative Learning and Memory

N. M. Weinberger, University of California, Irvine, CA, USA

3.11.1 Introduction

Cortical plasticity concerns the totality of nontransient changes in the structure and function of the cerebral cortex at the levels of hemispheres, lobes, systems, circuits, cells, and molecules. Restricted to the domain of learning and memory, its scope remains colossal. This chapter focuses on a central aspect of learning and memory – associative learning and memory and neurophysiological plasticity at the

levels of systems and cells in the primary sensory cortical fields: auditory (A1), somatosensory (SI), and visual (V1). For an earlier related account with a somewhat difference emphasis, see Edeline (1999). Space limitations preclude broad coverage of priming and related phenomena in humans (Schacter et al., 2004; Grill-Spector et al., 2006) and of cellular and molecular mechanisms of associative plasticity (Buonomano and Merzenich, 1998; Palmer et al., 1998; Rauschecker, 1999; Barth, 2002; Diamond et al., 2003; Edeline, 2003; Metherate and Hsieh, 2004; Weinberger, 2004b).

3.11.1.1 Rationale

Why focus on primary sensory cortices (PSCs)? There are several reasons. First, the primary sensory cortices are the last regions of the cerebral cortex to be included into the field of the neurobiology of learning and memory. Of course, there can be found no formal, and indeed only rarely a semiexplicit, denial of their importance in learning and memory. But PSCs have been largely ignored, particularly in the case of associative learning.

Second, general conceptions about cortical organization for learning and memory should be informed by the established, but still underappreciated, realization that primary sensory fields are not merely sensory analyzers. Rather, their functions, as related to intrinsic operations and integration of influences from the thalamus, other cortical areas, and neuromodulatory systems, render them as important nodes in the acquisition, representation, storage, and ultimate use of information in thought and action.

Third, beyond associative and mnemonic processes, PSCs are involved in a wide variety of functions that are not strictly sensory, including attention, motivation, the encoding of behavioral significance, motor acts, and higher cognitive functions such as learning strategy, expectancy and preparatory set, cross-modal integration, category learning, and concept formation. The emerging, broadened view of PSCs challenges normative conceptions of the structural/functional organization of the cerebral cortex as largely hierarchically sensory, associational, and motor and calls for a new cortical schema.

Fourth, but perhaps of paramount importance, is the issue of the specificity of plasticity. The substrates of memory must contain information that is sufficiently detailed to subserve cognitive processes and behaviors that are dependent on that memory. It is insufficient to merely identify structures that are involved in memory because involvement is only the first step. Without knowing the type of information that such involved structures acquire and hold, one cannot conclude that they actually do hold the type and level of detail (i.e., the contents) of memory that comprise the storage of experience.

Primary sensory cortices provide a convenient entry point into the search for specificity, largely because they contain systematic representations of their respective sensory epithelia. Of course, primary sensory cortices are not the sole sites of memories but, rather, are parts of probably widely distributed networks consisting of complex feedforward and feedback connections. But the study of PSCs contributes a powerful set of experimental tools from the field of sensory neurophysiology. Their application provides a level of specificity of plasticity beyond what can be obtained with standard approaches to the neurophysiology of learning. Furthermore, they permit the assessment of specificity for any learning task. Moreover, when appropriately employed, the use of sensory neurophysiological approaches yields posttraining determination of the specificity of plasticity that is exempt from the usually unavoidable influences of experimental extinction. In so doing, consolidation and the course of long-term retention can be studied without fear of contamination from repeated measures.

3.11.1.2 Neurophysiological Plasticity in Associative Learning and Memory

As used here, neurophysiological plasticity refers simply to any learning-related changes in the activity of neurons, regardless of the method of recording: electroencephalogram (EEG), evoked potentials, unit discharges, metabolic activity, and so forth. As generally understood, the minimum duration of change that is considered plasticity is on the order of minutes, to distinguish it from purely sensory responses that may last many seconds. This article concentrates on behaviorally validated cases of learning and memory rather than demonstrations of plasticity that are alleged to constitute learning. Conflating neural plasticity with memory is experimentally confusing and conceptually fallacious. Although learning and memory, which are behavioral-level constructs, undoubtedly are caused by neural plasticity, equating the two constitutes a category error (Ryle, 1963).

The recording of neural activity in learning and memory provides correlates of these processes and the behaviors that experimenters use to infer learning and

memory. Such correlates can gain importance for inferences about causality if they are predictive of later behavioral assessments of learning and memory. For example, the amount of conditioned stimulus (CS)-elicited gamma band activity in the EEG of A1 during training predicts the amount of specificity of behavioral memory tested 24 h later (Weinberger et al., 2006). Nonetheless, such predictive correlates cannot establish that the neural plasticity so identified is either necessary or sufficient for the learning or memory in question. Their major advantage is in identifying brain structures and systems that develop learning-based neural plasticity. In so doing, the use of neural correlates is perhaps the only way to find out what the brain is doing while it is doing it. Indeed, the discipline of sensory physiology is based essentially on neural correlates, specifically, correlations between a given stimulus and sensory system responses (Kiang, 1955). Such sensory physiology correlations have been used to understand processes such as developmental plasticity in PSCs (Weisel and Hubel, 1963).

The study of PSCs in learning and memory is more reliant on neurophysiological approaches than investigation of other structures, such as the amygdala and hippocampus, because lesions entail unique difficulties of interpretation. Because, as will be documented in the section titled 'Specificity of associative plasticity in primary sensory cortices,' PSCs develop associative plasticity during learning, their responses to sensory stimuli are governed not only by the physical parameters (e.g., sound frequency, locus of touch on the body surface) but also by the acquired behavioral relevance of those stimuli. Therefore, if lesions of a PSC disrupt learning, then resultant deficits could have been caused either by impairment of sensory/perceptual processing or by destruction of information stored in the removed tissue or both. One approach to circumvent this problem is to apply a treatment to a primary sensory cortex (e.g., stimulate, inactivate) after the sensory stimulus has ended but before a behavior dependent on the storage of that information is required (Harris et al., 2002).Investigations of plasticity in learning and memory in the primary sensory cortices vary greatly with the type of learning studied. Thus, associative learning, including classical and instrumental conditioning, has been investigated most extensively in the primary auditory cortex. Priming and perceptual learning have been most intensively examined in the visual cortex. The somatosensory cortex is becoming increasingly studied, particularly using the vibrissal system of animals, which has the advantage of a one-to-one correspondence between each whisker and its anatomically distinct recipient primary somatosensory cortex. This chapter reflects these characteristics of the literature.

3.11.2 What about Perceptual Learning?

As stated in the introduction, this chapter concerns associative learning. Where does that leave perceptual learning? Perceptual learning refers to an increase in sensory acuity within a stimulus dimension, usually as a result of increasingly difficult discrimination training (Kellman, 2002). Experiments of perceptual learning in humans typically involve thousands of trials over many days. For example, a recent study of human frequency discrimination learning involved 4000–5000 trials (Irvine et al., 2000), whereas a pitch discrimination experiment used more than 10 000 trials (Demany and Semal, 2002). Even when a single training session is employed, the number of stimulus trials is typically large. A study of learning of melodic patterns used 1200 different stimuli (Tervaniemi et al., 2001). Animal neurophysiological studies of perceptual learning typically employ very extensive discrimination training for each subject. For example, an investigation of primary visual cortex used ~130 000–325 000 trials (Schoups et al., 2001), and an experiment on inferotemporal cortical visual processing employed ~750 000–1 150 000 trials (Logothetis et al., 1995). There are reports of perceptual learning in considerably fewer trials under specific circumstances (Hawkey et al., 2004), but even so, specific plasticity in associative learning can develop in only five trials (Edeline et al., 1993).

Aside from the rate of learning, why make a distinction between perceptual learning and associative learning? One might expect that if any type of learning is characteristic of primary sensory cortices, then it must be perceptual learning. In fact, the existence of perceptual learning is often thought to subsume the category of associative learning, so that all learning-induced plasticity in PSCs is regarded as perceptual learning.

The distinction is actually critical. One might simply ask, "After a bout of perceptual learning, what is changed in a primary sensory cortex?" The answer would seem to be, "After perceptual learning, the machinery of the cortex has been altered to enable greater acuity. The sensory cortical machine now analyzes the same physical stimuli differently

(e.g., at a finer grain)." This effect certainly constitutes a type of learning by any definition. But interestingly, the study of perceptual learning does not include perceptual memory. This situation probably reflects the fact that investigators of perceptual learning are more concerned with sensory/perceptual processes than with learning and memory, and in any event, subjects do not actually remember the specific contents of their experience, that is, the particular stimuli or stimulus values given during certain of their multitude of trials. Thus, although perceptual learning alters the gateway to memory, increased acuity by itself is not necessary for memory, as the term is normally understood (i.e., as the contents of experience). However, the extant level of acuity can determine the precision with which the information is analyzed and may then be encoded and stored.

Consideration of the stages of training in perceptual learning indicates that, actually, it may be considered a subclass of associative learning. Subjects must first learn an association between a sensory stimulus and a reinforcer (simple classical conditioning) and, second, must learn an association between a specified response and a reinforcer contingent on whether a sensory stimulus is a CS+ (rewarded) or CS− (nonrewarded) (i.e., discriminative instrumental conditioning). After that, the discriminations simply become increasingly difficult. Because basic associative learning and its correlated cortical plasticity develop first (often in a few trials), understanding their substrates may help elucidate mechanisms of perceptual learning. Given this consideration and space limitations, perceptual learning is not reviewed. However, some brief comments will help to place it in perspective.

A general summary, necessarily imperfect, is that PSC plasticity is often (but not always) found after perceptual learning and in many instances correlates well with the type and amount of behavioral perceptual improvement, thus providing a potential explanation of the behavioral effects. For example, monkeys trained to discriminate between frequencies of vibration on a digit develop increased temporal precision of evoked discharges in S1 (i.e., decreased variance in the representation of each stimulus cycle) that could account for behaviorally measured frequency discrimination performance (correlation = 0.98) (Recanzone et al., 1992).

In addition, studies of perceptual learning can illuminate properties of PSC neurons because the extensive training allows for training the same subjects on multiple tasks. In a particularly noteworthy case, Gilbert and colleagues trained monkeys to perform two tasks using a single visual array consisting of five line segments: a central line flanked by two parallel lines at either end and either side. Subjects were trained to switch between a line bisection and a vernier task. The tuning properties of neurons in primary visual cortex (V1) changed depending on the task. Most importantly, an information theoretic analysis revealed that neurons "carried more information about a stimulus attribute when the animals were performing a task related to that attribute" (Li et al., 2004: 651). The authors suggested that V1 as a whole is an adaptive processing unit that performs different computations depending on the current problem to be solved (i.e., the behavioral context) (Li et al., 2004). These neuronal characteristics are certainly in line with the associative specificity obtained even in simple classical conditioning studies, as reviewed later.

A major issue concerns whether or not PSCs or higher cortical areas are responsible for perceptual improvement (Fahle, 2004). For example, in the case of successful frequency discrimination, the primary auditory cortex exhibits either extensive plasticity (Recanzone et al., 1993), a lack of plasticity (Brown et al., 2004), or partial plasticity (Witte and Kipke, 2005). There is no *a priori* reason why substrates of all perceptual learning should involve PSCs. It is sufficient for our present purposes to note that there is compelling evidence that some perceptual learning is tightly linked to the development of neuronal plasticity in primary sensory cortices. It seems likely that an adequate understanding of the neural bases of perceptual learning will require determination of precisely what has been learned in each study (e.g., absolute vs. relative discriminations). Interested readers should consult available reviews (Goldstone et al., 1997; Gilbert et al., 2001; Calford, 2002; Pleger et al., 2003; Ghose, 2004; Fahle, 2005; Skrandies, 2006). However, there remains a pressing need for an integration of conceptions and findings in the still separate disciplines of associative learning/memory and perceptual learning.

3.11.3 The Enduring Influence of Sensorimotor Conceptions of Cortical Organization, or Campbell's Ghost

Neurophysiological plasticity in PSCs is interesting both in its own right and as a case study in the intersection of sensory neurophysiology and the neurobiology of learning and memory, two fields that had developed

separately and with little crossover until the latter part of the last century. This is particularly remarkable because these are the two disciplines in neuroscience whose subject matter deeply involves the 'fate' of environmental stimuli in the brain. The former has traditionally been concerned with the coding and representation of the physical parameters of sensory stimuli. The latter has focused on how a previously neutral stimulus comes to influence cognition and behavior through learning. Furthermore, this topic provides a clear example of how assumptions constrained thought and experiment for most of the twentieth century. This is not merely of historical interest because the problem is still present.

Attempts to understand sensory cortex (as well as other brain systems and structures) began in the nineteenth century within the framework of a sensorimotor conception of the nervous system. Some of the first structural–functional relationships discovered concerned the spinal cord: The dorsal roots are sensory, and the ventral roots are motor. These seminal findings are attributed jointly to the separate but largely simultaneous studies of Charles Bell in England and Francois Magendie in France, roughly in the period 1812–1840 (Fearing, 1970). Although Bell can be given primacy for establishing the major function of the ventral roots, historical analysis has revealed that Magendie discovered the sensory function of the dorsal roots (as well as independently showing ventral root function), notwithstanding Bell's subsequent falsification of the record (Cranefield, 1974). After the discoveries of Magendie and Bell, much of the research program for the rest of the century concerned the extent to which the entire neuraxis was organized on sensorimotor principles (Young, 1970). The last 30 years of the nineteenth century witnessed the discovery of the motor cortex by Fritsch and Hitzig and the approximate delineation of sensory cortices based on modality specific sensory deficits following cortical ablations (Ferrier, 1886).

Still, sensory and motor areas did not comprise the entire neocortex. Could an overarching principle of cortical organization be discovered? In 1901 Flechsig, a neuroembryologist, reported that axons in different parts of the human cortex became myelinated at different times (Flechsig, 1901). Sensory and motor cortices exhibited myelination at birth, whereas other areas could require as long as 1 postnatal month to myelinate. Flechsig's observations of fibers in the internal capsule led him to the erroneous conclusion that only the sensory and motor cortices had subcortical connections, the association areas were thought to receive inputs only from other cortical regions. In short, Flechsig's schema was that the cortex consisted of sensorimotor zones that were connected to the thalamus and brainstem and were functional at birth, and association cortices that were connected only to other cortical regions and was not functional until well after birth. The late Irving Diamond pointed out that as association cortical areas myelinate later, this sequence of myelination "is just what would be expected if an infant sees sensory qualities such as color and brightness before these impressions are associated with another to form the perception of objects." (Diamond, 1979: 5). Thus, Flechsig had provided an anatomical basis for the distinction between lower (i.e., sensorimotor) and higher psychological functions.

It remained only to specify in greater detail, and perhaps with a more authoritative voice, the nature of these lower and higher functions. This was supplied by impressive cytoarchitectonic studies. In 1905 AW Campbell (Campbell, 1905) published a landmark monograph entitled *Histological Studies on the Localization of Cerebral Function*. Campbell asserted structural–functional relationships on the grounds of cytoarchitecture. While perhaps not the first worker to use the terms sensory and psychic cortex, his influence has been profound. For example, Campbell labeled the region now identified as V1 'visual sensory,' and called regions nearby (e.g., areas 17 and 18) 'visual psychic.' Similarly, the region now known as A1 was termed 'auditory sensory,' whereas adjacent areas, in modern parlance, auditory belt areas (Kaas and Hackett, 2000), were auditory psychic. In this, Campbell intended to make a clear distinction between cortical regions he considered to be purely sensory from those he believed concerned the understanding of the meaning of stimuli. His implicit assumption was one of strictly hierarchical cortical functional architecture, with what are now referred to as cognitive functions dependent on input from sensory structures (i.e., PSCs). Association cortex has come to denote both some modality-specific regions (e.g., auditory association) and cortical territory that lies between modality-dominated cortex, generally posterior to the central sulcus.

This conceptual schema of sensory-association-motor cortex as the basis for understanding cortical function has strong resonance today. Irving Diamond held that Campbell's monograph was instrumental in removing learning and memory from primary sensory cortices (Diamond, 1985). Although a less-sequential,

more parallel thalamocortical structural organization, championed by Diamond, is generally acknowledged, its influence on beliefs about cortical functional organization seems minimal.

Within the field of learning and memory, Pavlov's theory of conditioned reflexes provided authoritative support for the distinction between sensory fields that analyze stimuli and association fields, in which learning allegedly occurs. Pavlov's proposed physiological mechanism, that learning was due to spreading ripples of excitation from the cortical sensory fields of the CS and the unconditioned stimulus (US) that met in intervening association cortex (Pavlov, 1927), has long been superseded by action potentials. But the fundamental assumed functional architecture has not changed. The standard schema based on sensory-to-association-to-motor cortex fails to the extent that primary sensory cortices are involved in associative learning and memory. We now turn to a consideration of the relevant literature.

3.11.4 Overview of Cortical Plasticity in Associative Learning: 1935–1984

This section provides a brief summary of the 50-year period (1935–1984) during which PSC plasticity in associative learning was discovered and well characterized for training trials. The unspoken assumption was that recording during training trials would be sufficient to reveal the neural bases of learning. The following section provides a more detailed account of contemporary approaches that reveal the degree of specificity of associative PSC plasticity.

Near the dawn of electroencephalography, a serendipitous discovery launched neurophysiological studies of cortical plasticity in learning/memory. The alpha rhythm, an oscillation of 8–12 Hz in the human EEG prominent from occipital (i.e., visual cortical) leads, was known to be consistently blocked by visual stimulation. (The actual effect was a shift to higher-frequency, lower-amplitude waves (i.e., EEG desynchronization or activation). Durup and Fessard were investigating alpha blocking when they found that it occurred shortly before they turned on the flashing light intended to disrupt alpha waves (Durup and Fessard, 1935). Upon further consideration of this paradoxical result, they realized that the blocking was caused by the click sound made by the shutter of their camera, which they activated immediately preceding the repeated presentation of flashes, so that they could photograph alpha blocking displayed on the screen of their oscilloscope. Durup and Fessard had inadvertently been conducting a classical conditioning experiment, with the CS being the click and the US being the flashing light. This stimulus–stimulus (S–S) pairing produced conditioned blocking of the alpha, the first demonstration of learning-induced cortical plasticity. The signal importance of this finding was immediately recognized, and other laboratories quickly replicated and expanded the finding of conditioned alpha blocking (Morrell, 1961). Thus, perhaps ironically, primary visual cortex was the first discovered site of learning-induced cortical plasticity.

Studies of cortical plasticity, much of them involving further EEG studies, expanded greatly after the end of World War II and were extended to nonhuman animals (hereafter animals). Emphasis was directed to understand classical conditioning and the major focus was to find the locus of closure, that is, the place(s) in the cortex of convergence of input from the CS and US. The dominant finding, across species and modalities and types of sensory stimuli, was that EEG changes followed a particular trajectory according to the stage of learning. First, relaxed subjects exhibited widespread cortical activation to the US. Second, continued pairing of the CS and US rapidly produced the first signs of associative learning, consisting of widespread activation that was now elicited by the previously ineffective CS. Third, as learning progressed, the cortical domain of conditioned EEG desynchronization shrank, becoming confined largely to the PSCs of the CS and US. Various controls were used to establish that conditioned EEG activation was genuine, including the use of unpaired or randomly presented CSs and USs in control groups or the use of discrimination paradigms in which a CS+ was paired with the US, whereas a CS− was not paired (Gluck and Rowland, 1959; Rowland and Gluck, 1960). The CS+ developed the ability to produce EEG activation while the CS− failed to do so (reviewed in John, 1961; Morrell, 1961; Thomas, 1962; Galeano, 1963).

That the CS developed the ability to elicit EEG plasticity in its own primary sensory cortex was a critical demonstration that PSCs were involved in learning and memory. However, this fact received little recognition. To the best of my knowledge, there has been no historical analysis of these studies in the context of the extant *Zeitgeist*. My guess is that this finding was overshadowed by the disappointment at the apparent failure to find the locus of closure. According to Pavlov and the dominant thinking at

that time, the CS and US should have converged in association areas. But conditioned EEG effects were not uniquely found in association cortex and in fact soon disappeared from there during learning.

Experiments on sensory-evoked potentials overlapped with studies of the EEG and learning and ultimately gained dominance. In an influential early study, Robert Galambos and his colleagues performed a seminal experiment in which cats were classically conditioned by pairing an auditory (click) conditioned stimulus with a puff of air (US) to the face (Galambos et al., 1956). Learning was validated by the development of behavioral conditioned responses. Evoked potentials in the primary auditory cortex elicited by the CS became larger during conditioning. This study also addressed the critical issue of stimulus control. To show that inadvertent changes in CS intensity (level) were not responsible, the authors also tested subjects under neuromuscular blockade, maintaining stimulus constancy at the periphery while eliminating putative contractions of the middle ear muscles. Interestingly, the authors failed to include a nonassociative control, such as a group that received the CS and US randomly. However, subsequent investigations confirmed and extended this basic finding, showing that facilitation of response to the CS in A1 was associative (Marsh et al., 1961; Majkowski and Sobieszek, 1975).

During the period from the late 1950s until the 1980s, an extensive literature also documented associative learning effects in V1 both in classical and instrumental conditioning in a variety of species. The dominant finding was facilitation of responses to visual conditioned stimuli (John and Killam, 1959, 1960; Saunders, 1971; Peck and Lindsley, 1972; Buresova and Bures, 1973; Suzuki et al., 1974; Sasaki and Yoshii, 1984a,b). During this period of active research, even evidence of evoked potential correlates of memory retrieval in V1 was reported (John et al., 1973; Bartlett et al., 1975; John et al., 1975). Additionally, the associative plasticity of V1 was emphasized by demonstrations that an experimenter-selected component of evoked responses could be operantly conditioned to change amplitude, contingent on the receipt of rewarding intracranial stimulation in the rat (Hetzler et al., 1977) and reward of liver and milk in the cat (Rudell, 1977). In contrast, the use of somatosensory conditioned stimuli was rarely, if ever, employed during this period.

Not surprisingly, as techniques were further developed for recording from behaving animals, research was extended to multiple-unit and even single-unit studies of plasticity. Much of the evoked potential and unit research used sounds as CSs because of convenience. Numerous laboratories demonstrated that learning-related increases in the amplitude of CS-elicited evoked potentials and unit discharges in the primary auditory cortex were indeed associative. For example, multiple unit discharges in A1 increase to a sound (CS+) paired with shock, decrease in response to a nonreinforced sound (CS−), and exhibit reversal when the CS+ and CS− are reversed. Moreover, the CSs come to elicit responses in the PSC of the unconditioned stimulus (i.e., S1), although with less specificity with respect to reinforcement contingency than in A1 (Oleson et al., 1975). For a general review, see Weinberger and Diamond (1987).

However, PSC plasticity in learning was generally ignored both within the neurobiology of learning and memory and also in the discipline of sensory neurophysiology. Several factors may have contributed to this state of affairs. For example, within learning and memory, the discovery of patient HM understandably focused attention on structures that appeared to be essential for memory, such as the hippocampus. In animal conditioning, attention was drawn to model systems, such as conditioned eyeblink and fear conditioning. Second, there was no conceptual framework within which to incorporate the findings of associative plasticity in sensory cortices, particularly as dominant assumptions of brain function restricted sensory cortices to the status of stimulus analyzers. Third, workers in learning and memory had no vested interest in sensory systems and therefore were not concerned that the research initiated by Galambos and colleagues disproved the view that sensory systems encoded only sensory parameters, not psychological parameters, such as the acquired behavioral significance of a stimulus. The ghost of A.W. Campbell might have smiled.

Neglect from sensory neurophysiologists might seen particularly unexpected because PSC plasticity has major implications. Thus, that learning modifies sensory cortical responses to physically constant stimuli implies that such neural responses are inherently ambiguous. For example, an increase in stimulus-elicited response magnitude might be due to an increase in stimulus intensity, an increase in its behavioral significance, or both. But it seems likely that sensory neurophysiology paid little heed to the learning findings both because of the dominance of the Campbellian formulation and the impoverished stimulus set used by behavioral neurophysiologists (myself included). Studies of associative learning typically

employ a small number of different stimuli. For example, standard conditioning studies use a single acoustic CS and discrimination studies use only two, a CS+ and a CS−. However, the concept of the receptive field is fundamental to sensory physiology. No sensory physiologist would attempt to describe the response properties of a cell with such a limited stimulus set.

But even within the neurophysiology of learning, a certain disquiet was growing. The EEG and evoked potential findings seemed fairly easy to interpret as either increased excitability or increased response to a behaviorally important CS. But single-unit studies invariability reported not simply increased discharges to the CS but also many instances of decreased discharges, even within the same study (Gasanov and Galashina, 1976; Woody et al., 1976; Weinberger et al., 1984b; Dumenko and Sachenko, 1979a,b). Although such cortical plasticity was shown to be associative, the findings of opposite sign made little functional sense. Thus, although recording in PSCs during training had provided foundational information, this approach appeared to be yielding diminishing returns after 50 years of use.

New questions were being asked. Whereas most prior studies had documented cortical plasticity during various phases of learning and in different structures and diverse tasks, a critical aspect of the functional significance of plasticity had not been adequately addressed. Missing was information concerning the specificity of cortical plasticity. As noted in the introduction, knowledge of the specificity of plasticity transcends the detection of a structure or group of neurons as being involved in learning and memory. Rather, knowledge of the specific changes in neural activity (i.e., not merely the fact of plasticity but also the substance of plasticity) provides insights into the type of information being processed and its role in learning and memory.

3.11.5 Specificity of Associative Plasticity in Primary Sensory Cortices: The Overarching Importance of Experimental Design

3.11.5.1 Introduction

What may reasonably be termed the contemporary era began in the 1980s with the use of a new experimental paradigm. It involved two major departures from prior research, in which neurophysiological recordings had been obtained principally during training trials. First, the new approach obtained neuronal data either after training in between-groups designs (Gonzalez-Lima and Scheich, 1984, 1986) or before and after training for within-subjects designs (Diamond and Weinberger, 1986; Weinberger et al., 1984a). Assessing learning after training was not unprecedented, as it had been standard in purely behavioral studies of learning and memory. It just hadn't been much applied to the neurophysiology of learning and memory.

Second, the new paradigm combined basic methods from sensory neurophysiology to determine the effects of learning on neuronal tuning. This latter method required the presentation of many different stimuli (e.g., acoustic frequencies) to obtain receptive fields and assess potential receptive field plasticity. Obviously, there was nothing new about this approach in neurophysiology. Neither was this method novel in learning and memory. In fact, training with one (or a few) stimuli but later assessing learning with many stimulus values had been done starting with Pavlov; it is the method of obtaining stimulus generalization gradients in learning. Apparently, it had not been applied to neurophysiological studies of learning and memory.

Before proceeding directly to a review of major findings in the study of specificity in PSCs, it will prove helpful to take a short detour to consider why recording during training is insufficient to determine the specificity of plasticity and some other critical factors about the new experimental approaches.

3.11.5.2 Cortical Plasticity during Training and Its Limitations

The standard approach to neural correlates of learning consists of obtaining neurophysiological recordings during training trials (the DUR design; see the section titled 'Primary auditory cortex (A1) habituation'). This very logical approach, almost universally used since the inception of research in the 1930s, is not restricted to the study of cortical plasticity but is applied to all brain structures (John, 1961; Thompson et al., 1972). However, obtaining recordings during training trials has at least two major limitations: (1) they can be influenced by state factors, and (2) they do not permit assessment of the degree of specificity of plasticity.

3.11.5.3 State Factors

First, nonlearning factors are invariably present during training, due in part to the presence of positive or negative reinforcement. These factors include, but are not limited to, changes in attention, arousal state, motivational level, and motor performance. For example, arousal level and motivational state alter evoked potentials and unit discharges in the auditory cortex (Murata and Kameda, 1963; Teas and Kiang, 1964; Wickelgren, 1968; Molnar et al., 1988). Moreover, the degree of influence of performance factors can vary during training trials. It may be high early in training, when subjects have not yet solved whatever problem confronts them, and then later decrease as solutions are found and as performance improves.

It must be emphasized that cortical plasticity obtained during training trials is usually associative. That factors such as motivational state are operative in no way weakens the case for associativity, given that the plasticity in question does not develop under nonassociative circumstances, such as random CS–US presentation. However, the associative plasticity may be influenced by state and similar factors, so that it is difficult to obtain pure associative effects.

Rescorla has emphasized the dangers of relying on behavioral data obtained during training to infer the strength of learning and those aspects of an experience that enter into memory. Rather, these attributes are best determined by appropriate posttraining assessments of behavior (Rescorla, 1985, 1988). This counsel is equally applicable to neurophysiological plasticity that develops during training trials. Although such plasticity may constitute adequate evidence that associative learning has a neural correlate (given controls for sensitization and pseudoconditioning), the form and magnitude of that correlate are not necessarily a reflection of associative processes alone.

3.11.5.4 Specificity of Plasticity

Second, and probably of even greater importance, recordings during training do not permit determination of the overall specificity of plasticity, because training protocols necessarily employ a limited number of stimuli along a dimension. For example, subjects may be trained with a visual stimulus, such as a vertical line followed by food reinforcement. If neurons in the primary visual cortex develop increased responses to that stimulus during training, then one can conclude that V1 cells develop associative plasticity during the task. (Of course, this assumes a control group that did not develop the plasticity when the vertical line and food were presented randomly, or equivalent control.) However, one cannot determine from such data alone if this cortical plasticity reflects changes in the processing and representation of line orientation *per se*. To resolve this issue, it would be necessary to interrogate the visual cortex with lines of many orientations after training. This could be done in a posttraining extinction session, as is routinely done when investigators obtain behavioral stimulus generalization gradients. As seen later, it is quite easy to obtain such information about the overall specificity of cortical plasticity in the absence of complications endemic to the use of extinction training (i.e., new learning that inhibits the prior learning).

3.11.5.5 Unified Experimental Designs

Both the potential problems of performance factors and the determination of specificity of cortical plasticity can be overcome by expanding the experimental designs to include assessment of plasticity by sensory neurophysiological approaches (unified designs). We describe the basic Pre-Post design and the Post design approaches (**Figure 1**).

3.11.5.5.1 The Pre-Post training trials design

The Pre-Post design allows the experimenter to determine how PSC information processing changes as a result of learning. This design involves a minimum of three stages: (1) pretraining recording, (2) actual training or other designated controlled experience, and (3) posttraining recording. The Pre and Post periods should present many sensory stimuli of interest (e.g., different frequencies of tone bursts, deflection of different whiskers, locations of targets in different visual quadrants). This contrasts with the standard presentation of a stimulus during a discrete training trial. The effects of the experiential treatment, whether habituation, classical conditioning, instrumental discrimination learning, or any other task, are determined by comparing the Post data with the Pre data. If the Pre and Post data are not statistically different, then one can conclude that the experience has had no effect on the processing or representation of the particular information under study. Conversely, significant differences between

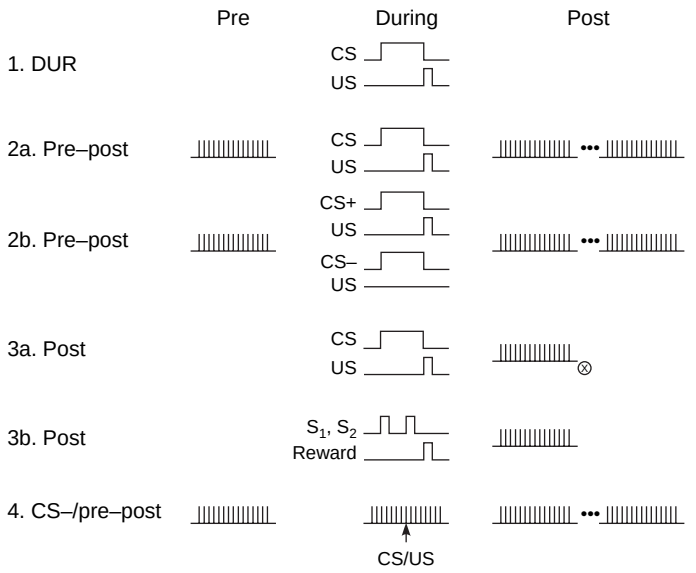

Figure 1 Schematic summary of experimental designs employed in the neurophysiological study of learning and the auditory cortex. Depicted are four basic designs (1–4) and their treatments during three experimental periods, Pre (before training), During (during training), and Post (after training). The DUR design is traditional, involving recording during training trials. Pre-Post designs 2a and 2b illustrate the fact that any training paradigm can be used. 2a shows single-tone conditioning, and 2b illustrates two-tone discrimination conditioning. Designs 3a and 3b also illustrate the fact that any training paradigms can be used with a Post design. 3a illustrates the case of single-tone conditioning, whereas 3b shows an example of two-tone instrumental training, in which reward is contingent on the correct response (i.e., one response if the two tones – S1 and S2 – are the same and another response if they are different) (responses not shown). The repeated vertical lines represent presentation of tone bursts. The dotted lines in the Post period for designs 2 and 4 indicate that additional Post periods can be used to determine long-term retention. In 3a, the x in the Post period signifies sacrifice of the animal for 2-deoxyglucose analysis following repeated presentation of a conditioned stimulus stone. In design 4, the conditioned stimulus (CS)/unconditioned stimulus (US) denotes that one of the frequencies in a series of tone bursts is designated as the CS and is paired with shock; the serial order of tones is random from one sequence to another. The problems with this design are that the behavioral state is likely to be different between the Post and Pre periods, and extinction is likely to occur in the Post periods (see text). Illustrations are not to scale.

the two periods can be attributed to the intervening experience (**Figure 1(2a), (2b)**).

It is essential that the test stimulus presentations be identical during the Pre and Post periods. Moreover, these data should be obtained in identical experimental settings to eliminate any confounds due to changes in the local environment context. No reinforcement is present during these Pre and Post tests, as that would defeat the goal of avoiding performance factors. However, despite the absence of a reinforcer, extinction learning does not develop during Post training assessment (see the section titled 'The importance of context').

It is also important to perform the training in a separate experimental setting, such as a different room with salient differences in visual and other nonauditory cues (see next section). Of course, it is important that the subjects be in the same state during the Pre and Post tests. This can be accomplished by amply habituating them to the testing (Pre and Post) situation, and this can be objectively assessed by recording heart rate or other physiological measures. Typically, heart rate is high when an animal is placed in a novel situation, but such tachycardia habituates fairly rapidly.

The Pre-Post design permits assessment of specificity while avoiding confounding performance factors that are present during training trials. Another advantage is that posttraining tests can be presented at desired intervals of hours to months, permitting detection of neural consolidation (i.e., increase in effect over time without additional training) and long-term retention or forgetting. This design also is very flexible because any desired training task can be used, yet the assessment of receptive field plasticity can be identical. This permits a direct comparison of the effects of learning on sensory representation for as many types of learning as may be of interest.

3.11.5.5.2 The importance of context: Elimination of performance factors and extinction

At least two issues are raised by this design. First, how does it eliminate or control for performance factors? Second, how does it avoid experimental extinction? (See also Diamond and Weinberger, 1989; Weinberger, 1998.)

Performance factors are reduced, if not eliminated, by minimizing similarities between the training context and the testing circumstances. The purpose of this maneuver is to reduce or eliminate any generalization from the training environment to the testing environment. For example, if an animal receives food or shock during training, it will also associate the location (context) of the training with these reinforcers. If tested in the same place, its arousal level and expectations could be affected.

Perhaps the most salient difference is the absence of a reinforcer in the Post period, which also reduces and can even eliminate changes in state (see the section titled 'The Post training trials design (POST)'). The Pre-Post design also permits sensory stimuli to be presented with several parameters that differ from the training session. Thus, training can consist of standard, discrete conditioning trials with standard parameters (e.g., an individual CS tone with a duration of 5s, a long intertrial interval of 1–2 min, and a stimulus level that is well above threshold (80 db SPL)). In contrast, determination of receptive fields can be accomplished with completely different parameters randomly presenting many tones to cover the frequency spectrum (e.g., 24 tones at quarter-octave intervals, 100 ms duration, intertone intervals of 400 ms, at stimulus levels of 0–80 dB SPL to cover the audible range). In short, the acoustic context of RF determination can be, and indeed must be, different from that during conditioning trials.

This difference in context has proven to be sufficient to eliminate any behavioral or arousal response to the CS frequency when it is embedded as a brief tone in a series of test tones. Objective measures indicate that subjects do not regard the CS frequency as a conditioned stimulus during determination of receptive fields (Diamond and Weinberger, 1989). In addition to the lack of performance confounds, elimination of potential effects of arousal to the CS frequency or any other tone can be accomplished by training subjects while they are awake (of course) but obtaining receptive fields while they are under general anesthesia (Weinberger et al., 1993).

Responses to the training stimulus during discrete trial presentation can, of course, be recorded, as long as the likely confound of performance factors is kept in mind. In such cases, it is beneficial to compare plasticity to a CS tone during training trials with plasticity in receptive fields as seen after training. Such a study revealed that there was little correspondence between changes to the CS during training with responses to that same frequency when it was presented as one of a series of rapidly presented frequencies in the Post period. In many cases, the sign of change was opposite (e.g., a decrement in response to the CS tone but a specific increase in response to that frequency during RF determination) when tuning might shift toward or to the frequency of the conditioned stimulus (Diamond and Weinberger, 1989).

The problem of experimental extinction is also eliminated by the Pre-Post design. As subjects do not regard the presentation of the frequency used as a CS as an actual CS, they neither respond to it nor extinguish during posttraining determination of receptive fields (Diamond and Weinberger, 1989).

A negative case illustrates the importance of appreciating the unified design (Ohl and Scheich, 1996, 1997, 2005). The authors failed to appreciate the difference between plasticity observed during training trials from plasticity observed in Post-training assessments. They used a tone-shock discrimination protocol in which a single CS+ tone was randomly intermixed with 11–30 different CS− (no shock) frequencies in a single training session. The same frequencies were presented before, during, and after training without break, so the presence of an occasional shock during training provided the only information that training was underway (**Figure 1(4)**). Relative to pretraining, the posttraining period exhibited a specific decrease in response to the CS frequency in A1. Unfortunately, no behavioral data were obtained, so there was no substantiation for the assumption that the animals had learned this unique, difficult discrimination. However, if learning had occurred, then the posttraining period would have constituted a period of extinction, due to the elimination of shock. Thus, the posttraining period undoubtedly differed from the pretraining period in the subjects' state of arousal and fear due to the anticipation of shock, and in the new extinction learning that shock was no longer forthcoming. Therefore, the findings might document a decrease in response to a CS frequency due to experimental extinction. The authors' claim that the behavioral importance of the CS is represented by a specific decrease in response seems unsupported.

3.11.5.5.3 The Post training trials design (POST)

The POST design has been used extensively in sensory neuroscience to determine the effects of peripheral sensory denervation or central insult (stroke) on the organization of primary auditory (Robertson and Irvine, 1989; Mount et al., 1991; Kaltenbach et al., 1992; Harrison et al., 1993), somatosensory (Kelahan et al., 1981; Rasmusson, 1982; Wall et al., 1986; Calford and Tweedale, 1988), and visual (Weisel and Hubel, 1963; Rauschecker et al., 1987; Heinen and Skavenski, 1991; Pettet et al., 1992) cortices.

Review of resultant plasticity is beyond the scope of this chapter, but a general conclusion is that peripheral denervation produces an expanded cortical representation of intact neighbors on the receptor epithelia: in the cochlea, on the body surface, and in the retina. However, these conclusions are necessarily oversimplifications, and the original sources should be consulted. What these sorts of studies do demonstrate is that adult PSCs are capable of considerable reorganization as a function of experience. Whether such experiences constitute genuine learning is unknown. Learning may well develop in animals and humans who find themselves with deficits in peripheral sensory capabilities. Of interest, prior learning can be necessary for adjustment or recalibration of a sensory system following peripheral impairment. Ferrets can relearn to localize sounds after reversible blocking of one ear, but only if they had been trained previously to use the relevant spatial cues (Kacelnik et al., 2006).

The considerations necessitating the Pre-Post design, and the advantages thereof, also apply to the POST design. Simply put, this design consists of recording only after the designated learning experience. Because of the absence of pretraining data, at least two groups are needed, one that receives the learning experience and a control group that either is not trained or preferably undergoes a different learning protocol (e.g., sensitization). The POST design has often been used when data can be obtained only once from a subject (e.g., in detailed terminal studies of cortical organization) (**Figure 1(3a), (3b)**).

3.11.6 Specificity of Associative Plasticity: Contemporary Approaches

The following sections review associative plasticity in the primary auditory, somatosensory, and visual cortices since 1985. The coverage is extensive but not exhaustive, as the goal is merely to establish PSC plasticity in learning and memory.

3.11.6.1 Primary Auditory Cortex (A1)

3.11.6.1.1 Habituation

Studies of habituation that used the DUR design had documented that repeated presentation of sounds results in a progressive response decrement in A1 (Marsh and Worden, 1964; Wickelgren, 1968). Specificity of habituation with control for state of arousal was first studied (before 1985) using a preliminary version of the Pre-Post design (Westenberg and Weinberger, 1976; Westenberg et al., 1976). Evoked potential was recorded in A1 of the waking cat. Two frequencies (A and B) were presented as alternating brief tone bursts (prehabituation). In the next stage, one tone (A) was presented repeatedly. Finally, the posttest was performed; the tones were again presented in an alternating pattern identical to the prehabituation phase. Average evoked potentials for each tone were determined separately for the pre- and posthabituation periods and compared. Because the Pre and Post tones alternated, the average responses were obtained for both A and B when the subjects were in the same state; hence, any differences between responses to the tones could be attributed to the effects of the intervening repeated stimulation with one frequency. The Post responses to the repeated tone (A) were significantly smaller than the Pre responses to this tone, but there was no difference for the nonrepeated (B) tone. Counterbalancing using repetitive presentation of B also yielded frequency specific decrements. These findings demonstrate that repeated acoustic stimulation produces frequency specific habituation.

The Pre-Post design has been expanded to determine the entire frequency receptive field (RF, tuning curves) of auditory cortical neurons in waking guinea pigs (Condon and Weinberger, 1991). After researchers determined the tuning of unit clusters and ensured their stability, subjects received single tone pips at the rate of 1.25 Hz for 5–7 min. Habituation produced a decreased response that was specific to the frequency that had been repeatedly presented; frequencies 0.125 octaves from the habituated frequency exhibited little or no response decrement. Consolidation, in the form of continued increased development of specific decrements, was often observed for periods as long as an hour. This attribute links frequency-specific habituation to other forms of memory.

3.11.6.1.2 Conditioning

In this section we consider studies of the specificity of plasticity in A1 induced by associative learning. Research to date has focused on classical and instrumental conditioning, with the implication that investigation of these heavily studied forms of learning is an appropriate entry point into the issue of specificity.

Gonzalez-Lima and Scheich (1984, 1986) investigated the specificity of plasticity by determining the effects of conditioning on the uptake of 2-deoxyglucose (2-DG) after training. As this necessitated a terminal treatment of the subjects, the authors used a between-groups POST design. (The use of metabolic measures permits investigation of specificity without using many different stimuli when the locus of stimulus representation in a PSC map is known.) Gerbils received tone paired with strong aversive electrical stimulation of the mesencephalic reticular formation or a control treatment (e.g., CS–US unpaired, CS alone, US alone). The paired group alone developed the behavioral index of learning, conditioned bradycardia. All groups received continual presentation of the CS alone during an injection of 2-DG in a posttraining session. As this treatment may involve some experimental extinction, the associative findings might be considered somewhat weakened. Nonetheless, analysis of patterns of 2-DG uptake in A1 revealed a CS-specific increase in metabolic activity for the cortical area that represented the CS frequency. The absence of similar effects in the other groups showed that the CS-specific plasticity was associative.

The first use of the Pre-Post design with receptive field (RF) analysis involved single units in two nonprimary auditory fields, secondary (AII) and ventral ectosylvian (VE) cortices (Diamond and Weinberger, 1986, 1989; Weinberger et al., 1984a). Cats were trained in a single, brief (20–45 trials) session of tone-shock pairing. Behavioral learning was validated by the formation of the pupillary dilation conditioned response. CS-specific plasticity was found in the paired group, but not when tone and shock were unpaired. Some cells developed a CS-specific increase, whereas others developed a CS-specific decrease. Extinction produced loss of the RF plasticity. The findings received little notice, probably because these auditory fields were not well understood.

Similar studies were then undertaken in A1 of the guinea pig with behavioral validation of associative learning (e.g., conditioned bradycardia). Following determination of frequency receptive fields, the frequency to be used as the CS was then selected to not be the best frequency (BF, peak of the tuning curve) to determine whether conditioning caused shifts of tuning toward the CS frequency. Animals then received a single session (30–45 trials) of tone paired with shock. A comparison of posttraining with pretraining RFs revealed a dominance of CS-specific increased responses. Moreover, responses to the pretraining BF and other frequencies tended to decrease. These opposing changes were often sufficiently large to produce frank shifts of tuning toward, and even to, the frequency of the CS, which could become the new BF (Bakin and Weinberger, 1990) (**Figure 2(a)**). RF plasticity was found to be associative, as it required stimulus pairing; sensitization training produced only a general increase in response to all frequencies across the RF (Bakin and Weinberger, 1990; Bakin et al., 1992).

CS-specific increased responses in RFs also can develop when tuning curves are complex and even nonexistent. **Figure 2(b)** shows an example of a pretraining double-peaked frequency RF. The CS frequency was selected to be in the valley between the peaks. Posttraining, the maximum change was an increase in response at the CS frequency. **Figure 2(c)** illustrates a case in which there was no response to any frequency before conditioning. Nonetheless, postconditioning observations revealed a clear excitatory response to the previously ineffective CS frequency, alone.

Several other attributes of RF plasticity make it an attractive candidate for a process that operates in normal concert with sensory coding processes to subserve the storage of behaviorally relevant auditory information. First, RF plasticity is highly specific to the CS frequency; responses to frequencies a small fraction of an octave away are attenuated. Second, it exhibits generality across different types of training (e.g., instrumental avoidance conditioning) (Bakin et al., 1996), two-tone classical discrimination training (i.e., increased responses to the CS+ frequency but decreased responses to the CS−, BF, and other frequencies) (Edeline and Weinberger, 1993; Edeline et al., 1990), and discriminative instrumental avoidance conditioning (Bakin et al., 1996). Third, RF plasticity develops very rapidly, after only five training trials, as rapidly as the first behavioral (e.g., cardiac) signs of association (Edeline et al., 1993). Fourth, RF plasticity exhibits long-term retention, enduring for the longest periods tested, up to 8 weeks after a single 30-trial conditioning session

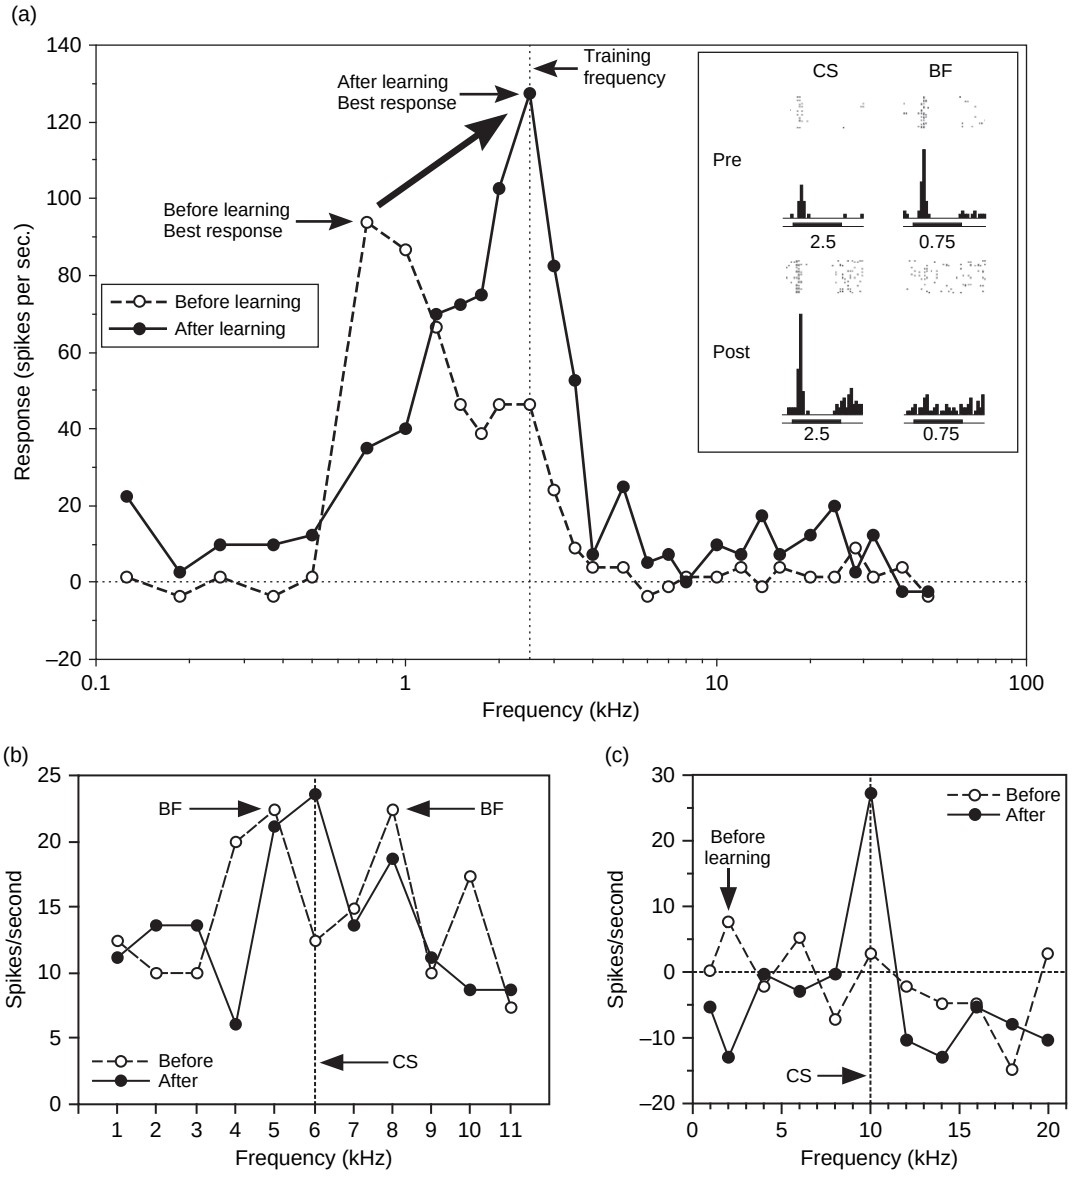

Figure 2 Classical conditioning produces conditioned stimulus (CS)-specific facilitation and tuning shifts. (a) An example of a complete shift of frequency tuning of a single cell in A1 of the guinea pig, from a pretraining best frequency (BF) of 0.75 kHz to the CS frequency of 2.5 kHz after 30 trials of conditioning. Inset shows pre- and posttraining poststimulus time histograms (PSTHs) for the pretraining BF and the CS frequencies. (b) Double-peaked tuning, with pretraining BFs at 5.0 and 8.0 kHz. The CS was selected to be 6.0 kHz, a low point. After conditioning (30 trials), responses to the CS frequency increased to become the peak of tuning. (c) A cell that exhibited minimal or no response to tones before tuning developed tuning specifically to the CS frequency after conditioning (30 trials).

(Weinberger et al., 1993). Fifth, RF plasticity exhibits consolidation (i.e., continues to develop increased responses to the frequency of the CS *vs.* decreased responses to other frequencies in the absence of further training over hours) (Edeline and Weinberger, 1993) and days (Weinberger et al., 1993; Galvan and Weinberger, 2002).

CS-specific associative tuning shifts develop in the primary auditory cortex of diverse taxa. Thus, studies of fear conditioning (tone, shock) in the big brown bat demonstrate not only that learning induces tuning shifts but that these can develop with small absolute differences in frequency in these echolocating animals (Gao and Suga, 1998, 2000; Ji et al., 2001; Ji and Suga,

2003; Suga and Ma, 2003). Nonassociative controls did not develop tuning shifts. In these studies, leg flexion was used to validate associative learning, but the use of a fixed (30-s) intertrial interval does not rule out possible effects of temporal conditioning.

Kisley and Gerstein questioned whether tuning shifts are caused by learning because they observed tuning changes over days in the absence of training (Kisley and Gerstein, 1999). This concern was rather curious because spontaneous shifts had previously been eliminated as tuning shifts are directional (toward the CS), associative, and discriminative, that is, toward the CS+, not the CS– (Bakin and Weinberger, 1990; Bakin et al., 1992; Edeline and Weinberger, 1993).

The authors next studied classical conditioning, pairing a tone with intracranial self-stimulation (Olds, 1962). In so doing, they extended inquiry to another species, the rat, and another type of motivation, reward (Kisley and Gerstein, 2001). Animals underwent a single 30-trial session of classical conditioning. Subjects were studied under light ketamine anesthesia throughout, rather than in an undrugged waking state (see also Edeline, 1990). Behavioral evidence of conditioning to the tone was nonetheless obtained. The authors did find that conditioning produced CS-specific plasticity, including shifts of tuning toward or to the frequency of the CS. Also in agreement with prior studies, this RF plasticity was associative because it required CS–US pairing. The learning effects were above and beyond any spontaneous changes, which were indexed by reduced day-to-day correlation coefficients actually between entire tuning curves. However, the authors did not actually measure tuning by tracking the best frequency over days. The reduced correlations reflect the fact that responses to all frequencies within a tuning curve received equal weighting in the statistical analysis. Thus, decreased correlations might well be caused by loss of weak responses to frequencies distant from the BF (i.e., at the lower and upper limits of the tuning curves). The stability of tuning has been established over periods of 2–4 weeks, during which time there were no drifts of the best frequency (Galvan et al., 2001).

As RF plasticity is not an artifact of spontaneous changes in tuning, neither is it an artifact of state. As noted earlier, whereas animals exhibit arousal and related responses to sustained (e.g., 2–5 s) CS frequencies during training trials, they do not exhibit any behavioral responses to the frequency of the CS when it is presented as one of a number of rapidly presented, brief (e.g., 200-ms) sequential tone pips during RF determination (Diamond and Weinberger, 1989). Moreover, animals trained in the waking state exhibit RF plasticity when tested under deep general anesthesia (Lennartz and Weinberger, 1992b; Weinberger et al., 1993).

Learning induced tuning plasticity is not limited to animals. The same paradigm of classical conditioning (tone paired with a mildly noxious stimulus) produces concordant CS-specific associative changes in the primary auditory cortex of humans (Molchan et al., 1994; Schreurs et al., 1997; Morris et al., 1998).

In summary, RF plasticity has major characteristics of associative memory. It is not only associative but is also highly specific, discriminative, rapidly acquired, retained at least for many weeks, develops consolidation over hours and days, and exhibits generality across training tasks, types of motivation, and species. Thus, RF plasticity in the auditory cortex reflects the learned importance of experiences. **Figure 3** summarizes changes in tuning for conditioning, sensitization, and habituation.

The associative specificity of tuning for acoustic frequency raises the issue of whether the observed effects indicate a special type of adaptation for frequency or are exemplars of a general neural strategy for the processing, representation, and storage of experience. Recent studies have addressed this issue by determining the effects of associative processes on parameters other than acoustic frequency.

Bao and colleagues (2004) trained rats in a sound maze in which food reward was contingent on successful navigation using only auditory cues. In this task, the repetition rate of noise pulses increased as the distance between the rat and target location decreased. After subjects had learned this maze, the responses of neurons in A1 were investigated in a terminal posttraining session. A1 cells exhibited enhanced responses to high-rate noise pulses and stronger phase-locking of responses to the stimuli. The effects were due to learning because controls that had received identical sound stimulation, but were given free access to food, failed to exhibit such plasticity of temporal processing and, in fact, were not different from naive subjects. Thus, learning produced a shift in tuning to high repetition rates (i.e., the stimulus feature that was most closely associated with procurement of food).

The plasticity of sound intensity (level) processing has been investigated in A1 (Polley et al., 2004b). Rats were trained to move to a place in a small arena at which sound levels to ongoing sound bursts

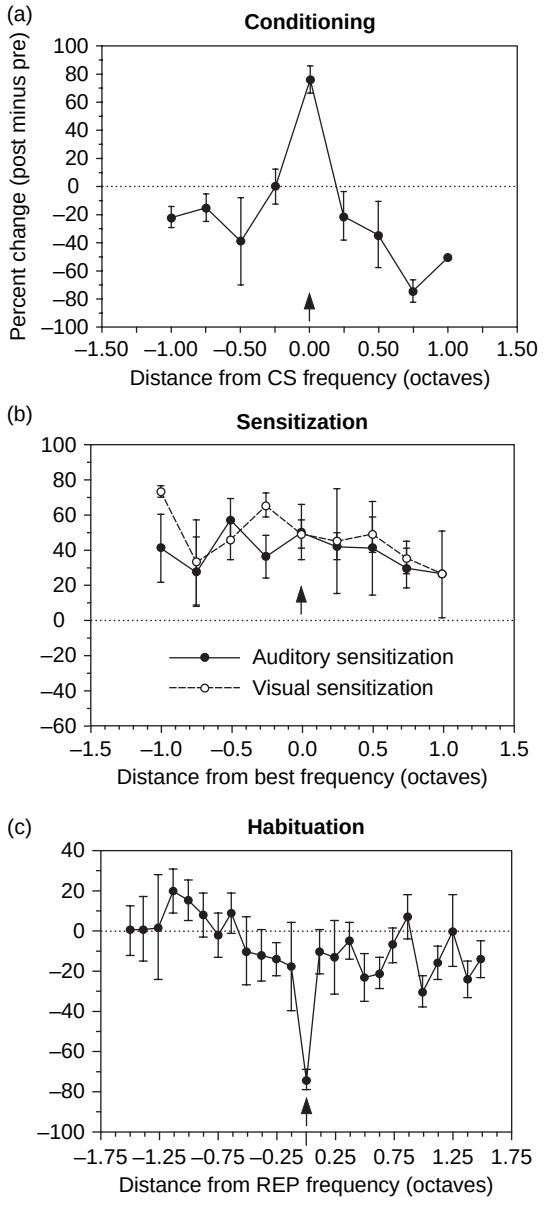

Figure 3 Summary of the effects of conditioning, sensitization, and habituation on frequency receptive fields in the primary auditory cortex of the guinea pig. Data are normalized to octave distance from (a) the conditioned stimulus (CS) frequency, (b) the presensitization best frequency, or (c) the repeated frequency. Note that conditioning produces a CS-specific increased response, whereas sensitization (tone–shock or light–shock unpaired) produces general increases across the spectrum. Habituation produces frequency-specific decreased response.

became maximal. They were guided by having stimulus levels increase as the subject moved closer to the otherwise unidentified locus, and contrary, levels were reduced as the rats moved farther away. Yoked controls received the same acoustic experience, which was not linked to their behavior. In trained animals only, A1 responses became selective to more restricted ranges of sound intensities. The findings indicated that associative processes can selectively modify the representation of stimulus magnitude.

3.11.6.2 Primary Somatosensory Cortex (S1)

Stimulation (deflection) of the mystacial vibrissae of the rat has often been the conditioned stimulus of choice in the study of associative plasticity in S1, specifically in the posteromedial barrel subfield (PMBSF, hereafter whisker barrel field) (Welker, 1976; Simons, 1978). Early studies simply paired the deflection of a vibrissa that elicited little response at a particular barrel recording site with that of a subsequent deflection of a whisker that did elicit an excitatory response; a typical CS–US interval was 500 ms. In many cases, pairing produced an increased response to the CS (Delacour et al., 1987, 1990a,b). When a whisker is stimulated alone continuously, the response in S1 declines, probably due to habituation, whereas subsequent pairing with shock enhances response amplitude (Kublik, 2004). Such studies were not concerned with the specificity of plasticity and included neither nonassociative controls nor behavioral evidence of learning. However, the findings attested to the malleability of the vibrissal system in the adult, waking animal.

The specificity of plasticity, with nonassociative controls, has been studied in this system. The findings appear to be generally concordant with studies of auditory cortex. That is, tactile stimuli that gain behavioral significance as signals for reinforcement appear to gain cortical territory. For example, pairing the deflection of a row of mystacial vibrissae (CS) with a tail shock (US) in mice produces behavioral evidence of conditioning (e.g., postural changes and/or CS-elicited bradycardia). The following day, S1 was analyzed using with 2-DG mapping of functional activity. Conditioning sessions produced an increase of the functional representation in somatosensory cortex of the specific CS row of the whiskers stimulated during the training. The effect is associative, as it did not develop in pseudoconditioned mice or in animals that received only the CS. When training was discontinued, the enlargement of vibrissal representation returned to baseline. This loss of

specific associative plasticity could be accelerated by extinction training (CS alone) (Siucinska and Kossut, 1996).

As in the case of the auditory cortex, CS-specific increased representation is not limited to aversive reinforcement. Mice received pairing of whisker stimulation with a drop of sweet water. Cortical representations of rows of whiskers were mapped by 2-DG autoradiography after 3 days or 2 months of training. No quantified behavior was obtained, although the authors noted increased activity to the CS. In any event, conditioning resulted in enlargement of the cortical representation of vibrissae comprising the CS, compared with the contralateral representation of a row of whiskers that were not stimulated. Interestingly, the duration of training affects laminar plasticity. Three sessions increased the width of the 2-DG activity in supra (II/III) and infragranular (V/VI) layers, whereas the effects of 2 months of training were confined to layer IV. The changes were not observed in animals that received whisker stimulation alone or unpaired stimuli (Siucinska and Kossut, 2004).

Recently, Disterhoft and colleagues have used the well-studied conditioned eyeblink response to study associative changes in the representation of vibrissae in S1 (Galvez et al., 2006). Rabbits received deflection of a single row of whiskers (CS), followed by corneal air puff after a 500-ms trace period. Trace conditioning is known to require an intact hippocampus in contrast to delay conditioning (i.e., no intervening trace period) (Solomon et al., 1986; see also Beylin et al., 2001; Bangasser et al., 2006). The subjects developed conditioned responses over a period of 7–9 days, in contrast to pseudoconditioned rabbits. Barrels were identified by cytochrome oxidase staining and confirmed by single-unit electrophysiology. The authors found a specific expansion in the representation of the CS row of whiskers, compared both to the control animals and to the nontrained hemisphere, showing specific associative plasticity.

Matthew Diamond and coworkers have argued that, "if memories are stored within topographically organized sensory cortical areas, then access to those memories should be topographically distributed" (Harris et al., 2001b: 316). In one study, rats were trained on a gap-crossing task using the only whisker that had not be trimmed. After successful learning, the trained whisker was clipped and a prosthetic whisker attached to a different whisker stub. Transfer was tested by the rate of new learning, which was inversely related to the distance between the original and new whisker. Electrophysiological recordings revealed that the degree of overlap between cortical response patterns of two whiskers could account for the degree of transfer ($r = 0.98$) (Harris et al., 1999).

They also trained humans to use one fingertip to discriminate between two stimuli in the submodalities of vibration, punctate pressure, and roughness. Tests of posttraining generalization (transfer) to digits on the trained and untrained hands revealed no transfer for vibration but positive transfer for pressure and roughness discrimination as a function of topographic distance from the trained fingertip. The authors concluded that "tactile learning is organized within a somatotopic framework" (Harris et al., 2001a: 1056). Interestingly, Pavlov had predicted the existence of somatotopic cortical organization on the basis of similar training and generalization tests in dogs (Pavlov, 1927).

3.11.6.3 Primary Visual Cortex (V1)

In contrast to the primary auditory and somatosensory cortices, there appear to be no studies of the specificity of associative processes in the primary visual cortex. This is curious in light of the previous extensive investigation of V1 in classical and instrumental conditioning in animals during the period of 1935–1984. As noted earlier, most subsequent studies of V1 have focused on perceptual learning. Recent reports of classical conditioning in humans may indicate a resurrection of interest in associative learning. Functional magnetic resonance imaging (fMRI) has been used to investigate Pavlovian delay fear conditioning, using a blinking red light as the CS and shock as the US (Knight et al., 1999). Paired subjects exhibited a larger amount of active tissue in V1 compared to controls that received light and shock unpaired. However, the individual group effects were a decrease in response in the controls and no change in the paired group, suggesting that associative processes prevented habituation in this case. The absence of a behavioral measure of learning limits interpretations as well.

A further study of both delay and trace (10 s) conditioning has been more revealing. Using a discrimination protocol in which the three conditioned stimuli (CS+, CS+ trace, and CS−) were different colored shapes, the authors found significant behavioral learning and discrimination (development of conditioned galvanic skin responses, GSR) for both delay and trace protocols. Functional MRI responses

were larger to the CS+ versus CS− in delay conditioning and also larger to the CS+ trace versus the CS− in trace conditioning.

Perhaps similar studies will be conducted in animals using a stimulus dimension (e.g., line tilt) that could determine receptive field plasticity and thus reveal the extent of specificity of associative processes in V1. Given the earlier EEG and evoked potential studies, as well as the recent fMRI experiments, there is reason to expect that, like A1 and S1, V1 is specifically involved in associative learning and memory.

3.11.7 Do Lesions of PSCs Impair or Prevent Learning and Memory?

A frequently asked question (which I paraphrase) is, "As associative plasticity develops in PSCs, shouldn't lesions of PSCs impair or prevent conditioning? If not, why be interested in plasticity that would appear to be epiphenomenal?" The answer to the first question is based on studies of A1, for which the relevant findings are known. The simple answer is "No." It has long been known that simple (i.e., single-tone, nondiscriminative) classical conditioned responses can develop after ablation of A1 alone or as part of extensive cortical destruction (DiCara et al., 1970; Berntson et al., 1983; Romanski and LeDoux, 1992).

However, these questions are based on certain assumptions, which include (1) neurophysiological studies of conditioning seek stimulus–response (S-R) circuitry, (2) the memory trace formed is localized, (3) neurophysiological plasticity that develops is the substrate of the CR, and (4) destruction of the site of such plasticity should disrupt the CR (see Ohl and Scheich, 2004, vs. Weinberger, 2004a).

These assumptions may be relevant to learning a single, specific S-R relationship, such as learning to produce a conditioned eyeblink to a tone paired with air puff (Christian and Thompson, 2005). However, they do not apply to the vast majority of associative learning, which involves stimulus–stimulus (CS–US) links. First, classical conditioning transcends stimulus–response associations. Even S-R conditioning involves prior stimulus–stimulus (CS–US) associations. Moreover, other associations are invariably formed, such as between a stimulus and the location or general context within which learning occurs. Second, CS–US associations are known to develop rapidly, in a few trials, preceding CS–CR associations (Lavond et al., 1984), and therefore are likely be involved in the development of S–R links (Schlosberg, 1937; Mowrer, 1947; Konorski, 1967; Lennartz and Weinberger, 1992a). Third, multiple behavioral CRs develop during rapid CS–US learning (e.g., changes in heart rate, respiration, blood pressure, pupillary diameter, skin resistance, behavioral freezing), any one of which can be used to verify that a CS–US association has developed (of course, given appropriate nonassociative controls). Fourth, although its components may be localized, the total memory for a given event is almost certainly distributed across the cortex and other brain regions, including relevant sensory systems. Fifth, although circuitry for an association can be completely subcortical, the cerebral cortex also can store information in parallel with subcortical systems. Sixth, the cerebral cortex has access to a much greater range of information than the subcortex. It undoubtedly stores information that can be used in a highly flexible manner to subserve adaptive behaviors in an unknown future. For example, although simple auditory conditioning is not destroyed by lesions of A1, as soon as two-tone discrimination is demanded, A1 is required (Teich et al., 1988). A1 is also obligatory to achieve experimental extinction (Teich et al., 1989).

Thus, in response to the question posed at the outset of this section, PSCs can be profitably studied to determine the cortical fate of stimuli that enter into associations. In short, such studies of neurophysiological plasticity can be directed to issues of the representation of stimuli and the transformations, which they may develop during learning, without any reference to particular behaviors that index the establishment of stimulus–stimulus associations.

3.11.8 Memory and Retrieval in Primary Sensory Cortices

As primary sensory cortices develop highly specific representational plasticity in learning, they may be expected to exhibit memory. One such case has already been mentioned, that of a 2-month retention of CS-specific tuning shifts in A1 (Weinberger et al., 1993). Further, memory codes in PSCs have been proposed. Memory codes specify the relationship between an experience and the nature of its neural storage (e.g., the memory code for the acquired behavioral importance of a stimulus might be the number of cells that become tuned to that stimulus)

(Weinberger, 2001). We now summarize additional evidence of mnemonic processes in A1, S1, and V1.

3.11.8.1 Working and Reference Memory

If PSCs store at least some contents of memory, then they should hold that information for a period of time following presentation of a stimulus. There is evidence that the primary somatosensory cortex is involved in working memory. Monkeys trained in a haptic delayed matching to sample (DMTS) task (two different objects), with an 18-s delay period, exhibit sustained changes in activity of neurons in S1 (Koch and Fuster, 1989). Similar effects were also found in a haptic DMTS study in which objects were identical in shape but differed in surface features (Zhou and Fuster, 1996). Patterns of spike trains, not merely changes in unit firing, also are correlates of working memory in S1 (Bodner et al., 1998; Bodner et al., 2005).

Disruption of working memory in S1 also has been found. Humans were trained to discriminate the frequencies of two vibrations presented at an interval of 1500 ms. A pulse of transcranial magnetic stimulation (TMS) applied to the contralateral S1 early in the retention period of the first vibratory stimulus (600 ms or less) impaired discrimination performance. There was no effect when TMS was applied to the ipsilateral S1. The authors concluded that S1 serves as a temporary site of information storage (Harris et al., 2002).

Sakurai's laboratory has documented neural correlates of working memory and also long-term storage (reference memory) in A1. Rats were trained in a continuous nonmatching-to-sample working memory task to remember whether or not the current tone frequency was the same or different from the preceding tone. About 20% of single units in A1 (and the medial geniculate as well) developed sustained differential activity during the delay period after exposure to the sample tone, leading the authors to conclude that the thalamocortical auditory system retains auditory information in working memory (Sakurai, 1990). The task was then modified so that either working memory (WM) or reference memory (RM) could be tested in alternating fashion within a single session (Sakurai, 1992). Unit recordings were obtained from hippocampus CA1, CA3, dentate gyrus, and A1. Only the auditory cortex showed differential responses to the physical characteristics of the stimuli, low and high tones, respectively, in both WM and RM tasks. This itself is not surprising. Cells in the hippocampal formation exhibited changes in firing related to either WM or RM but not both. In contrast, neurons in A1 could exhibit increased activity for both the WM and RM tasks, indicating the flexible involvement of A1 in both working and reference memory (Sakurai, 1994). Further research using cross-correlations between pairs of neurons to detect cell assemblies revealed that most correlated pairs in the hippocampal formation occurred during WM, whereas correlated cells in A1 could participate equally in WM and RM (Sakurai, 1998). The results highlight the flexibility of the same cells in PSCs to participate in multiple functional networks.

3.11.8.2 Procedural Memory

There is at least one report that links PSC neural plasticity to procedural memory. Rabbits trained in eyeblink conditioning (tone/corneal air puff) developed tone-elicited neural responses in primary somatosensory cortex together with conditioned eyeblink responses. However on trials of CR failure, there was also an absence of S1 responses to the acoustic CS. It might be thought that both omissions were due to a failure to process the CS, perhaps in the lower auditory system. However, on such failure trials, the unconditioned response was still modulated by the CS, as indexed by more vigorous unconditioned responses, compared to unconditioned response–alone trials. Another explanation might be that the response in S1 represented sensory feedback from CRs, but its latency preceded CRs. The authors concluded that the response of S1 to the acoustic CS reflects the efferent copy of the memory of the response that was elicited by the CS from the cerebellum, which they view as a procedural memory trace (Wikgren et al., 2003).

3.11.8.3 Imagery

If cortical networks involved in memory storage and retrieval include PSCs, then they should reveal themselves in the absence of relevant sensory stimulation. That is, neural activation should occur when the prior sensory experiences are recalled. Although probably less widely accepted than some other approaches, studies of imagery in humans support such involvement. Imagery often is considered to be a higher cognitive function, but it seems most relevant to retrieval in the present context. Bearing in

mind caveats concerning precise localization and the need to validate the presumptive imagery behaviorally, there is evidence for the involvement of PSCs. For example, imaging studies have detected activation of V1 after subjects studied novel visual stimuli while they had to make decisions about visual details with their eyes closed. Further, the extent of activation of V1 was proportional to the size of the stimulus feature being remembered, supporting the view that imagery was taking place within the retinotopic map (Kosslyn et al., 1995, 1999).

Somatosensory imagery effects also have been reported. S1 was imaged in humans during the tapping of a finger. When subjects later imagined tapping the finger, the same region of S1 was activated (Porro et al., 1996). One cannot rule out undetected kinesthetic stimuli or subthreshold motor contributions to these findings, however. Studies of musical imagery are less subject to such problems. For example, imagery for musical timbre activates the primary auditory cortex with some right-side asymmetry, also present for timbre perception (Halpern et al., 2004; see also Halpern and Zatorre, 1999; Halpern, 2001; Zatorre and Halpern, 2005).

3.11.9 Nonsensory and Higher Cognitive Functions

In addition to associative processes, PSCs are also involved in nonsensory and higher cognitive processes. These are summarized alphabetically.

3.11.9.1 Attention

Attention has long been known to modulate sensory cortices. Although many effects are seen in higher areas, PSCs are also subject to selective attention, such as auditory (Alho, 1992), somatosensory (Johansen-Berg and Lloyd, 2000), and visual (Sengpiel and Hubener, 1999). However until recently, studies of attention had not been able to demonstrate the extreme specificity of rapid attentive modulation in PSCs. Fritz, Shamma, and colleagues devised a clever and sensitive method of obtaining spectrotemporal receptive fields (STRFs) while ferrets waited to detect a previously learned tone to avoid shock. They found that attention modulates primary auditory cortex by facilitating responses to the target frequency while suppressing responses to other frequencies (Fritz et al., 2003). When trained in both frequency detection and frequency discrimination tasks, the reinforced and target frequencies were enhanced, as might be expected, but because the target during tone detection (CS+) could be the nonreinforced (CS−) frequency during discrimination, the authors were able to show that responses to the same physical stimulus could be facilitated or suppressed depending on the task (Fritz et al., 2005b). In a third study, ferrets learned both tone detection and gap detection tasks. As expected, tone detection had the same target-specific enhancement. Additionally, during gap detection, the STRF was changed along the temporal dimension, specifically, the temporal dynamics of discharge were sharpened (Fritz et al., 2005a). In all the studies, the effects could last for hours in some cases, suggesting an involvement in memory as well as in selective attention. Overall, the findings demonstrate that attention has a strong influence on A1. At least some of this plasticity is due to top-down processes because switching tasks, and therefore the significance of a particular frequency, differentially affects responses to the same physical stimulus. The findings also highlight the ability of the same cells to participate in multiple adaptive networks. Of course, RF shifts in learning could be the result of top-down, bottom-up, or a combination of these influences.

3.11.9.2 Category Learning and Concept Formation

Perceptual category formation involves grouping sensory stimuli by abstract relationships based on some aspect of similar physical attributes. Ohl et al. (2001) trained rats to form the categories of rising and falling frequency modulation of tones (i.e., independent of their absolute frequencies). They detected category learning by a sudden change in learning strategy. Recordings from A1 revealed that the transition to category formation was correlated with the emergence of patterns of stimulus representation in the EEG in which frequency-modulated tones are distinguished into the categories of rising and falling modulation. The authors believe that the electrographic plasticity reflects the abstraction that defines these categories (Ohl et al., 2001). Categorical effects have also been observed in monkeys trained for more than 2 years to classify steps in acoustic frequency (Selezneva et al., 2006). The authors found that phasic activity of cells in A1 indicates the direction of frequency steps, whereas slow changes in activity are tied to procedures involved in solving the task.

A recent related experiment extends the involvement of auditory cortex to humans. Subjects were required to classify sound on the basis of either the direction of change (rising or falling frequency modulation) or the duration of stimulation (short or long). fMRI revealed activation in the right auditory cortex for categorization by direction of change, whereas categorization by duration of stimulation activated the left auditory cortex (Brechmann and Scheich, 2005). The hemispheric specializations for the two types of stimulus parameters are consistent with prior studies of the human auditory cortex, but the linkage of the findings to categorization, rather than to the physical parameters of the stimuli *per se,* demonstrates that the human auditory cortex is involved in higher cognitive processes.

3.11.9.3 Cross-Modality Effects

Associative involvement of PSCs is also evident in cross-modal effects, consisting of a stimulus in one sensory modality being able to elicit responses in the PSC of another sensory modality. Indeed, cross-modality effects are so numerous that their significance is generally overlooked. They began with the EEG studies of conditioning. For example, the development of the ability of the click of a camera shutter to block alpha waves in the human occipital cortex when it preceded a flashing light US is evidence for cross-modal effects, although in this serendipitous seminal study, the authors could not have detected actual auditory evoked responses in visual cortex (Durup and Fessard, 1935). In animal studies of conditioning, the ability of the CS to elicit EEG activation in the PSC of the US is similarly an example of cross-modality effects. Beyond EEG findings, direct studies of evoked sensory responses consistently documented the development of CS-elicited responses in the PSC of the US (Oleson et al., 1975).

Recent studies reinforce these earlier findings. For example, studies in which primates are cued to perform a tactile discrimination by an auditory or visual stimulus found the development of responses to the auditory (Zhou and Fuster, 2004) and visual cues (Zhou and Fuster, 1997, 2000), respectively, in the primary somatosensory cortex. The reverse relationships also exist. For example, monkeys were trained to perform a complex auditory discrimination. Following presentation of a cue light, they could initiate a sequence of tones by pressing a bar. Many neurons in A1 developed responses elicited by the bar press, of course, prior to the presentation of the sounds. And given the prevalence of cross-modality neural responses, one would predict that presentation of the cue light also would elicit responses in A1, and this also was observed (Brosch et al., 2004).

Similar effects are reported in A1 of humans. Several studies have linked the primary auditory cortex of humans to speech in the absence of sound. Thus, the presentation of visual stimuli associated with language sounds, whether the sight of a letter or of silent speech, elicits neural activity in the primary auditory cortex (Sams et al., 1991; van Atteveldt et al., 2004; Pekkola et al., 2005; Ruytjens et al., 2006). This cross-modal effect might derive from earlier associative learning, as the sight of a face, especially the lips, during speech is highly correlated with hearing the emitted speech. Some effects are not limited to putative associations. Visual stimuli can be transformed into a phonological code. Apparently, the left primary auditory cortex is activated during such recoding (Suchan et al., 2006).

A recent anatomical study in the gerbil may provide an anatomical basis for some cross-modality effects. The authors found a surprisingly large number of inputs to A1 from nonauditory regions of both the cortex and the thalamus. They argue against the view that primary sensory cortices are unimodal (Budinger et al., 2006).

3.11.9.4 Expectancy, Preparatory Set

Subjects previously trained on a task form expectancies or preparatory sets that are based on the probability that a certain stimulus or event is likely to occur. Although generally regarded as a higher cognitive function, they are manifest in PSCs. In one such case, rats were trained in a visual reaction time task with a very brief (10-ms) warning tone, 1.4 s preceding the light stimulus. A subset of single neurons in A1 developed a significant sustained increase in discharge rate during the warning period that did not occur when the same warning stimulus was given by itself. The authors suggested that this activity constitutes a substrate of preparatory set (Shinba et al., 1995). A phasic increase in arousal might have been responsible for increased cellular activity, as preparatory set and expectancy often involves increased arousal. Direct measures of arousal level and recordings taken in arousing situations outside the task would help resolve this issue.

A more detailed study by Villa and coworkers provides compelling evidence for an expectancy function in A1 (Villa et al., 1998). They obtained

simultaneous single-unit spike trains while rats performed a complex cognitive task, specifically a two-choice task (Go/NoGo) with a two-component (pitch and location) auditory stimulus lasting 500 ms. They observed that functional interactions (cross-correlations) are dynamically modified in the waiting period preceding the onset of auditory stimulation. Further, they found spatiotemporal firing patterns both within and across spike trains several seconds before the actual stimulus delivery. These patterns have a very precise repetition of spike discharges separated by long intervals (up to several hundreds of milliseconds) in the absence of a change in mean rate. The authors suggested that network activity in A1 reflects "participation of recurrent neuronal networks in processes anticipating the expected sensory input" (Villa et al., 1998: 269).

3.11.9.5 Motivation, Behavioral Importance

Several studies have found plasticity in PSCs based on motivational level or the acquired behavioral importance of sensory stimuli. In a complex appetitive instrumental task, rats were trained in three phases, and the amount of c-Fos expression was determined in different subgroups at the end of each phase: (1) tone–food association, (2) two-tone discrimination, and (3) two-tone discrimination contingent on location of the sound source. Auditory stimuli were bursts of complex sounds lasting 500 ms. Compared to various control groups, successful animals exhibited no difference in phase 1 but had significantly greater cFos activity in primary auditory cortex during the next two phases. No subcortical auditory structures (cochlea through medial geniculate) differed from controls (Carretta et al., 1999). The authors concluded that auditory cortex is involved in the coding of stimulus significance. Of note, their failure to find an effect after simple tone–food association suggests that not all associative learning involves PSC plasticity. Moreover, it is clear that more complex learning (i.e., discrimination problems) is more likely to engage a PSC.

Although the previous study neither manipulated the level of motivation nor determined specificity of plasticity, a recent experiment addressed these issues directly. Rats were trained to bar press for water contingent on the presence of a tone (6.0 kHz), each at different levels of water deprivation. Terminal mapping of A1 revealed a specific increase in area of representation of the CS frequency in the tonotopic map. More importantly, the amount of area was directly proportional to the level of correct performance, itself controlled by the level of motivation for water (**Figure 4**) (Rutkowski and Weinberger, 2005). These findings were predicted by the memory code hypothesis that the level of behavioral significance of a stimulus is encoded by the increase in the number of cells that become tuned to that stimulus (Weinberger, 2001).

The primary visual cortex has been studied during associative learning only rarely during the past 30 years. However, V1 has now been linked to reward processes. Rats wearing goggles that provided controlled stimulation to either eye were trained to associate whole-field illumination with water reward. Many neurons in V1 that originally responded only to the visual stimuli developed discharges that accurately predicted the timing of the reward (Shuler and Bear, 2006).

There is evidence of motivational effects in the barrel field of S1. Rats were studied under conditions of (1) searching for an object with their vibrissae for a food reward, (2) whisking in the air for the goal of returning to the home cage, or (3) whisking in the absence of reward (Ganguly and Kleinfeld, 2004). The amount of phase-locking of neurons in S1 was greatly increased when whisking resulted in reward compared to whisking without reward.

3.11.9.6 Learning Strategy

The strategies used to solve problems are significant factors in human cognition. However, the role of learning strategy has been neglected in studies of learning and brain plasticity. A recent study reveals that learning strategy can be decisive in the development of specific plasticity in the primary auditory cortex. Two groups of animals were trained to solve the same problem, achieve the same asymptotic level of performance, and exhibit the same degree of learning about absolute frequency, but accomplish these goals using two different learning strategies. Specifically, adult male rats were trained to bar-press for water contingent on the presence of a 5.0-kHz tone. A bar-press response made during the silent intertrial interval resulted in a time out (i.e., 3–7 s lengthening of time to the next trial) signaled by a flashing cue light. This apparently simple problem can be solved two ways: 'bar-press during tone presence' ('tone duration strategy') or 'bar-press from tone onset until receiving the error signal' ('onset-error strategy'). However, these alternatives cannot

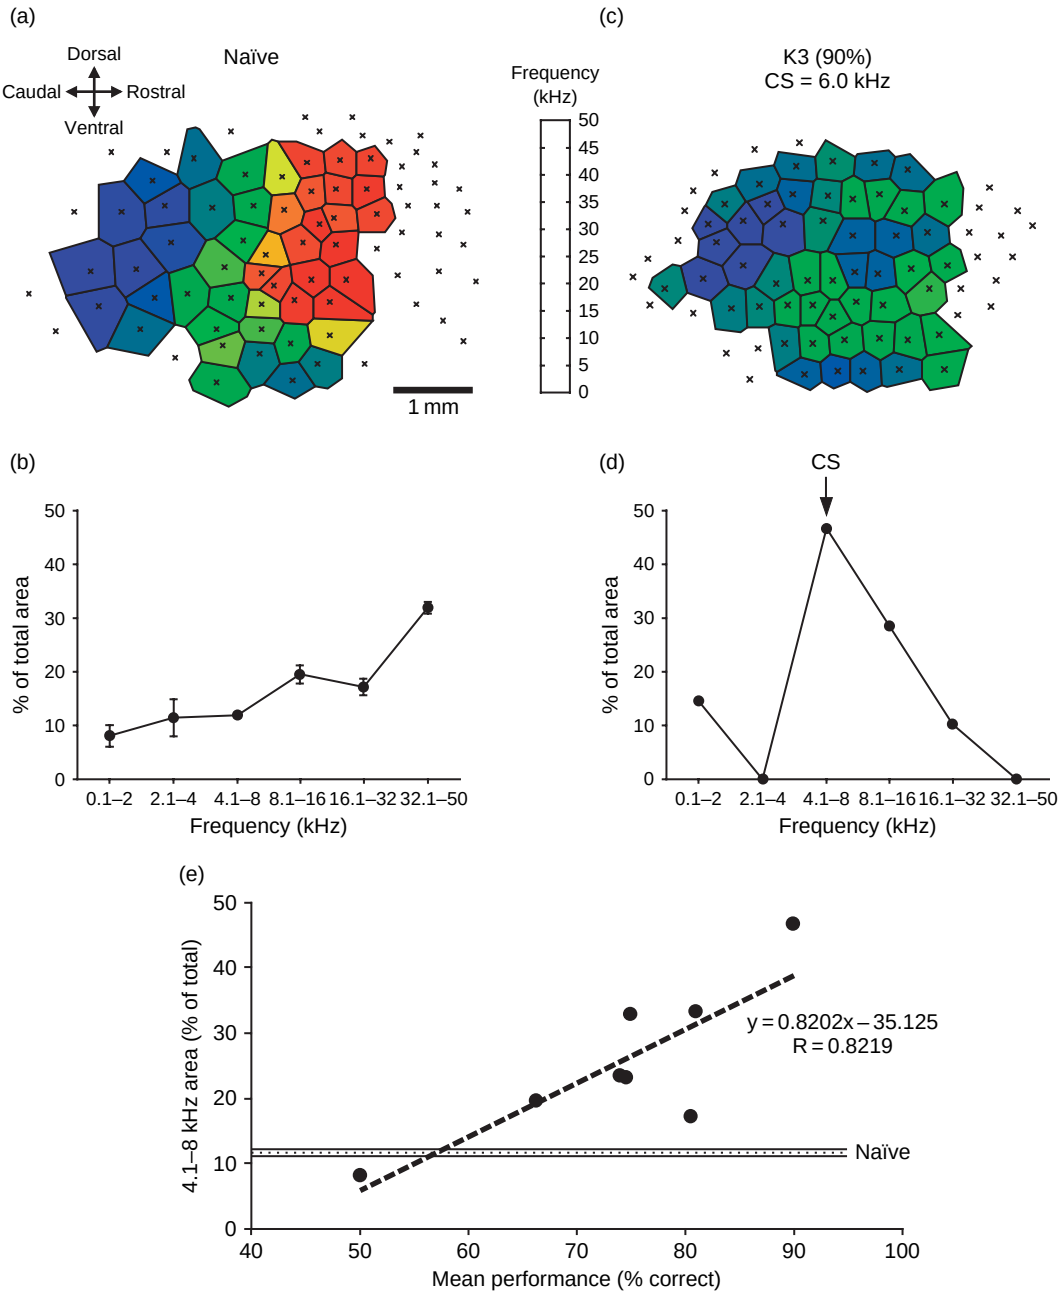

Figure 4 Motivational effects on area of frequency representation in tonotopic map of A1. Trained rats received water reward for bar-presses in the presence of a 6.0-kHz tone. (a). The tonotopic maps of a naive rat. (b). Quantification of the percent of total area for each six octave bands for the map above. (c). The tonotopic map of a subject that attained over 90% correct performance. (d). The corresponding quantification. Note that the band containing the CS frequency is much greater (~50% vs. ~10% in the naive). (e). Evidence of a memory code for the acquired behavioral importance of sound. Level of tone importance was controlled by the motivation for water (amount of water deprivation). Asymptotic performance was significantly correlated with motivation level. The area of representation of the frequency band containing the 6.0-kHz tone signal increases as a direct function of the level of behavioral importance of the tone, as operationally indexed by the level of correct performance. For details, see Rutkowski RG, and Weinberger NM (2005) Encoding of learned importance of sound by magnitude of representational area in primary auditory cortex. *Proc. Natl. Acad. Sci. USA* 102: 12664–13669.

be distinguished because error signals are always given for responses made starting immediately after tone offset. Therefore, although one group was trained in the standard manner, a second group was given a 2-s grace period starting at tone offset, during which bar-presses did not produce the error signal (or water reward). Evidence for the 'onset-error strategy' would be continued bar-pressing after tone-offset during the grace period.

Both groups achieved the same high levels of correct performance, and both groups revealed equivalent learning of absolute frequency during training. Analysis of behavior showed that the second group did indeed use the 'onset-error strategy.' Posttraining 'mapping' of the auditory cortex revealed that this group alone developed specific plasticity. Threshold was decreased ~10 dB, and tuning bandwidth was narrowed by ~0.7 octaves. Moreover, this plasticity was restricted to the frequency band of the 5.0-kHz tone cue. The findings show both that auditory learning can develop without plasticity in threshold or bandwidth and, perhaps more important, that learning strategy – not learning performance – can determine cortical plasticity (Berlau and Weinberger, 2008).

3.11.9.7 Motor Processes

It might seem most unlikely that primary sensory cortices could be intimately linked to motor functions, but there is clear evidence of motor involvement. Within A1, patterns of neuronal activity constituted predictive neural correlates of later motor behavior. Rats were trained in a Go/NoGo task to distinguish combinations of two frequency-modulated sounds (based on low- [3.0 kHz] or high- [12.0 kHz] base frequencies) and two speaker locations (left or right). They were rewarded for correct Go and NoGo behavior (e.g., Go to low tone on left, NoGo to high tones simultaneously from left and right). Single-unit discharges were recorded simultaneously from up to 15 neurons while animals waited for the auditory cues. Using a pattern-detection algorithm, the authors detected 235 reliable spatiotemporal patterns of activity, 55% of which were significantly related to the type of response that the animal made several seconds later. Patterns predictive of Go and NoGo behaviors were about equal in number. Note that the predictive correlates were not elicited by the acoustic stimuli, which were delivered after the waiting period (by definition). Of particular interest, mean discharge rates did not vary, emphasizing the importance of the analysis of temporal parameters of cellular discharge. The patterns in A1 might be parts of motor programs that are engaged in auditory tasks (Villa et al., 1999).

3.11.10 Concerning the Direction of Plasticity

Heretofore, we have not focused on the direction or sign of changes in the magnitude of PSC plasticity. (Plasticity of temporal aspects of cellular discharge may be equally important but has not yet been studied extensively in PSCs during learning; see Edeline, 1999.) The dominant, almost exclusive, finding in conditioning has been that stimuli that gain behavioral importance become facilitated, as indexed by the fact that they come to elicit increased magnitude of response. (Of course, memory in habituation is indexed by a decrease in response magnitude.) Larger responses could be advantageous by increasing the signal-to-noise ratio when the task at hand is stimulus detection. In many cases, increased response involves CS-specific tuning shifts and increased area of representation, indicative of the recruitment of more cells to the CS or other important stimulus. As noted previously, the amount of increased area of representation is directly proportional to the level of behavioral importance of a tone (Rutkowski and Weinberger, 2005). More cells could also increase the probability of attention to stimuli whose behavioral significance has increased due to learning. The strength of memory might be an increasing function of the number of cells that preferentially involved the sensory experience. The favored processing of important stimuli by more cells could also increase the probability of complete processing in an unknown future, including one of neuropathology. In the latter case, more cells could serve the function of a safety net. Thus, increased response magnitude would seem to make good functional sense. If associative processes produced decreased responses or reduced the number of cells tuned to an important stimulus, in the limit to zero, then the stimulus in question would seem to decrease, or lose, its ability to be stored and to guide current and future behavior.

But increased magnitude of response is undoubtedly only part of the complete story of PSC plasticity. Observations from studies involving naturalistic environmental situations indicate that specific decreased responses are the likely outcome of at least some

experiences (for review, see Frostig, 2006). For example, many formulations of PSC plasticity are based on a competition model, in which stimuli that produce more afferent input win (i.e., elicit larger responses and/or gain control of more cells). This outcome is prevalent in the whisker barrel field of S1 for surviving whiskers when others are clipped (Armstrong-James et al., 1994; Diamond et al., 1993). However, when the vibrissae are not altered, the representation of a whisker is smaller during active exploratory whisking than during quiet wakefulness (Fanselow and Nicolelis, 1999). Spared whiskers exhibit reduced representation when rats are permitted to explore for brief periods outside their home cages (Polley et al., 1999), and the same occurs for the intact vibrissal system when animals live for weeks in a naturalistic habitat, including tunneling, which makes increased demands on the use of whiskers (Polley et al., 2004a). Behavioral arousal, expected during active whisking, produces reduced representation coupled with increased synchronization of firing, resulting in sharper receptive fields that could subserve increased discrimination (Castro-Alamancos, 2004).

These studies did not involve explicit associative learning. However, one cannot discount the possibility of associative learning during naturalistic whisking. That is, an episode of whisking involves numerous instances of stimulus–stimulus relationships (e.g., successive tactile stimuli constituting within-modality sensory preconditioning). However, naturalistic situations are not optimal for determining fine-grain stimulus relationships. The trade-offs between increased ecological relevance in field or fieldlike studies and decreased manipulation of stimulus relationships are well known.

Exploratory whisking may also be related to .-perceptual learning, as animals have had uncountable trials of experience, discriminating objects by use of their vibrissae. The possibility that decreased responses reflect mechanisms underlying perceptual learning is supported by a recent study of frequency discrimination in A1 of the cat. Decreased responses were found for frequencies between the CS+ and CS−, during extended tonal perceptual learning. The authors suggest that such plasticity may facilitate the classification of stimuli with different behavioral outcomes by reducing similarity between reinforced and nonreinforced stimuli (Witte and Kipke, 2005). This finding contrasts with rapid two-tone discriminative learning (i.e., a single training session), in which responses to the CS+ are increased while responses to the CS−, pretraining BF, and other frequencies are reduced, the effects becoming even more pronounced during a subsequent silent period of consolidation (Edeline and Weinberger, 1993).

In summary, rapid associative learning appears to be dominated at present by findings of increased responses to behaviorally important stimuli. In contrast, extensive discrimination learning, particularly formal learning of increasingly difficult discriminations (i.e., perceptual learning), may involve reduced response magnitude with concomitant increased precision of receptive fields. However, a comprehensive understanding of the sign of plasticity must await further research of the relationships between the direction of PSC plasticity and its functional and behavioral significance.

3.11.11 Implications

The primary auditory, somatosensory, and visual cortices develop associative plasticity during behaviorally validated learning. They exhibit evidence of the storage of memory, including procedural, working, and reference memory, the latter validated for an indefinite period of at least months after training. Recent studies have revealed a high degree of specificity of plasticity in A1 and S1 (appropriate studies of V1 have not been conducted), including a remodeling of cortical processing that emphasizes responses to signal stimuli of acquired behavioral importance and indicative of the storage of discrete details of experience. Moreover, A1, S1, and V1 are clearly involved in a number of higher processes including attention, expectancy/preparatory set, category learning/concept formation, cross-modality interactions, imagery, learning strategy, motivation, and the degree of acquired behavioral importance of stimuli and motor actions.

This range of involved functions amply documents the extensive engagement of PSCs in adaptive cognitive and behavioral processes that far transcend their presumptive normative sensory functions. Space permits brief consideration of four implications.

First, primary sensory cortex, as commonly functionally understood, does not exist. There is probably no region of the cerebral cortex that is devoted only to the analysis of sensory stimuli; certainly, A1, S1, and V1 are not so limited. It follows that the responses of all neurons in these PSCs are almost certainly affected both by nonsensory processes (such as the acquired meaning of a stimulus) and the physical parameters of modality-specific stimuli as commonly studied in sensory neurophysiology. The caveat is that the cell type

that generates each type of neural response cannot yet be known, a task that may require many years to complete. So it is possible that some types of PSC cells respond only to the physical parameters of stimuli but so far have escaped detection.

Second, the developing concept that information is stored where it is processed, which attributes mnemonic functions to PSCs (as well as myriad other cerebral structures) may be correct but highly incomplete. For example, concept and category formation deal with abstract properties of stimuli, not merely their root physical parameters. Therefore, PSCs appear to serve supra-stimulus functions.

Third, and a related point, because the degree of plasticity reflects the level of acquired behavioral importance (Rutkowski and Weinberger, 2005), motivational information that is presumably not assessed in PSCs is nonetheless represented therein (see also Shuler and Bear, 2006). Therefore, PSCs appear to serve extrastimulus functions.

Fourth, normative concepts of cortical organization need to be revised. Because of specific, associative plasticity in PSCs, they cannot be distinguished from other cortical regions on the basis of sensory versus associative functions. Campbell was wrong, and all theories based on such a distinction are obsolete. Formulation of new, testable organizational principles is perhaps the major task facing the integrative neurobiology of the cerebral cortex.

3.11.12 Toward a New Functional Architecture of the Cerebral Cortex

Kuhn's analysis of scientific revolutions holds that extant but outmoded paradigms are not discarded until a new paradigm accounts both for old facts and newer, inharmonious findings (Kuhn, 1970). The issue of new principles for the functional organization of the cerebral cortex is far beyond the capabilities of this chapter. However, as its major point has been to show that primary sensory cortices are involved much more broadly in learning, memory, cognition, and adaptive behavior than generally recognized, one approach to thinking anew about cortical organization is to consider PSCs from a different point of view. With that in mind, I suggest the following.

First, the sensory specialization of each PSC must be retained. Regardless of cross-modality influences, V1 is specialized for vision, S1 for somatic sensation, and A1 for audition. But if they are not purely sensory, then what are they?

Second, I propose that PSCs deal with their modality-specific information in the context of solving whatever problem, challenge, or opportunity faces the organism. We may regard them as continually assembling components to form situational functional systems (see also Anokhin, 1974).

Thus, PSCs are reconceptualized as having three types of function: (1) modality-specific sensory, (2) learning/memory, and (3) broadly integrative with respect to modality-dominated problem solving.

For example, if a specific motor act is required with respect to acoustic stimulation, then the auditory cortex integrates (unknown aspects of) motor function with the analysis, acquisition, and storage of information about the relevant sound. The result would not be confined to auditory information but, rather, auditory information combined with relevant motor and spatial information for the situation in question. This may explain why selective lesions of frequency bands within the tonotopic map of A1 in the cat produce selective impairment of locomotion to the source of the corresponding sound frequency (Jenkins and Merzenich, 1984).

In no case would A1, S1, or V1 execute the requisite behavioral act. Nor would they assess or determine the motivational state or determine the nature goal object, such as food, water, or opportunity for sex. Nonetheless, they would be major sites in which the relevant information is brought together. PSCs would not be the only sensory cortical sites because belt and higher sensory regions would be involved as well. In fact, the manner in which all PSCs and their related higher fields work together, with both feedforward and feedback interactions, remains a central problem for cortical function.

As animals face many problems, including gathering information without the need for immediate effector action (overt behavior), it follows that their PSCs must be able both to store a multiplicity of relevant modality-specific information while also being able to rapidly organize and mobilize the appropriate information as environmental situations, challenges, and opportunities appear – often rapidly. The available data do indicate that the same PSC cells not only participate in multiple behaviorally relevant networks but also can rapidly switch mode as the task changes (Sakurai, 1994, 1998; Fritz et al., 2005a,b; see also Gilbert et al., 2001).

We currently have little information about multifunctional aspects of PSCs because the issue has seldom been broached and so few appropriate experiments have been conducted. Fortunately, their

involvement in learning and memory is now on such solid ground that it can provide a foundation for further inquiry about other cognitive processes. Although learning-induced plasticity is now widely accepted, it is often contrasted with much greater plasticity during development, the adult animal being regarded as retaining some developmental plasticity. However, instead of regarding associative plasticity as an add-on to sensory processing, the default position probably should be that PSCs store information as a normal part of their functions.

Clearly, this liberalized view of PSCs is preliminary and really little more than an outline of an idea. However, even in its nascent state, it offers an alternative to the traditional sensory role of primary auditory, somatosensory, and visual cortices. If it does nothing more than provoke thought and reaction, it will have served a beneficial purpose. However, I believe that although further characterization of PSCs is needed, it is now time to seek the functional principles governing the involvement of A1, S1, and V1 in learning, memory, and a multiplicity of nonsensory processes.

We may currently be as explorers in a strange land, approaching a barely discernible, yet clearly existing, mountain range. At present, details cannot be seen, and perhaps different peaks can barely be distinguished, but by continuing the journey, the detailed topography will be discovered eventually, as well as the inner geology. Perhaps we truly have only a dim view of the functional principles of the cerebral cortex. The next steps should be revealing, but they require a willingness to travel from the comfort of the conceptually comfortable to the extreme discomfort of a landscape fraught with unknown and perhaps strange hazards.

Acknowledgments

This chapter was supported by research grants from the National Institutes of Health/National Institute on Deafness and Other Communication Disorders (NIDCD), DC-02938 and DC-05592 to N.M.W.

3.12 Visual Priming

K. Grill-Spector, Stanford University, Stanford, CA, USA

3.12.1 Introduction

A fundamental property of the brain that distinguishes it from artificially constructed computational devices is its ability to continuously update its functional properties based on prior experience. This property, plasticity, is apparent in many forms of learning and memory in humans. One important manifestation of plasticity in the brain is priming: the behavioral phenomenon of improved processing of a stimulus following prior experience. Priming typically manifests as increased accuracy and/or faster speed in making judgments on a stimulus that has been previously encountered (**Figure 1**). It is thought to reflect an implicit form of memory and learning, as it does not involve explicit memory of the prior experience.

This chapter is concerned with visual priming (priming related to presentation of visual stimuli) and the neural correlates underlying this phenomena. Visual priming is one of the most ubiquitous manifestations of priming and has been extensively studied in many levels from the behavioral level to the neural level in both humans and animals. Thus, visual priming is an excellent model to study plasticity in the visual system and its relation to object perception. Studying the neural mechanisms of visual priming is important because it enables understanding the neural bases of cortical representations as well as the mechanisms involved in rapid implicit learning. In particular, recent interest for understanding priming and its neural correlates has been heightened as an increasing number of scientists use priming methods to characterize representations in the human brain.

This chapter is organized into three main sections: it begins with a review of the behavioral aspects of visual priming, then examines neuroimaging experiments of the neural correlates of priming, and concludes with a theoretical overview of three models that have been recently suggested for explaining the neural bases of priming.

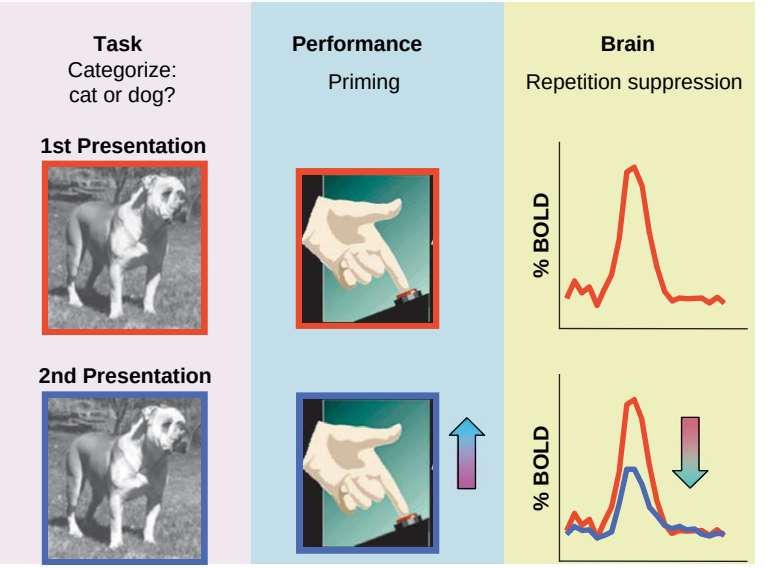

Figure 1 Schematic illustration of priming and repetition suppression/adaptation. *Left:* subjects are asked to perform a task, for example, classify an object. *Middle:* performance is measured on the first presentation and subsequent presentations of the same stimulus. During repeated presentations (e.g., the second presentation), performance improves (i.e., priming), as indicated by the arrow. Typically, accuracy increases and response time decreases. *Right:* Brain activity in object-selective cortex measured during the same experimental conditions shows lower BOLD responses for repeated presentations (blue) of the object compared to the initial presentation (red).

3.12.2 Behavioral Aspects of Visual Priming

In a typical priming experiment, subjects are shown an initial stimulus (prime) and are required to make a decision (e.g., categorize the stimulus; **Figure 1**) or produce a response (generate a word) on a subsequent stimulus (test) that is identical or related to the initial stimulus (e.g., the same object in different views, or a new object that is related perceptually, conceptually, or semantically to the prime). The priming effect (i.e., improvement in performance) is largest when the repeated stimulus is identical to the initial stimulus (prime). In some behavioral paradigms of priming, many intervening stimuli occur between the test and the prime. However, in other paradigms, the test immediately follows the prime. One particular striking aspect of priming is that it can be manifested after a single exposure to an object and is preserved in timescales ranging from seconds to even an year (Cave, 1997).

The level of priming is modulated by several factors such as the number of stimulus repetitions, the number of intervening stimuli, and the time between repeats (**Figure 2(a)**). The magnitude of response time (RT) priming increases with the number of stimulus repetitions both in short timescales (seconds/minutes) and in longer timescales (days and weeks), and this advantage remains over week-long delays compared to single exposures of stimuli (Brown et al., 1996). Similarly, RT priming is largest when there are no intervening stimuli between the prime and the test stimulus and when the temporal interval between them is shortest (**Figure 2(a)**). Thus, immediate repetitions produce a larger priming effect compared to when repetitions occur after several minutes or days (van Turennout et al., 2000; Sayres and Grill-Spector, 2006). Interestingly, the graded nature of priming is reliable even in patients who are unable to remember the stimuli or judge the frequency of these stimuli in explicit tests (Wiggs et al., 1997).

Another important aspect of visual priming is its specificity, because visual priming has been used as an experimental tool to infer the characteristics of object representations. Visual priming is preserved even when the appearance of objects changes across repetitions. Visual priming is invariant to changes in object size (Cooper et al., 1992; Fiser and Biederman, 1995), position (Cooper et al., 1992), color (Cave et al., 1996), symmetry (Fiser and Biederman, 2001), and to some degree the viewing angle of the object (Biederman and Bar, 1999; Biederman, 2000). However, a recent experiment suggests that there

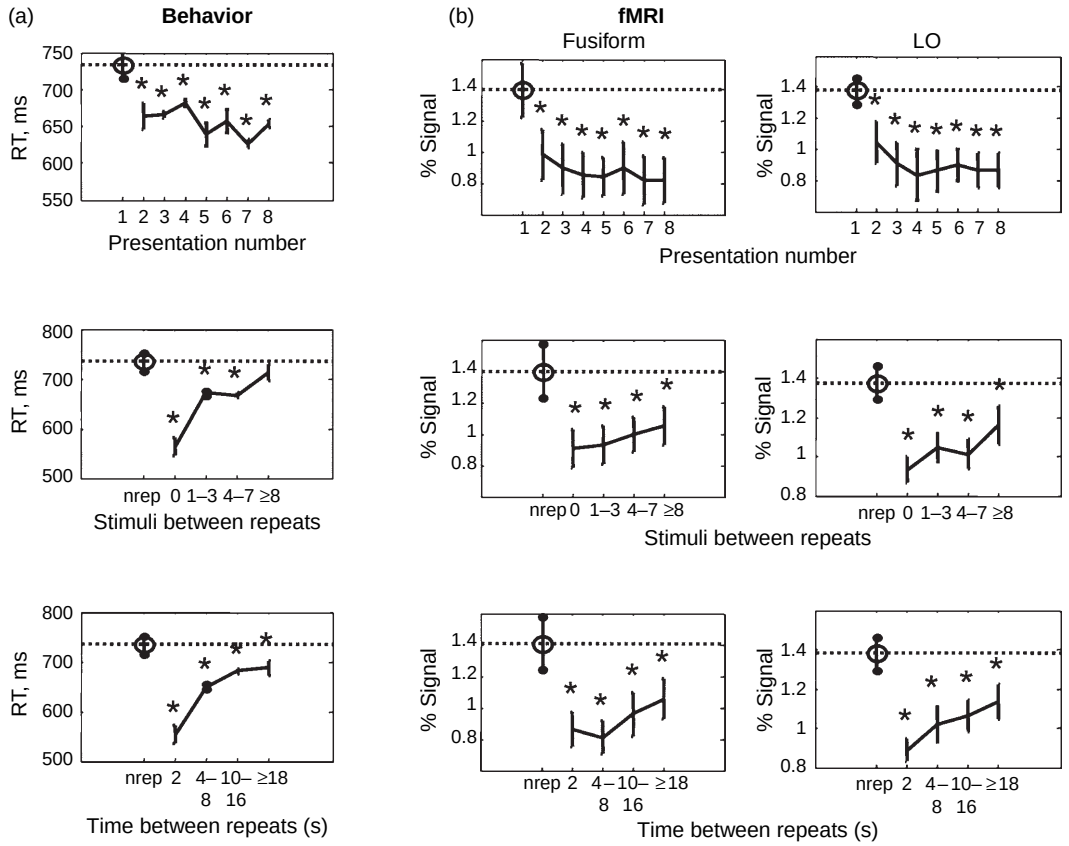

Figure 2 Effect of repetition parameters on priming and repetition suppression in object-selective cortex as measured with functional magnetic resonance imaging (fMRI). (a) Mean response time. (b) BOLD response amplitude for object-selective regions in the fusiform gyrus (middle) and lateral occipitus (LO) (right). Error bars indicate SEM across eight subjects. BOLD responses are averaged across hemispheres. Asterisks indicate significantly lower than first presentation ($p < .05$). Dashed line: response to the first presentation. *Top:* sorting by presentation number. *Middle:* sorting by intervening stimuli between repeats. *Bottom:* sorting by time between repeats. Adapted from Sayres R and Grill-Spector K (2006) Object-selective cortex exhibits performance-independent repetition suppression. *J. Neurophysiol.* 95: 995–1007.

may be an interaction between the effects of shape and location on visual priming (Newell et al., 2005). Further, visual priming is diminished but still preserved for new exemplars from the same category (e.g., upright piano vs. grand piano). Experiments in which subjects viewed stimuli that were presented either in the right or left visual field suggest differential priming effects across the left and right hemispheres; priming effects show higher specificity when stimuli are presented to the left visual field, as they do not generalize across object rotation and exemplars of a category, whereas priming effects generalize across exemplars and rotation when stimuli are presented to the right visual field (Marsolek, 1995; Burgund and Marsolek, 2000; Koutstaal et al., 2001; Vuilleumier et al., 2002; Simons et al., 2003). These experiments have led to suggestions that object representations in the right hemisphere are more specific than left-hemisphere representations, which may be more abstract in nature (Marsolek, 1995; Burgund and Marsolek, 2000; Koutstaal et al., 2001; Vuilleumier et al., 2002; Simons et al., 2003).

Several lines of research suggest that visual priming is an implicit form of learning and memory. A particularly important finding is that priming occurs in amnesic patients even though they are unaware of prior exposure to the primed stimulus (Tulving et al., 1991; Hamann and Squire, 1997) and they are significantly impaired on explicit tests (such as recognition memory, recall, and recollection of contextual information) on the same stimuli (Hamann and Squire, 1997).

Another striking aspect of priming is subliminal priming (Dehaene et al., 1998; Bar and Biederman,

1999; Naccache and Dehaene, 2001), that is, priming without awareness of the content of the priming stimulus. For example, Bar and colleagues (Bar and Biederman, 1999) showed subjects briefly presented stimuli (average 47 ms) that were masked. Subjects' naming performance on these stimuli was low (~14%). However, when the same stimuli were presented for the second time, naming performance on primed stimuli significantly increased (to about 35%). Subliminal priming may show higher specificity than suprathreshold priming, as it generalizes only to objects presented in the same hemifield. Therefore, Bar and colleagues have suggested that subliminal priming may be mediated by neural mechanisms distinct from suprathreshold priming. Other priming experiments of briefly presented masked stimuli show that the magnitude of priming is larger for the specific items that were primed compared with other exemplars of the category (Furmanski and Engel, 2000; Grill-Spector et al., 2000), and that priming effects increase across days and repeated exposures (Grill-Spector et al., 2000) and generalize across object size (Furmanski and Engel, 2000). Further, experiments of subliminal priming of words show generalization of priming effects across fonts and letter size (Naccache and Dehaene, 2001).

Overall, evidence from amnesic patients and subliminal priming experiments suggests that awareness may not be necessary for priming. These experiments lead to the prevailing theory that posits that priming reflects an implicit form of memory that is distinct from explicit memory and that relies on distinct neural and cognitive mechanisms.

3.12.3 Neural Correlates of Priming

Many studies have investigated the neural correlates of priming in humans using functional magnetic resonance imaging (fMRI), electroencephalography (EEG), and magnetoencephalography (MEG). Under experimental situations similar to behavioral paradigms of visual priming, the most robust and consistent finding with fMRI is reduced brain activations to repeated presentations of a stimulus relative to the initial presentation of that stimulus (**Figure 3**). This reduction has been referred to as repetition suppression (RS), fMRI-adaptation (Sobotka and Ringo, 1994; Ringo, 1996; Grill-Spector and Malach, 2001), mnemonic filtering (Miller et al., 1993), repetition suppression (Desimone, 1996), decremental responses (Brown and Xiang, 1998), and neural priming (Maccotta and Buckner, 2004). We use RS to refer to decreased neural responses following stimulus repetition. However, it remains mysterious how reduced cortical responses provide for improved performance. Further, although the most ubiquitous cortical phenomenon related to stimulus repetition is reduced responses, in some cases there is evidence for increased responses with stimulus repetition or repetition enhancement (RE) (Dolan et al., 1997; George et al., 1999; Grill-Spector et al., 2000; Henson et al., 2000; James et al., 2000; Kourtzi et al., 2005; James and Gauthier, 2006; Turk-Browne et al., 2006). We consider both phenomena and their relation to priming in turn.

3.12.3.1 Repetition Suppression

When stimuli are repeated, as in typical priming paradigms, neural activity is usually reduced. This neural repetition effect has been reported at multiple spatial scales, from the level of individual cortical neurons in monkeys (Li et al., 1993; Miller and Desimone, 1994; Sobotka and Ringo, 1996) to the level of hemodynamic changes (measuring the pooled activation of millions of neurons) in humans, using functional imaging such as fMRI (Buckner et al., 1995; Demb et al., 1995; Stern et al., 1996; Grill-Spector et al., 1999; Henson et al., 2000; Jiang et al., 2000; Naccache and Dehaene, 2001). Repetition-related reductions also occur at multiple temporal scales, both in their longevity – from milliseconds (Sobotka and Ringo, 1996) to minutes (Henson et al., 2000) and days (van Turennout et al., 2000) – and in the latency of their expression (Dale et al., 2000; Henson et al., 2004). Therefore, RS is a robust phenomenon that occurs across many timescales, in multiple brain regions, and across an impressively large number of experimental conditions.

In experiments when subjects view repeated presentations of objects and scenes, there is robust and reproducible RS as measured with fMRI also referred to as fMRI-adaptation (for reviews, see Grill-Spector and Malach, 2001; Kourtzi and Grill-Spector, 2005; Grill-Spector et al., 2006a). RS/fMRI-adaptation typically occurs in object-selective cortex (**Figure 3**) including the lateral occipital complex (LOC – consisting of regions overlapping the lateral occipital sulcus, inferior occipital gyrus, and occipitotemporal sulcus), as well as more ventral regions including the fusiform gyrus (Fusiform) and the parahippocampal

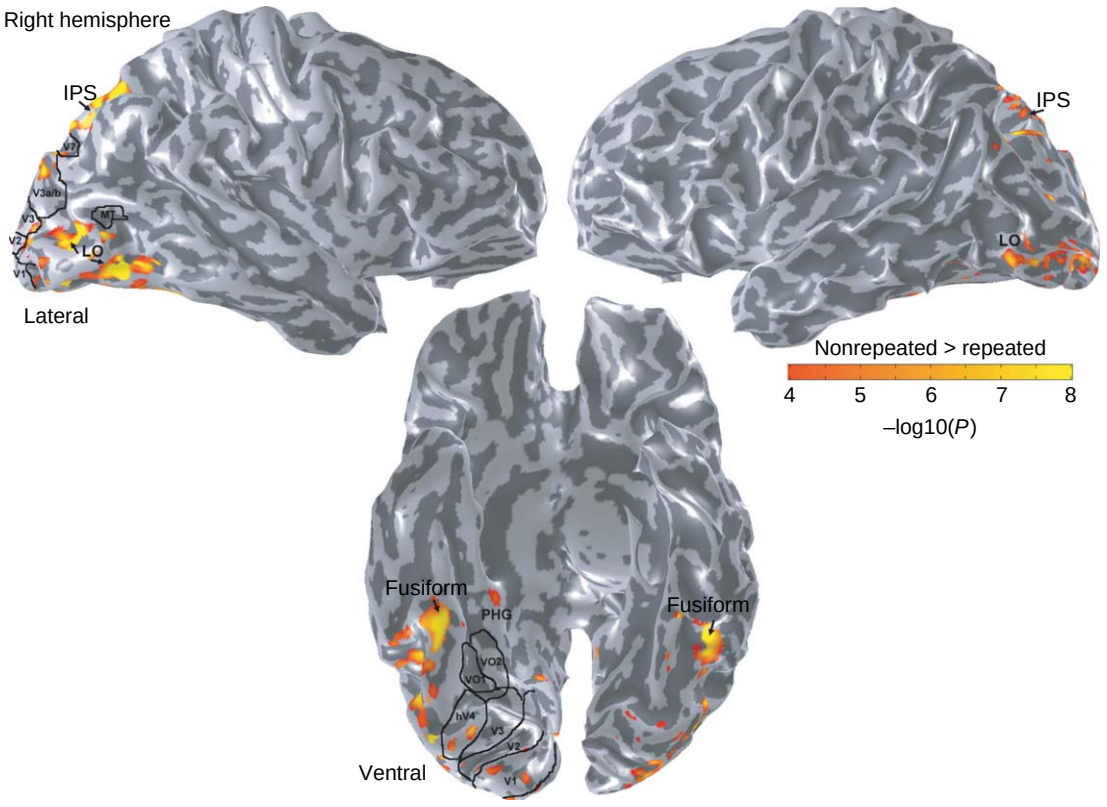

Figure 3 Occipitotemporal regions that show reduced responses to repeated versus nonrepeated stimuli ($p < 10^{-4}$, voxel level uncorrected). Color bar indicates statistical significance. Data are shown for a representative subject on her partially inflated brain. Dark gray regions indicate sulci, and lighter gray regions indicate gyrii. Retinotopic visual areas (delineated by black lines) were defined from independent retinotopic scans of polar angle and eccentricity and are shown for simplicity only on the right hemisphere. Abbreviations: PHG, parahippocampal gyrus; IPS, intraparietal sulcus.

gyrus (PHG). RS also occurs in dorsal regions (**Figure 3**), including regions lateral to and partially overlapping V3a and regions in the posterior bank of the intraparietal sulcus (IPS). Other regions that show RS to repeated presentation of object and scene images include medial temporal cortex (Stern et al., 1996) and frontal cortex (Wagner et al., 1997; Buckner and Koutstaal, 1998; van Turennout et al., 2003).

RS is not an all-or-nothing phenomenon: The magnitude of RS in object-selective cortex increases with repetition number and with fewer intervening stimuli between repetitions (**Figure 2(b)**). Therefore, the magnitude RS in block-design fMRI experiments is typically larger than during event-related fMRI experiments in which many intervening stimuli occur between repetitions of the same image (**Figure 4**). A recent study (Ganel et al., 2006) suggests that RS to immediate repetitions of identical stimuli is more prominent in object-selective regions of the LOC and fusiform cortex, whereas RS effects for stimuli that had been presented several minutes previously and occur after many intervening stimuli are more prominent in more anterior and medial regions of the temporal lobe. Further, they suggest that effects of immediate repetition and long-lagged repetition with intervening stimuli are largely additive (except for the left fusiform gyrus).

Repetition suppression in high-level visual areas has been associated with visual priming (Schacter and Buckner, 1998; Wiggs and Martin, 1998) because both phenomena occur under the same experimental conditions (**Figure 1**). However, it is mysterious why reduced cortical responses provide for improved behavioral performance. Notably, RS measured by fMRI may be related to other factors (unrelated to priming), such as repetition effects independent of behavioral improvements (Sayres and Grill-Spector, 2006), attentional differences between conditions (Yi and Chun,

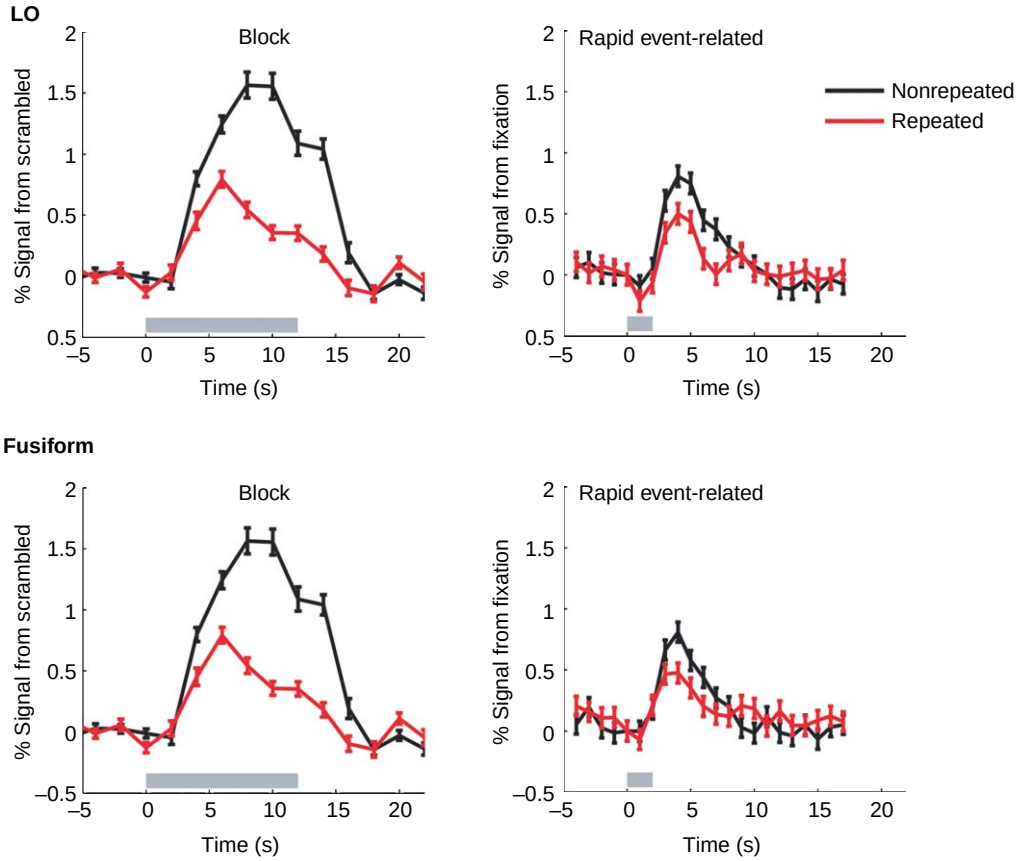

Figure 4 Repetition suppression in object-selective cortex: time course data. Data are shown for one representative subject. Object-selective cortex regions were defined as regions that showed higher activation for animals than scrambled animals with $p < 10^{-3}$ at the voxel level. *Black:* first presentation of the stimulus; Red: Repeated presentations of the same stimulus. In the block design fMRI experiment, stimuli were repeated up to 12 times within a block. In the rapid event-related fMRI experiment, stimuli were repeated up to eight times across a 4-min and 38-s experiment. Horizontal gray bar: duration in which stimulus was presented. Error bars indicate SEM across trials for this subject. Adapted from Grill-Spector K, Henson R, and Martin A (2006) Repetition and the brain: neural models of stimulus-specific effects. *Trends Cogn. Sci.* 10: 14–23.

2005; Yi et al., 2006), and/or learning of a response mapping between a stimulus and a cognitive decision (Dobbins et al., 2004; Schacter et al., 2004). Conversely, behavioral effects, such as visual priming, may be a consequence of activity in multiple cortical regions. Thus, RS in specific cortical regions may not relate directly to the behavioral changes associated with priming.

While keeping these caveats in mind, the section titled 'Investigations of the relation between RS and priming' describes several experiments that investigated the relation between priming and RS, and the section titled 'Neural models of repetition suppression and priming' lays out three models of the neural bases of priming, providing hypotheses for the relation between reduced cortical responses to repeated stimuli and improved performance – namely, visual priming.

3.12.3.1.1 Characterizing neural representations using repetition suppression

In addition to examining the relation between RS and priming, many neuroimaging experiments use RS to probe the functional properties of neural populations. This tool has been termed fMRI-adaptation (Grill-Spector and Malach, 2001) and also the priming method (Naccache and Dehaene, 2001; Vuilleumier et al., 2002). In the basic paradigm used in fMRI experiments, one first measures the basic RS (or fMRI-adaptation) effect induced by repetitions of identical stimuli. This is done by measuring the level of RS or adaptation to repeated presentations of identical stimuli relative to the response of nonrepeated stimuli (**Figure 5** – identical). Subjects are also presented with repeated stimuli that vary along

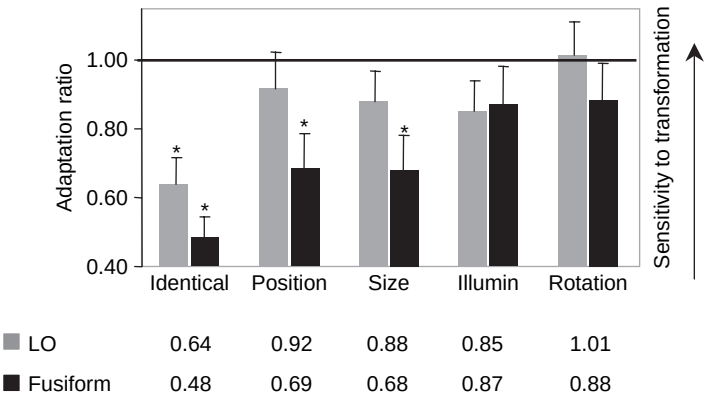

Figure 5 Using fMRI-adaptation to measure sensitivity to face transformations. To examine the level of adaptation to face transformations, we measured the adaptation ratio: repeated/nonrepeated. Repeated reflects blocks in which the same face was repeated, and nonrepeated reflects blocks that included nonrepeated presentations of different male faces in the same view, illumination, size, and position. An adaptation ratio of 1 indicates no adaptation (solid line); ratios that are significantly less than 1 are indicated by asterisks. Identical: repetitions of identical images of the same face; Position: repetitions of the same face in different retinal positions (~6° around fixation); Size: repetitions of the same face in different sizes (~threefold size change); Illumin: repetition of the same face illuminated from different directions; Rotation: Same face at different rotations around the vertical. Gray bars: lateral occipitus; Black bars: Fusiform; Error bars indicate SEM across 14 subjects. Numbers indicate adaptation ratios for each of the conditions. Data from Grill-Spector K and Malach R (2001) fMR-adaptation: A tool for studying the functional properties of human cortical neurons. *Acta Psychol. (Amst.)* 107: 293–321.

some dimension (e.g., the same object, but different sizes). The hypothesis tested is whether the underlying neural representation is sensitive or not to change along this dimension. If the underlying neural representation is insensitive to the change in the stimulus, then neurons will show a reduced response to repeated transformed versions of the object, and the fMRI signal will be reduced (i.e., fMRI-adaptation will be observed) similar to the reduction produced by repetitions of identical stimuli. Alternatively, if the neurons are sensitive to the change, the level of the fMRI signal will be similar to the initial level, and no RS/adaptation will be measured.

An example of using fMRI-adaptation to characterize neural representations is shown in **Figure 5**. In these experiments, subjects were shown either repeated presentations of the same image of a face (identical) or images of the same individual that varied in size (up to threefold changes in size), position (~6° around fovea), illumination (five different illuminations), viewpoint (rotation around the vertical, −90° to 90°). Activations to repeated versions of the same face were compared to nonrepeated presentations of faces of different individuals that were taken under the same viewing conditions (e.g., same size, position, illumination, and view). We found differential effects of fMRI-adaptation across object-selective cortex: LO regions show fMRI-adaptation for repetitions of identical images of objects but no fMRI-adaptation when the object varied in position, size, illumination, or viewing angle. In contrast, more ventral regions along the fusiform and occipitotemporal sulcus showed fMRI-adaptation for changes in object position and size but no fMRI-adaptation for different illuminations or rotations of the same object. These experiments provide evidence for differential sensitivity to object transformations across the human ventral stream.

fMRI-adaptation has been widely used by researchers to examine sensitivity in object-selective cortex to object size and position (Grill-Spector et al., 1999; Vuilleumier et al., 2002), viewpoint (Grill-Spector et al., 1999; James et al., 2002; Vuilleumier et al., 2002; Epstein et al., 2003), object format (Kourtzi and Kanwisher, 2000), perceived shape (Kourtzi and Kanwisher, 2001), contrast (Avidan et al., 2002; Murray and He, 2006), contour completion (Kourtzi et al., 2003), and face representation (Grill-Spector et al., 1999; Andrews and Ewbank, 2004; Winston et al., 2004; Eger et al., 2005; Loffler et al., 2005; Rotshtein et al., 2005; Jiang et al., 2006). fMRI-adaptation has also been used to probe higher-level conceptual representations using object pictures (Koutstaal et al., 2001) and words (Wheatley et al., 2005). Overall, these studies have documented that RS in occipitotemporal cortex is not limited to the identical image but also occurs, albeit to a lesser

extent, to transformed versions of the same object, to different exemplars that share the same name (e.g., two different umbrellas), and even to different words that are conceptually related (Wheatley et al., 2005).

3.12.3.2 Repetition Enhancement

Although the most ubiquitous cortical phenomenon is repetition suppression, there is evidence also that some aspects of visual priming are related to repetition enhancement (RE) (Dolan et al., 1997; George et al., 1999; Grill-Spector et al., 2000; Henson et al., 2000; James et al., 2000; James and Gauthier, 2006; Kourtzi et al., 2005; Turk-Browne et al., 2006). RE effects have been reported for improved recognition of repeated degraded stimuli (compared to performance on their initial presentation). RE was observed when repeated exposure to subthreshold, briefly presented objects led to better recognition (Grill-Spector et al., 2000) (**Figure 6**), when repeated exposure to unfamiliar shapes made them familiar (Henson et al., 2000), when inverted contrast faces (that were initially unrecognizable) were primed with positive contrast faces and became recognizable (George et al., 1999), and when observers learned to detect low-salience shapes in noisy backgrounds (Kourtzi et al., 2005; Turk-Browne et al., 2006).

One possibility is that RE and repetition suppression reflect dissociable forms of visual priming (Henson et al., 2000; Gruber and Muller, 2005); thus, repetition suppression may reflect suprathreshold priming, and RE may reflect subliminal priming (see also Kourtzi et al., 2005). These findings suggest that learning of unfamiliar or degraded stimuli is mediated by increased neural activity across high-level visual areas as new representations are formed for these previously unseen or unfamiliar stimuli. In contrast, learning of prominent suprathreshold (and/or familiar) stimuli is mediated by the sharpening of existing representations, leading to sparser coding of objects. An alternative account suggests that there is only one underlying mechanism, but it produces differential signals below and above recognition threshold (James et al., 2000; James and Gauthier, 2006). James and colleagues (James and Gauthier, 2006) proposed an accumulation model for recognition, in which recognition occurs when sufficient evidence for identifying an object has accumulated (*See* Chapter 2.23). Accumulation predicts a faster rise of activity

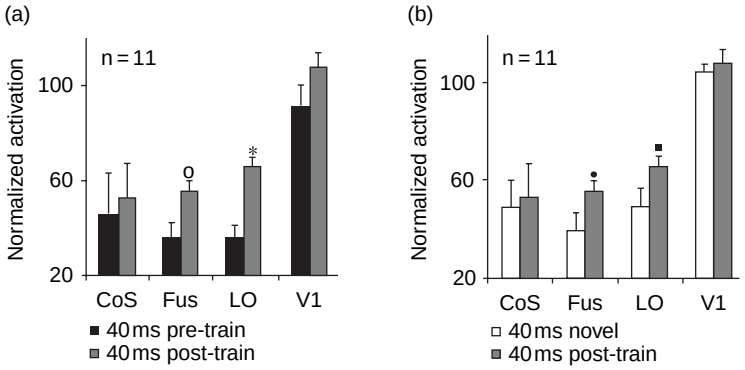

Figure 6 Repetition enhancement in object-selective cortex. Subjects were first scanned in the pretrained session when they viewed briefly presented images for 40 ms followed by a 460-ms mask. Subjects then viewed these masked images during five training sessions, and then they were scanned again in a second posttraining scan in which they viewed the same briefly presented stimuli (posttrain) and another set of novel masked images shown for the same duration (40 ms – novel). Initial recognition performance (40 ms pretrain) was about 25% and posttraining about 60%. (a) Normalized BOLD signal elicited by identical images viewed for 40 ms during pretraining and posttraining scans. Activations are plotted as percentage of activation to object stimuli shown for 120 ms followed by a mask for 380 ms. Recognition of 120 ms stimuli was close to ceiling. *X*-axis, brain area; *Y*-axis, normalized signal compared to activation elicited by stimuli presented for 120 ms. Dark bars: pretraining; Gray bars: identical stimuli posttraining. Error bars: SEM. Asterisks ($p < .001$) and circles ($p < .03$): significantly larger signal posttraining versus pretraining. (b) Normalized BOLD signal in the posttraining scan for two sets of images (trained and novel) shown for 40 ms. White bar: novel images; Gray bars: trained images; Error bars: SEM. Square ($p < .01$) and circle ($p < .05$): significantly stronger signal for trained images compared to novel images. Abbreviations: CoS: collateral sulcus; Fus: Fusiform gyrus; LO: lateral occipital. Adapted from Grill-Spector K, Kushnir T, Hendler T, and Malach R (2000) The dynamics of object-selective activation correlate with recognition performance in humans. *Nat. Neurosci.* 3: 837–843.

for primed compared to unprimed stimuli, as the evidence accumulates faster for primed stimuli. Another consideration for interpreting RE effects is that, close to perpetual threshold, recognition performance on trials in which subjects recognize objects (hits) is correlated with a higher signal than trials in which subjects fail to recognize objects (misses) (Bar et al., 2001; Grill-Spector, 2003; Grill-Spector et al., 2004). Thus, RE associated with improved recognition of previously unrecognized stimuli could reflect a higher hit rate for repeated stimuli that is not related to priming per se.

Although RE has been suggested to reflect a distinct form of priming than RS, to date there is no parametric study that systematically varied factors that affect RE and visual priming to test whether RE and visual priming are quantitatively linked.

3.12.3.3 Repetition Effects Measured with EEG and MEG

Repetition effects have also been studied by measuring changes in the electrical (EEG) or magnetic (MEG) field, usually recorded above the scalp. These effects reflect changes in the amplitude and/or synchrony of local field potentials (LFPs) caused by transmembrane currents in large numbers of neurons.

Most EEG studies examine event-related potentials (ERPs), which reflect changes in electrical potential during the few hundred milliseconds following stimulus onset, averaged across trials. The earliest object repetition effects are typically observed approximately 200 ms after stimulus onset (Eimer, 2000; Doniger et al., 2001; Schendan and Kutas, 2003; Henson et al., 2004; Schweinberger et al., 2004; Gruber and Muller, 2005), but some experiments show earlier repetition effects 150–170 ms after stimulus onset. Campanella, Henson, and colleagues (Campanella et al., 2000; Henson et al., 2004) found repetition effects when the same view of an object was repeated, as early as 160–190 ms when there were no intervening objects; with one or more intervening objects, repetition effects only emerged from approximately 200 ms onward.

Other EEG studies concentrate on changes in the power of electrical or magnetic oscillations that are induced by stimulus repetition (high-frequency oscillations are not observed in ERPs if they are not phase-locked across trials). Some studies report decreased high-frequency (>40 Hz) power around 220–350 ms for repetition of familiar objects across lags of one or two intervening objects (Gruber and Muller, 2005). Such changes in power in certain frequency bands have been shown to correlate with the blood-oxygen-level-dependent (BOLD) changes measured by fMRI (Brookes et al., 2005; Sayres and Grill-Spector, 2006).

3.12.3.4 Investigations of the Relation between RS and Priming

One useful approach used to examine the relation between priming and RS is to parametrically manipulate factors that influence the level of priming and/or RS and to examine whether the modulation of priming and RS effects covary or follow distinct profiles. Researchers have shown that many factors modulate the level of priming and also the level of RS. These include the number of stimulus repetitions (Henson et al., 2003; Sayres and Grill-Spector, 2006), frequency of repetition (Sayres and Grill-Spector, 2006), duration of stimulus presentation (Zago et al., 2005; Sayres and Grill-Spector, 2006), stimulus contrast (Avidan et al., 2002), and amount of noise added to the stimulus (Turk-Browne et al., 2006), as well as high-level cognitive factors such as attention (Eger et al., 2004; Murray and Wojciulik, 2004; Yi and Chun, 2005; Yi et al., 2006), relevance to the task (Henson et al., 2002b; but see Jiang et al., 2000), familiarity (Henson et al., 2000), and emotion (Ishai et al., 2004, 2006).

Recently, researchers have used this approach to examine the correlation between RS and priming (Dobbins et al., 2004; Maccotta and Buckner, 2004; Zago et al., 2005; Sayres and Grill-Spector, 2006). Results of these experiments are mixed. Some experiments suggest that some factors modulate the level of priming and RS in a similar way, suggesting a quantitative relation between priming and RS (Maccotta and Buckner, 2004; Zago et al., 2005). However, other factors may affect priming, but not RS (or RS but not priming), suggesting that RS in specific occipito-temporal regions may not be a direct neural correlate of visual priming (Henson et al., 2003; Dobbins et al., 2004; Sayres and Grill-Spector, 2006).

3.12.3.4.1 Evidence for a correlation between priming and repetition suppression

Several recent studies have reported a correlation between the level of response time priming and RS in prefrontal cortex (PFC) (Dobbins et al., 2004; Lustig and Buckner, 2004; Maccotta and Buckner, 2004). Lusting and Buckner (2004) report across-subject correlation between the level of

priming during a meaning-based word classification task and PFC activity across young adults, older adults, and adults with initial signs of Alzheimer's disease (Lustig and Buckner, 2004). Similarly, Maccota and Buckner (2004) showed that the level of priming as a function of number repetitions of a word and the level of RS in PFC was correlated across subjects. Dobbins and colleagues (Dobbins et al., 2004) also reported a positive within-subject correlation between response time priming induced by repeated presentations of visually presented objects and RS in PFC. In the same study they reported a negative within-subject correlation between priming and RS in the left fusiform cortex.

Zago and colleagues (Zago et al., 2005) showed that both visual priming and RS vary as a function of the initial exposure of the stimulus, which varied between 40 and 1900 ms. The largest priming and RS effects were observed for 250-ms exposure durations. Further, the average level of priming across subjects is correlated with the average level of RS in occipito-temporal object-selective regions. However, Zago and colleagues do not report within-subject correlations between visual priming and RS.

Together, these studies suggest that under some circumstances there is a correlation between priming and RS. The most consistently reported cortical region in which activation is associated with priming is PFC. Further research is necessary to examine the generality of these results to additional stimulus manipulations to understand whether these effects are modality specific and to investigate more comprehensively whether the correlation between priming and RS can be found within individual subjects, as responses and brain activations are likely to vary across individuals.

3.12.3.4.2 Evidence for dissociable effects of performance and repetition on the level of repetition suppression

Priming effects can be reduced when the responses to a stimulus are changed across repetitions. A recent study examined whether changes in priming effects and RS effects were dependent on the particular response/judgment made about the stimulus. Dobbins and colleagues (Dobbins et al., 2004) measured priming and RS effects as a function of repetition number under two experimental conditions – when the same judgment was made on the stimulus (indicate whether an object is larger than a shoebox, for both initial and repeated presentations) and when different judgments were made (initially subjects judged whether the item was larger than a shoebox, and when the item was repeated they were asked if it was smaller than a shoebox). Priming effects were larger when the question was identical in the initial and repeated conditions. However, priming was observed even when the judgment differed. RS in PFC was correlated with priming effects in both experimental conditions. In contrast, RS in fusiform cortex was observed when items were repeated and the judgment was identical but was abolished when the judgment changed. These data suggest that RS in fusiform cortex was related to the ability of the subject to use prior responses during repeated trials, rather than reflecting a priming effect.

Another consideration when relating BOLD responses to performance is that several factors may contribute to BOLD responses measured in a specific brain region, and performance is likely to be an outcome of activation across several brain regions. Therefore, while RS and priming occur in the same experimental situations, the two phenomena may not coincide under all experimental conditions. For example, RS may be driven by shorter RT (e.g., shorter RT may produce lower BOLD responses) but not repetition. This alternative predicts lower BOLD responses for trials with shorter RT regardless of whether these trials contain stimuli shown for the first time or contain stimuli that have been seen previously. Alternatively, repetition may produce lower responses independent of performance changes. This alternative suggests that repeated trials will correspond to trials with lower BOLD response, even if there is no change in performance – that is, a memory component to RS that is independent of performance.

Another question is whether RS and visual priming reflect changes in neural activity during the recognition process, or whether they reflect changes after recognition has occurred. Under many experimental conditions the stimulus is presented for longer periods than the minimal time necessary for recognition (Grill-Spector and Kanwisher, 2005) (~67–120 ms), yet both performance and BOLD signals are measured after recognition has occurred.

In a recent study (Sayres and Grill-Spector, 2006), we examined both factors: Is RS in object-selective cortex correlated with response time priming or repetition independent of performance changes? Second, do RS and priming occur during or after recognition? To quantitatively examine the relation between priming and RS, we first measured the

relation between priming and RS in object-selective cortex as we parametrically varied repetition parameters (number of repetitions, number of intervening stimuli, time between repeats). We then measured whether there are independent contributions of RT and repetition to RS effects. Second, to assess whether RS and priming occurred during or after recognition, we compared RS and priming effects for long exposure durations (1750 ms) and for short exposures (67–101 ms). Exposure durations were set for each subject to be the minimal duration for 85% accuracy performance on a classification task (67–101 ms for our subjects). Stimuli were presented briefly and then masked for the remainder of a 2-s trial. These brief presentations allowed us to tap into repetition effects during recognition.

We found that both RT priming and RS occurred for both long and short exposures, and these effects were modulated by repetition parameters (**Figure 2**). The level of RS also varied with stimulus duration, as the magnitude of RS was lower for short compared to long exposure durations. In contrast, the magnitude of RT priming was not significantly different across these exposure durations. We did find an improvement in accuracy for short exposures, but not long exposures (perhaps due to a ceiling effect), but this did not depend on repetition parameters.

Importantly, we found that when exposure durations were long (1750 ms), there was significant correlation between RS in object-selective cortex and RT priming for some repetition parameters (stimuli between repeats, time between repeats) but not others (number of repeats). When exposures were short (67–101 ms), we observed significant priming and significant RS, but they were not correlated. Thus, both priming and RS can occur under the same experimental conditions, but they do not always covary. These data suggest that RS in object-selective cortex may not reflect improved RT performance observed during priming.

Finally, we examined whether there are separable contributions of response time and repetition to RS by sorting our data into repeated and nonrepeated conditions. For each condition, we ranked each subject's trials according to response time and grouped the trials into four equally sized bins according to RT. Responses to repeated trials were lower than nonrepeated trials even when response times were equated between conditions (**Figure 7**). Importantly, for both long and short image durations and all object-selective regions of interest (ROIs), we found a significant effect of repetition independent of response time. In contrast, we did not find significant effects of response time independent of repetition. There was a weak, statistically significant effect present in LO and only for stimuli that were presented for 1750 ms. Finally, we found no significant interaction between repetition and response times. Taken together, these data reveal that RS in object-selective cortex reflects stimulus-specific repetition, even when performance is matched between repeated and nonrepeated objects and when stimuli are presented close to the minimum time required for recognition. This suggests that there is a

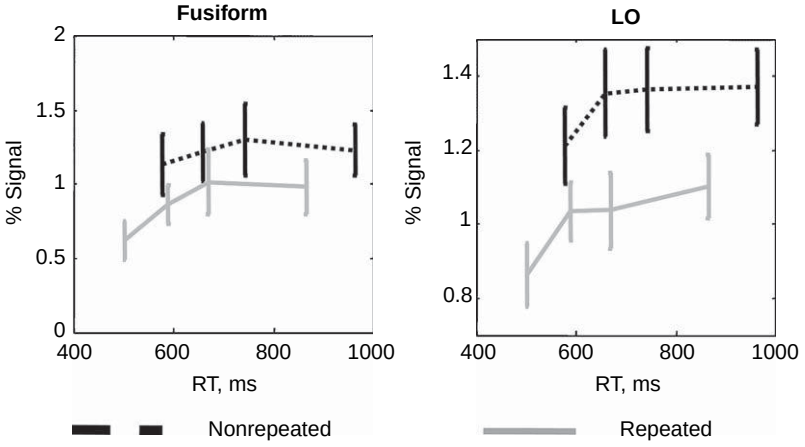

Figure 7 Separable contributions of repetition and response-time. Data were sorted first into repeated (solid gray) and nonrepeated (dashed black) correct trials and then grouped into four response time bins for each subject. The first response time bin represents fastest quartile of correct trials for each subject. Error bars indicate SEM across seven subjects. Adapted from Sayres R and Grill-Spector K (2006) Object-selective cortex exhibits performance-independent repetition suppression. *J. Neurophysiol.* 95: 995–1007.

performance-independent component to RS in object-selective cortex that may be an implicit form of memory.

Overall, our experiments show that both priming and RS effects depend on repetition parameters. However, different factors have dissociable effects on priming and RS. These experiments underscore the importance of conducting future experiments using parametric designs, systematically varying factors that modulate priming and RS to quantitatively measure the relation between these phenomena.

3.12.4 Neural Models of Repetition Suppression and Priming

Experiments have provided important insights about the characteristics of priming, RS, RE, and their relation. However, the neural mechanisms underlying visual priming and RS are yet unknown.

Three models have been suggested for the neural mechanisms underlying repetition suppression that may explain priming effects (Grill-Spector et al., 2006a) (**Figure 8**): (1) the Fatigue model, whereby the amplitude of firing of stimulus-responsive neurons decreases (Miller and Desimone, 1994; Grill-Spector and Malach, 2001), (2) the Sharpening model, whereby fewer neurons respond (Li et al., 1993; Desimone, 1996; Wiggs and Martin, 1998), and (3) the Facilitation model, whereby the latency (James and Gauthier, 2006) and/or duration of neural activity is shortened (Sobotka and Ringo, 1996; Henson and Rugg, 2003). An important consideration to keep in mind is how each of these models may account for visual priming.

3.12.4.1 Fatigue Model

According to this model, all neurons initially responsive to a stimulus show a proportionally equivalent reduction in their response to repeated presentations of the same stimulus. As a consequence the mean population firing rate declines, but there are no changes in the pattern of relative responses across

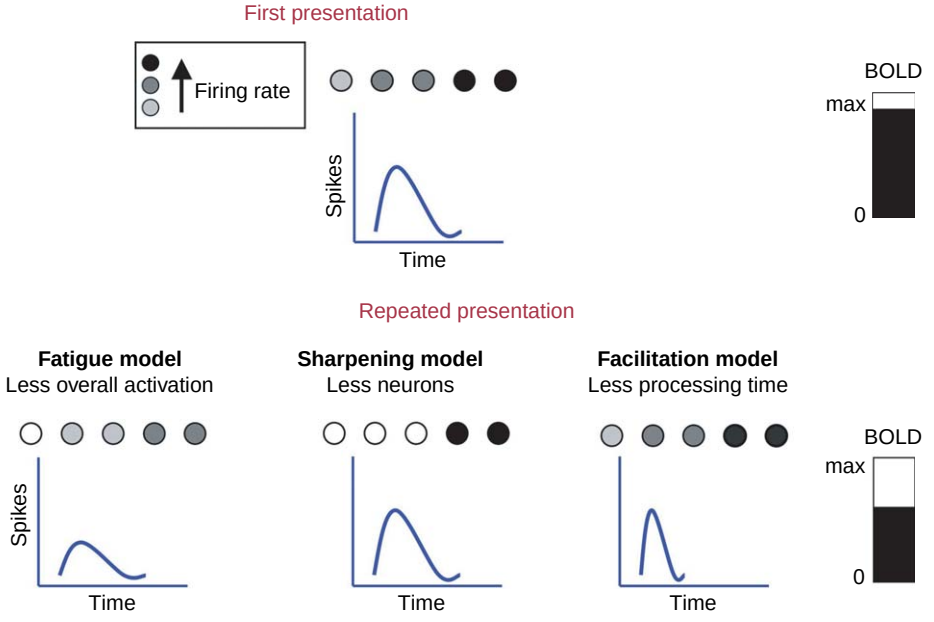

Figure 8 Models for repetition suppression. The top panel indicates neural responses in a putative brain region to the initial presentation of a stimulus. The bottom panels indicate responses in this region to repeated stimuli as posited by each of the three models. *Left:* Neural responses. Circles indicate the peak spiking rate of neurons in this region (darker circles indicate higher spiking rates). Blue time courses illustrate the spiking rate as a function of time for the most responsive neurons (indicated by black circles). *Right:* BOLD response in this region of cortex. Since the BOLD signal integrates neuronal activity over time, all of these models predict reduced BOLD responses for repeated stimuli, but due to different reasons: Fatigue: lower firing rates across the entire time window; Sharpening: fewer neurons respond, but those which remain active show similar spiking as for the first presentation; Facilitation: shorter duration of neural processing, but the peak firing is similar to the initial presentation. Adapted from Grill-Spector K, Henson R, and Martin A (2006) Repetition and the brain: neural models of stimulus-specific effects. *Trends Cogn. Sci.* 10: 14–23.

neurons or in the temporal window in which neurons are responding. One mechanism for fatigue may be firing-rate adaptation, in which the reduction in a neuron's firing rate is proportional to its initial response (Li et al., 1993; Avidan et al., 2002) (similar to a gain mechanism; Carandini and Ferster, 1997). However, this mechanism does not explain the specificity of RS, that is, why the neuron's response is reduced to some stimuli, yet resumes high firing rates to other stimuli. An alternative mechanism is reduced synaptic efficacy of specific synapses from connected neurons (synaptic depression). In this manner, only specific patterns of presynaptic input to the neuron (which are stimulus dependent) reduce its firing rate. This type of mechanism has been implicated in early visual cortex and usually occurs with prolonged repetitive stimulation.

One prediction from this model is that the amount of RS will be greater in neurons that respond optimally to a stimulus than in other neurons. As a result, the sensitivity of the system to stimuli that are different from the repeating stimulus is increased, thereby providing a mechanism for 'novelty detection.' Reducing the firing rate may also help prevent saturation of the neural response function by increasing its dynamic range. Another advantage hypothesized for such a mechanism is that it reduces redundancies in the neural code, which increases the efficiency of information encoding (Muller et al., 1999).

However, it is not immediately clear how reduced firing rates can account for increased speed and accuracy of processing repeated stimuli (in addition to increased sensitivity to novel stimuli), as arises in priming. One explanation is provided in a computational model by Gotts (2002), in which a reduction in the mean and variance of firing rates allows for greater synchrony of neural responses. Since greater synchrony of presynaptic input is believed to be more effective in triggering a postsynaptic response (Fries et al., 2001), this would imply more rapid transmission of information throughout the network, resulting in faster responses (priming). A key prediction of this model is that synchrony can increase while stimulus-specific firing rates decrease. While there is evidence in support of this possibility (Stopfer and Laurent, 1999), others have argued for the opposite effect (Chawla et al., 1999). An increase in synchrony may also be difficult to reconcile with observations of reduced oscillatory power following stimulus repetition (Gruber and Muller, 2005), though it is possible that decreased amplitude of local field potentials outweighs the increased synchrony of those potentials.

3.12.4.2 Sharpening Model

Desimone (1996) and Wiggs and Martin (1998) have suggested that repetition results in a sparser representation of stimuli across cortex. According to this model, some, but not all, neurons that initially responded to a stimulus will show RS to subsequent presentation of that stimulus. Thus, repetition-related changes are viewed primarily as a learning process, in which representations (e.g., tuning curves) are 'sharpened,' and as a consequence, the distributed representation becomes sparser, resulting in fewer responsive neurons in total (**Figure 8**). An important difference between the Sharpening and Fatigue models is that for Sharpening, many of the neurons that are optimally tuned to the repeating stimulus show little or no response reduction, rather than exhibit the greatest response reduction, as in the Fatigue model.

Sparser representations clearly have adaptive value in terms of a reduced metabolic cost. Also, because the representation becomes sharper (tuning curves become narrower), the neurons become more sensitive to change. Sparser representations may also allow for more efficient or faster processing, though this depends on the manner in which their information is read out by downstream neurons. Because the Sharpening model suggests a changed and improved representation for repeated stimuli, this model has been widely used to explain priming (Wiggs and Martin, 1998; Henson and Rugg, 2003; Zago et al., 2005). However, a recent study suggests that RS in object-selective cortex may reflect response learning and implies that object representations do not necessarily reorganize as a consequence of repetition (Dobbins et al., 2004).

The mechanism underlying the formation of sparser representations is unknown but could reflect inhibition from lateral connections between neurons within a population. For example, Norman and O'Reilly (2003) used a competitive Hebbian learning rule to simulate the sharpening of representations with repetition (within medial temporal cortex). Initially, many neurons respond weakly to a distributed input pattern representing the stimulus. Through competitive interactions, the neurons with the strongest initial response get 'stronger' and inhibit the 'weaker' neurons. Thus, some neurons show increased firing rates following repetition, whereas

others show decreased firing rates. By assuming that the number of 'strong' units is less than the number of 'weak' units, the population response decreases with repetition because there are more neurons showing reduced activity than showing increased activity. If information only from those neurons with high firing rates is 'read out' by downstream neurons, their increased firing rate following repetition (despite the global decrease) could explain the faster processing of repeated stimuli.

3.12.4.3 Facilitation Model

At its simplest, this model predicts that repetition causes faster processing of stimuli, that is, shorter latencies or shorter durations of neural firing, and thereby may explain faster response times observed during priming. One example is the 'accumulation' model of James and Gauthier (2006), in which stimulus information is accrued faster following repetition. Given that the hemodynamic signal measured by fMRI integrates over several seconds of neural activity, a shorter duration of activity results in a decreased amplitude of the fMRI signal. A shorter duration of neural activity is also consistent with earlier peaking of the fMRI response (Henson et al., 2002a) and might explain why decreases in firing rate can appear to arise after the initial visual response (Ringo, 1996): The neurons initially fire robustly to both first and repeated presentations, but this firing stops sooner for repeated presentations.

An extension of the Facilitation model assumes that the cause of this faster processing is synaptic potentiation between neurons following an initial stimulus presentation, and that this potentiation can occur at many levels in the processing stream. As a consequence, information flows through the stream more rapidly, and hence processing of a repeated stimulus occurs faster. In terms of attractor neural network models, synaptic potentiation might be viewed as deepening the basin of attraction, resulting in a shorter time for the network to settle on a stable pattern corresponding to identification of the stimulus. An example of such a dynamical network model is sketched by Friston (2005). The key idea behind this model is that the firing rate of the long-range excitatory (output) neurons in a population codes 'prediction error' (Rao and Ballard, 1999), which is the difference between bottom-up input ('evidence') and top-down input ('prediction'). The dynamics of the network are such that prediction error decreases over time after stimulus onset, and synaptic changes serve to accelerate this decrease when the stimulus is repeated (i.e., repetition improves prediction).

This emphasis on recurrent activity between many levels of the processing stream is consistent with the spatiotemporal pattern of repetition effects emerging from MEG/EEG data. Moreover, if interregional interactions require an initial volley of activity through the network (Sugase et al., 1999), this model could further explain the relatively late onset of long-lag repetition effects recorded with EEG/MEG. However, such a model would not explain why much earlier repetition effects have been observed in some neurons (e.g., 75–100 ms, which is thought to be too early for feedback; Xiang and Brown, 1998), and further, this model does not necessarily predict decreases in the peak firing rate of individual neurons.

Each of the above models would clearly benefit from further elaboration, including instantiation as detailed computational models. It is possible that different models may apply in different brain regions and under different experimental conditions (e.g., different paradigms/tasks). Nevertheless, specific neural mechanisms matter, because the interpretation and design of experiments depend on the nature of the underlying neural model. For example, models differ as to whether RS reflects quantitative or qualitative changes in representations. One important possibility is that there are multiple models that vary in their relevance across space, time, and task, which may parallel the multiplicity of potential neural/synaptic mechanisms. Finally, it is yet unknown whether the same or different mechanisms operate in different brain regions.

3.12.4.4 Distinguishing the Neural Models

There are three main directions in which these models can be distinguished: (1) examining the relationship between RS and stimulus selectivity, (2) examining the effect of repetition on the tuning of cortical responses along a stimulus dimension, and (3) examining the temporal window in which processing occurs for new and repeated stimuli.

3.12.4.4.1 Examining the relationship between RS and stimulus selectivity

The models differ in their predictions on whether RS is strongest for the preferred stimulus or for nonpreferred stimuli. The Sharpening model predicts that neurons showing little or no RS to a repeated

stimulus are highly selective for that stimulus. In contrast, both the Fatigue and Facilitation models predict that RS is proportional to the initial response. Thus, neurons that respond optimally for a stimulus should show the largest suppression. These hypotheses can be tested with single-cell recording.

3.12.4.4.2 Examining the effect of repetition on neural tuning

Another way to distinguish the models would be to find a single dimension (e.g., motion, orientation) along which stimuli differ and examine the effect of repetition on the tuning curves of different neurons along that dimension. The models differ in their prediction of how repetition will change the shape of neuronal tuning. According to the Fatigue model, repetition reduces the response in proportion to the initial response, but the tuning width does not change. Most likely, the reduction will be maximal for tuning curves centered on the location of the repeating stimulus along the stimulus dimension, and lesser for tuning curves centered farther away. This is consistent with adaptation of V1 neurons to orientation (Dragoi et al., 2002), spatial frequency (Movshon and Lennie, 1979), and motion direction (Kohn and Movshon, 2004). In contrast, according to the Sharpening model, repetition sharpens tuning curves. This is consistent with studies of learning-related changes in IT cortex and V4 (Baker et al., 2002; Sigala and Logothetis, 2002; Rainer et al., 2004). Finally, the Facilitation model does not suggest any particular effect on tuning curves. Indeed, even a widening of the curves might be possible if repetition enlarged the attractor basin in an attractor network model.

3.12.4.4.3 Examining the temporal window of processing for new and repeated stimuli

The models may also be distinguished in the temporal domain. In particular, the Facilitation model suggests that the latency and/or duration of the response to repeated items will be shorter than to first presentations. The Fatigue and Sharpening models do not suggest a difference in the temporal processing window for repeated stimuli. The latency and duration of processing might be examined via single-cell recordings and/or EEG/MEG techniques.

3.12.5 Conclusions and Directions for Future Research

Visual priming is one of the most studied cognitive processes, as it is a window to understanding the underlying representations and mechanisms of rapid implicit learning and memory in the human brain. Progress has been made using priming to infer the nature of representations in different cortical regions or as a marker for increased processing efficiency, without a complete understanding of its neural basis. Nevertheless, specific neural mechanisms matter, because interpretation of experimental data depends on the nature of the underlying neural mechanisms.

Clearly, many questions remain regarding the neural basis of visual priming. For example, how do the Fatigue and Sharpening models account for improved performance during priming? Do different mechanisms occur in different timescales (e.g., immediate priming vs. priming with many intervening stimuli)? Do fundamentally different mechanisms underlie RE and RS? How does the specificity of priming correlate with particular representations in different visual regions? Are there different mechanisms underlying subliminal and suprathreshold visual priming?

Notably, any empirical data relevant to the models presented here is likely to depend on other factors, such as the lag between repetitions. One of the central outstanding questions is whether different models apply at different timescales. One possibility is that the mechanisms related to the Fatigue model operate during immediate repetitions of a stimulus within a few hundred milliseconds and reflect transient stimulus-specific effects that onset rapidly, whereas the effects of repetition across many intervening stimuli may be more consistent with the Sharpening or Facilitation models and reflect long-term learning that leads to changes in the spatial pattern of stimulus-selective responses and/or dynamics of those responses. Also models differ as to whether priming is associated with quantitative or qualitative changes in cortical representations. One possibility is that there are multiple mechanisms that vary across space, time, and task. Finally, it is yet unknown whether the same or different mechanisms operate in different brain regions.

Progress will be aided by integrating data using a combination of behavioral and neuroimaging methods such as fMRI and EEG/MEG (provided important differences between these measurements

are kept in mind), linking between electrophysiology data in animals and neuroimaging data in humans, and improvements in the spatial resolution of fMRI (Beauchamp et al., 2004; Schwarzlose et al., 2005; Grill-Spector et al., 2006b). Future experiments will yield important empirical data that will validate (or refute) current theoretical predictions. Understanding the neural bases of priming will be critical for understanding whether priming reflects quantitative or qualitative changes in the brain and will allow a fundamental understanding of implicit learning and memory in the adult brain.

3.13 Short-Term and Working Memory Systems

B. R. Buchsbaum and M. D'Esposito, University of California, Berkeley, CA, USA

3.13.1 Introduction

Humans and other animals with elaborately evolved sensory systems are prodigious consumers of information: each successive moment in an ever-changing environment nets a vast informational catch – a rich and teeming mélange of sights, sounds, smells, and sensations. Everything that is caught by the senses, however, is not kept; and that which is kept may not be kept for long. Indeed, the portion of experience that survives the immediate moment is but a small part of the overall sensory input. With regard to memory storage, then, the brain is not a pack rat, but a judicious and discerning collector of the most important pieces of experience. A good collector of experience, however, is also a good speculator: The most important information to store in memory is that which is most likely to be relevant at some time in the future. Of course, a large amount of information that might be important in the next few seconds is very unlikely to be of any importance in a day, a month, or a year. It might be stated more generally that to a large degree the relevance of information is time-bounded – sense-data collected and registered in the present is far more likely to be useful in a few seconds than it is to be in a few minutes. It would seem, then, that the temporary relevance of information demands the existence of a temporary storage system – a kind of memory that is capable of holding onto the sense-data of the 'just past' in an easily accessible form, while allowing older information to discreetly expire.

The existence of this kind of 'short-term memory' has been well established over the past century through the detailed study of human performance on tasks designed to examine the limits, properties, and underlying structure of human memory. Moreover, in recent years, much has been learned about the neurobiological basis of short-term memory through the study of brain-damaged patients, the effect of cortical ablations on animal behavior, electrophysiological recordings from single cells in the nonhuman primate, and regional brain activity as measured by modern functional neuroimaging tools such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). In this chapter, we examine how the psychological concept of short-term memory (STM) has, through a variety of neuroscientific investigations, been validated as a biological reality.

3.13.2 Evidence for the Existence of Short-Term Memory

An important scientific tenet, often referred to as the principle of parsimony, dictates that when two competing theories are put forth to explain a phenomenon,

and neither one is clearly superior to the other in its explanatory power, then the simpler of the two is to be preferred. The simplest conceivable theory of memory is that it is a unitary mental faculty; that all memories, no matter how recent or how remote, are made possible by a single functional system. This idea also appears to be the way in which people naturally conceive of memory, inasmuch as the single term 'memory' has been sufficiently expressive and precise to refer to the act of remembering in all its everyday variety. But soon after psychologists began to characterize memory in terms of human performance, a strong case emerged for the existence of different kinds of memory involving separate systems for the storage of old and new experiences.

In the mid-1960s, evidence began to accumulate in support of the view that separate functional systems underlie memory for recent and memory for more distant events. A particularly robust finding came from studies of free recall in which it was demonstrated that when subjects are presented a list of words and asked to repeat as many as possible in any order, performance is best for the first few items (the primacy effect) and for the last few items (the recency effect) – a pattern of accuracy that when plotted as a function of serial position (see **Figure 1**) appears U-shaped (Waugh and Norman, 1965; Glanzer and Cunitz, 1966). When a brief filled retention period is interposed between stimulus presentation and recall, however, performance on early items is relatively unaffected, but the recency effect disappears (Postman and Phillips, 1965; Glanzer and Cunitz, 1966). These findings suggest that in the immediate recall condition the last few items of a list are recalled best because they remain accessible in a short-term store, whereas early items are more permanently represented (and thus unaffected by the insertion of a filled delay) in a long-term store. This idea that memory, as a functional system, contains both short- and long-term stores is exemplified by the two-store memory model of Atkinson and Shiffrin (1968). In this prototype psychological memory model, comprising a short-term store (STS) and long-term store (LTS), information enters the system through the STS, where it is encoded and enriched, before being passed on to the LTS for permanent storage (**Figure 2**). Although the idea that short-term storage is a necessary prerequisite for entry into the LTS has not held up, the two-store model of Atkinson and Shiffrin crystallized the very idea of memory as a divisible, dichotomous system and provided the conceptual framework for the interpretation of patterns of memory deficits observed in patients with brain damage.

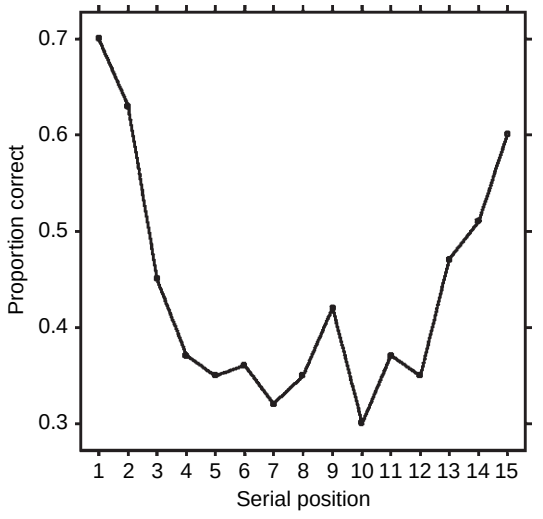

Figure 1 Plot of recall accuracy as a function of serial position in a test of free recall. Primacy and recency effects are evident in the U-shaped pattern of the curve. Adapted from Glanzer M and Cunitz A-R (1966) Two storage mechanisms in free recall. *J. Verbal Learn. Verbal Behav.* 5: 351–360; used with permission.

3.13.2.1 Evidence from Neurology and Neuropsychology

Perhaps the most compelling evidence for the existence of two memory stores comes from case studies of persons with focal brain lesions. In the early 1950s an astonishing, if tragic, discovery was made. A surgical procedure for the treatment of intractable epilepsy that involved bilateral removal of the medial temporal lobe in patient H. M. resulted in a catastrophic impairment in his ability to form new long-term memories, though, remarkably, his STM was left intact (Scoville and Milner, 1957). Thus, H. M., although perfectly capable of repeating back a string of digits – the classic test of STM – was unable to permanently store new facts and events. In the following decade, when Warrington and Shallice (Warrington and Shallice, 1969; Shallice and Warrington, 1970) reported a number of case studies of patients with temporoparietal lesions who had dramatically impaired STM for numbers and words coupled with a preserved ability to learn supra-span (e.g., greater than 10 items) word lists with repeated study, the case for a separation between STM and long-term memory (LTM) was immeasurably strengthened. It is important to emphasize that

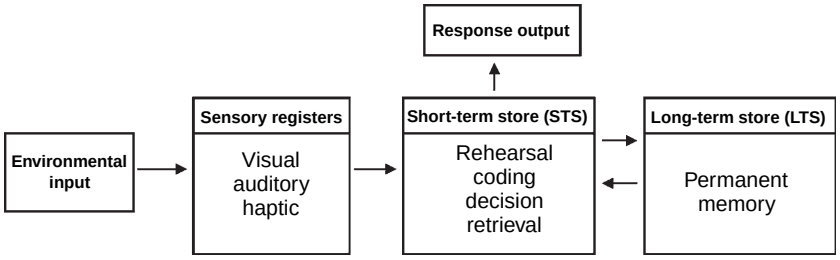

Figure 2 An information-flow diagram of Atkinson and Shiffrin's (1968) memory model. Information arriving to senses enters a short-term store (STS), where it can be maintained temporarily before entering a long-term store (LTS).

the STM deficits exhibited by such patients were, in the purest cases (Shallice and Warrington, 1977), not accompanied by any obvious deficits in ordinary language comprehension and production. Thus, for instance, patient J. B. was able to carry on conversations normally and to speak fluently without abnormal pauses, errors, or other symptoms of aphasia; in short, the 'language faculty,' considered to encompass the processes necessary for the online comprehension and production of meaningful speech, need not be disturbed even in the presence of a nearly complete eradication of verbal STM (Shallice and Butterworth, 1977). This established an important dissociation between the STM syndrome and the aphasic syndromes – a class of neurological disorders that specifically affect language ability – and argued, again, for a dedicated system in the brain for the temporary storage of information.

In summary, the discovery of 'short-term memory patients,' as they were to be called in the neuropsychological investigations of Warrington, Shallice, and others, provided a kind of evidential death blow to extant single-store hypotheses of memory (e.g., Melton, 1963), insofar as it established a double dissociation both in brain localization (LTM – medial temporal lobe, verbal STM – temporoparietal cortex) and patterns of performance, between short- and long-term memory systems. In addition, the STM disorder could be clearly distinguished, at the behavioral level at least, from the major language disorders such as Broca's and Wernicke's aphasia.

3.13.2.2 From Short-Term Memory to Working Memory

STM had, until the landmark work of Baddeley and colleagues (Baddeley and Hitch, 1974; Baddeley, 1986), typically been viewed as a more or less passive and amorphous medium for the brief storage of information derived from the senses. Questions tended to focus on the principles governing the mnemonic 'life cycle' of an item in memory – that is, why and at what rate are items forgotten? What is the role of passive decay? What is the role of interference, both proactive and retroactive, in forgetting? What is the route from STM to LTM, and what are the factors that influence this process? These questions, though of fundamental importance to understanding how memory works, tended to emphasize the general mechanisms – the procedures and principles of memory – rather than the underlying functional architecture of the system. What was missing from this line of research was the recognition that the contents of STM are not physical elements governed by certain lawful and inexorable processes of decay and interference, but rather dynamic representations of a fluid cognition, capable of being maintained, transformed, and manipulated by active, executive processes of higher control. Thus, for instance, two of the most important variables in studies of STM before the emergence of the Working Memory model were time (e.g., between stimulus presentation and recall) and serial order (e.g., of a list of items), both of which variables are defined by the inherent structure of the environmental input. (The term working memory has taken on the general meaning in much of psychology and neuroscience as active maintenance or manipulation of information held in memory, independent of the specific model of Baddeley and colleagues to which we refer with initial capital letters as 'Working Memory' or 'the Working Memory model.') In more recent years, at least as great an emphasis has been placed on variables that reflect an ability or attribute of the subject, for instance, his or her rate of articulation (Hulme et al., 1999), memory capacity (Cowan, 2001), or degree of inhibitory control (Hasher et al., 1999). Interest in these 'internal variables' is a recognition of the fact that what is 'in memory' at a moment in time is defined to various degrees by the structure of the input (e.g., time, serial order), the passive properties

of the storage medium (e.g., rate of decay, interference susceptibility), and the active processes of control that continually monitor and operate on the contents of memory. It is this last ingredient that puts the 'work' into working memory; it makes explicit the active and transformative character of mental processes and acknowledges that the content of memory need not mirror the structure and arrangement of environmental input, but rather may reflect the intentions, plans, and goals of the conscious organism.

With that introduction in mind, let us now give a brief overview of the Working Memory model of Baddeley and colleagues (Baddeley and Hitch, 1974; Baddeley, 1986). Whereas contemporary models of STM tended to emphasize storage buffers as the receptacles for information arriving from the senses, Baddeley and Hitch (1974) focused on rehearsal processes, that is, strategic mechanisms for the maintenance of items in memory. Thus, for example, when one is trying to keep a telephone or license plate number 'in mind,' a common strategy is to repeatedly rehearse, either subvocally or out loud, the contents of the numeric or alphanumeric sequence. Research had shown that in tests of serial recall, when subjects are prevented from engaging in covert rehearsal during a delay period that is inserted between stimulus presentation and recall, overall performance is dramatically impaired (Baddeley et al., 1975). In the case of verbal material, then, it was clear that in many ways the ability to keep words in memory depended in large part on articulatory processes. This insight was central to the development of the verbal component of Working Memory, the 'phonological loop' (see the section titled 'The phonological loop'), and led to a broader conceptualization of STM that seeks not only to explain how and why information enters and exits awareness, but rather how resources are marshaled in a strategic effort to capture and maintain the objects of memory in the focus of attention.

The central tenets of the Working Memory model are as follows: (1) It is a limited capacity system; at any moment in time, there is only a finite amount of information directly available for processing in memory. (2) The specialized subsystems devoted to the representation of information of a particular type, for instance, verbal or visuospatial, are structurally independent of one another; the integrity of information represented in one domain is protected from the interfering effects of information that may be arriving to another domain. (3) Storage of information in memory is distinct from the processes that underlie stimulus perception; rather, there is a two-stage process whereby

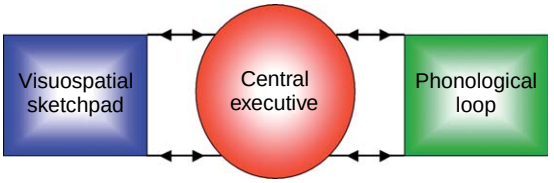

Figure 3 The Working Memory model comprises a control system, the central executive, and two storage systems, the visuospatial sketchpad and the phonological loop.

sensory information is first analyzed by perceptual modules and then transferred into specialized storage buffers that have no other role but to temporarily 'hold' preprocessed units of information. Moreover, the pieces of information that reside in such specialized buffers are subject to passive, time-based decay as well as interitem interference (e.g., similar sounding words such as 'man, mad, map, cap, mad' can lead to interference within a specialized phonological storage structure); finally, such storage buffers have no built-in or internal mechanism for maintaining or otherwise refreshing their contents – rather, this must occur from without, through the process of rehearsal, which might be a motor or top-down control mechanism that can sequentially access and refresh the contents that remain active within the store.

The initial Working Memory model proposed by Baddeley and Hitch (1974), but later refined somewhat (Salame and Baddeley, 1982; Baddeley, 1986), argued for the existence of three functional components of working memory (**Figure 3**). The 'central executive' was envisioned as a control system of limited attentional capacity responsible for coordinating and controlling two subsidiary slave systems, a phonological loop and a visuospatial sketchpad. The phonological loop was responsible for the storage and maintenance of information in a verbal form, and the visuospatial sketchpad was dedicated to the storage maintenance of visuospatial information.

3.13.2.3 The Central Executive

As has already been mentioned, working memory is viewed as a limited capacity system. There are a number of reasons for this capacity limitation, but an important one relates to what one might call the allocation of attention. Although many people are perfectly capable of walking and chewing gum at the same time, it is far more difficult to simultaneously perform more attention-demanding tasks, such as, to choose an unlikely example, monitoring the price of a stock for a quick trade while cogitating about one's next move in a highly competitive game

of chess. Thus, quite apart from the structural limitations inherent to memory storage systems (e.g., the natural inclination of memory traces to fade with time and interference), there also appear to be certain fundamental constraints on 'how much' attention can be allocated to the set of active tasks at any one time (Kahneman, 1973). The central executive component of working memory sits, as it were, at the helm of the cognitive apparatus and is responsible for the dispensation of attentional resources to the subsidiary components (e.g., the phonological loop) in working memory (Baddeley, 1986). Because total attentional capacity is finite, there must be a mechanism that intervenes to determine how the pool of attention is to be divided among the many possible actions, with their different levels of priority and reward contingencies, that are afforded by the environment. Thus, in dual-task paradigms, the central executive plays a crucial role in the scheduling and shifting of resources between tasks, and it can be used to explain the decline in performance that may be observed even when the two tasks in question involve different memory subsystems (Baddeley, 1992). Finally, it has often been pointed out that the central executive concept is too vague to act as anything other than a kind of placeholder for what is undoubtedly a much more complex system than is implied by the positing of a unitary and homunculus-like central cognitive operator (for a model of executive cognition, see Shallice, 1982). Provided, however, that the concept is not taken too literally, it can serve as a convenient way to refer to the complex and variegated set of processes that constitute the brain's executive system.

3.13.2.4 The Phonological Loop

Built into the architecture of the Working Memory model is a separation between domain-specific mechanisms of memory maintenance and domain-general mechanisms of executive control. Thus, the verbal component of working memory, or the phonological loop, is viewed as a 'slave' system that can be mobilized by the central executive when verbal material has to be retained in memory over some uncertain delay. Within the phonological loop it is the interplay of two components – the phonological store and the articulatory rehearsal process – that enables representations of verbal material to be kept in an active state. The phonological store is a passive buffer in which speech-based information can be stored for brief (approximately 2-s) periods. The articulatory control process serves to refresh and revivify the contents of the store, thus allowing the system to maintain short sequences of verbal items in memory for an extended interval. This division of labor between two interlocking components, one an active process and the other a passive store, is crucial to the model's explanatory power. For instance, when the articulatory control process is interfered with through the method of articulatory suppression (e.g., by requiring subjects to say 'hiya' over and over again), items in the store rapidly decay, and recall performance suffers greatly. The store, then, lacks a mechanism of reactivating its own contents but possesses memory capacity, whereas, conversely, the articulatory rehearsal process lacks an intrinsic memory capacity of its own, but can exert its effect indirectly by refreshing the contents of the store.

3.13.2.5 The Visuospatial Sketchpad

The other slave system in the Working Memory model is the visuospatial sketchpad, which is critical for the online retention of object and spatial information. Again, as is suggested by the term 'sketchpad,' the maintenance of visuospatial imagery in an active state requires top-down, or strategic, processing. As with the phonological loop, where articulatory suppression interferes with the maintenance of verbal information, a concurrent processing demand in the visuospatial domain, such as tracking a spot of light moving on a screen, random eye movements, or the presentation of irrelevant visual information during learning, likewise impairs memory performance. Although the symmetry between sensory and motor representations of visuospatial information is less obvious than it is in the case of speech, it has been demonstrated that saccadic rehearsal is important for the maintenance of spatial information (Postle et al., 2005). Baddeley (1986) initially proposed that in the context of spatial memory, covert eye movements can act as a way of revisiting locations in memory and thus operate very much like the articulatory rehearsal process known to be important for the maintenance of verbal information. Moreover, requiring subjects to perform a spatial interference task that disrupts or otherwise occupies this rehearsal component significantly impairs the performance of tests of spatial working memory, but has no effect on nonspatial visual memory tasks (Cocchini et al., 2002). In contrast, retention of visual shape or color information is interfered with by visual perceptual input, but not by a concurrent demand in the spatial domain (Klauer and Zhao, 2004). Thus, the principles that underlie the operation of the

phonological loop are qualitatively similar to those that underlie the operation of the visuospatial sketchpad; in both cases, maintenance processes consist of covert motor performance that serves to reactivate the memory traces residing in sensory stores. This mechanism might be most simply described as 'remembering by doing,' a strategy that is most effective when a motor code, which can be infinitely regenerated and which is under the subject's voluntary control, can be substituted for a fragile and less easily maintained perceptual memory code.

3.13.2.6 Summary

Working Memory is a system for the maintenance and manipulation of information that is stored in domain-specific memory buffers. Separate cognitive components are dedicated to the functions of storage, rehearsal, and executive control. Informational encapsulation and domain segregation dictate that auditory-verbal and visual information is kept in separate storage subsystems – the phonological loop and the visuospatial sketchpad, respectively. These storage subsystems themselves comprise specialized components for the passive storage of memory traces, which are subject to time and interference-based decay, and for the reactivation of these memory traces by way of simulation or rehearsal. Thus, storage components represent memory traces, but have no internal means of refreshing them, whereas rehearsal processes (e.g., articulatory, saccadic) have no mnemonic capacity of their own, but can reactivate the decaying traces held in temporary stores.

3.13.3 The Emergence of Working Memory as a Neuroscientific Concept

In the writings of the great neurologist Carl Wernicke, the idea that discrete pieces of cerebral cortex function as storehouses for 'memory images' is ubiquitous. For instance, the speech-perception deficit that accompanies lesions to the posterior superior temporal gyrus (STG), and that is one of the most characteristic symptoms of what is now referred to as Wernicke's aphasia, arises because this region of the auditory pathway, according to Wernicke, constitutes a location wherein 'auditory word images' are stored (Eggert and Wernicke, 1977). Indeed, Wernicke had a view of memory that shares much with some more modern formulations (Damasio, 1989; Wheeler et al., 2000; Cowan, 2001; Ruchkin et al., 2003) insofar as he viewed 'memories' as a reactivation of percepts originally formed during the sensory processing of an external stimulus:

> The sense impressions projected onto the cerebral cortex from the outside world last longer than the external stimulus affecting the sense organ; they can reappear in the form of memory images independently of the stimulus that produced them, although in less vivid form. (Eggert and Wernicke, 1977: 35)

Wernicke's ideas on memory, of course, predated the modern distinction between STM and LTM and were not intended to address the phenomenon that is today referred to as 'working memory.' Indeed, to Wernicke, perception and memory were part and parcel of the same functional–anatomical unit, whereby memory is perception evoked in the absence of direct external stimulation. The modern concept of working memory, however, distinguishes between stimulus recognition and discrimination, and the systems required to keep the products or residue of such sensory processes in the focus of attention during the temporal delays that often naturally intervene between stimulus perception and a contingent action. That is, unlike the memory images of Wernicke, which are punctate events, singular episodes, working memory entails sustained and persisting attention to an object or set of objects that exist in some upper register of the individual's consciousness. In this sense, then, the first insights into the neurobiological underpinnings of a memory whose purpose is to bridge cross-temporal contingencies (Fuster, 1997) comes from the work of Jacobsen, who studied nonhuman primate behavior after ablation to the prefrontal cortices. In comparing normal chimpanzees to those that had suffered extensive injury to the prefrontal cortex (PFC), Jacobsen (1936) noted:

> The normal chimpanzee has considerable facility in using sticks or other objects to manipulate its environment, e.g., to reach a piece of food beyond its unaided reach. It can solve such problems when it must utilize several sticks, some of which may not be immediately available in the visual field. After ablation of the prefrontal areas, the chimpanzee continues to use sticks as tools but it may have difficulty solving the problem if the necessary sticks and the food are not simultaneously present in the visual field. It exhibits also a characteristic 'memory' defect. Given an opportunity to observe a piece of food being concealed under one

> of two similar cups, it fails to recall after a few seconds under which cup the lure has been hidden. . . . (Jacobsen, 1936: 317)

In his pioneering experimental work, Jacobsen (1936) discovered that damage to the PFC of the monkey produces selective deficits in a task requiring a delayed response to the presentation of a sensory stimulus. The delayed-response tasks were initially devised by Hunter (1913) as a way of differentiating between animals on the basis of their ability to use information not currently available in the sensory environment to guide an imminent response. In the classic version of this test, a monkey is shown the location of a food morsel that is then hidden from view and placed in one of two wells. After a delay period of a few seconds, the monkey chooses one of the two locations and is rewarded if the choice corresponds to the location of the food. Variations on this test include the delayed alternation task, the delayed match-to-sample task, and the delayed nonmatch-to-sample task. The family of delayed-response tasks measures a complex cognitive ability that requires at least three clearly identifiable subprocesses: to recognize and properly encode the to-be-remembered item, to hold an internal representation of the item 'online' across an interval of time, and finally, to initiate the appropriate motor command when a response is prompted. Jacobsen showed that lesions to the PFC impair only the second of these three functions, suggesting a fundamental role for the region in immediate or short-term memory. Thus, monkeys with lesions to PFC perform in the normal range on a variety of tests requiring sensorimotor behavior, such as visual pattern discrimination and motor learning and control (i.e., tasks without a short-term mnemonic component). Although the impairments in the performance of delayed-response tasks in Jacobsen's studies were caused by large prefrontal lesions that often extended into the frontal pole and orbital surface, later studies showed that lesions confined to the region of the principal sulcus produced deficits equally as severe (Blum, 1952; Butters et al., 1972).

Fuster and Alexander (1971) reported the first direct physiological measures of PFC involvement in STM. With microelectrodes placed in the PFC, they measured the firing patterns of neurons during a spatial delayed-response task and showed that many cells showed increased firing, relative to an intertrial baseline period, during both cue presentation and the later retention period. Importantly, some cells fired exclusively during the delay period and therefore could be considered pure 'memory cells.' The results were interpreted as providing evidence for PFC involvement in the focusing of attention "on information that is being or that has been placed in temporary memory storage for prospective utilization" (p. 654). Many subsequent electrophysiological studies have demonstrated memory-related activity in the PFC of the monkey during delayed-response tasks of various kinds (e.g., Niki, 1974; Niki and Watanabe, 1976; Joseph and Barone, 1987; Quintana et al., 1988), although it was Patricia Goldman-Rakic who first drew a parallel (but see Passingham, 1985) and then firmly linked the phenomenon of persistent activity in PFC to the cognitive psychological concept of 'working memory.' In a monumental review of the existing literature on the role of the PFC in STM, Goldman-Rakic (1987), citing lesion and electrophysiological studies in the monkey, human neuropsychology, and the cytoarchitectonics and corticocortical connections of the PFC, argued that the dorsolateral PFC (the principal sulcus of the monkey) plays an essential role in holding visuospatial information in memory before the initiation of a response and in the absence of guiding sensory stimulation. In this and later work (especially that of Wilson et al., 1993), Goldman-Rakic developed a model of PFC in which visuospatial and (visual) object working memory were topographically segregated, with the former localized to the principal sulcus and the latter localized to a more ventral region along the inferior convexity of the lateral PFC (**Figure 4**).

This domain-specific view of the prefrontal organization, which was supported by observed dissociations in the responsivity of neurons in dorsal and ventral areas of the PFC during delayed-response tasks, could be viewed as an anterior expansion of the dorsal ('where') and ventral ('what') streams that had been discovered in the visual system in posterior neocortex (Ungerleider and Mishkin, 1982). In addition, the parallel and modular nature of the proposed functional and neuroanatomical architecture of PFC was in keeping with the tenet of domain independence in the Working Memory model of Baddeley and colleagues.

The connection between persistent activation in the PFC of the monkey and a model of memory developed in the field of cognitive psychology might seem tenuous, especially in light of the fact that the Working Memory model was originally formulated on the basis of evidence derived from behavioral

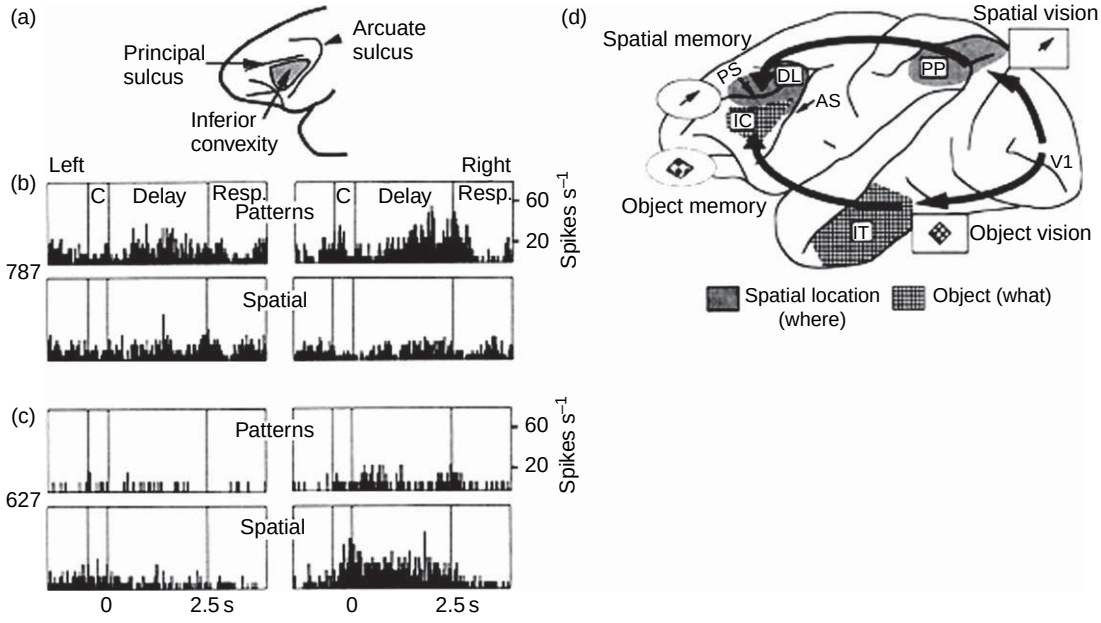

Figure 4 (a) Diagram of the frontal lobe and location of principal sulcus and inferior convexity. (b) Responses of inferior convexity neuron with visual object-specific activity in the delayed-response task. Upper panels show delay-period activity for object memory trials; lower panels show lack of response on spatial memory trials. (c) Responses of dorsolateral prefrontal neuron with spatial memory selectivity. Upper panels show lack of responsivity on object memory trials; lower panels show delay-period activity on spatial memory trials. (d) Schematic diagram illustrating the dorsal and ventral streams in the visual system and their connections with PFC. The posterior parietal (PP) is concerned with spatial perception, and the inferior temporal (IT) cortex with object recognition. These regions are connected with the dorsolateral (DL) and inferior convexity (IC) prefrontal cortices where, according to the Goldman-Rakic model, memory for spatial location and object identity are encoded in working memory. PS, principal sulcus; AS, arcuate sulcus. studies using linguistic material – an informational medium clearly unavailable to monkeys. For Goldman-Rakic, though, the use of the term 'working memory' in the context of nonhuman primate electrophysiology was not intended as an offhand or otherwise desultory nod to psychology (Goldman-Rakic 1990), but rather as a reasoned and deliberate effort to unify both our understanding of, and manner of referencing, a common neurobiological mechanism underlying an aspect of higher cognition that is well developed in primate species. Certainly, in retrospect, the decision to label the phenomenon of persistent activity in PFC with the term 'working memory' has had an immeasurable impact on memory research and indeed may be thought of as one of the two or three most important events contributing to the emergence of an integrated and unified approach to the study of neurobiology and psychology. Nowhere was this fusion between psychology and neurobiology more apparent, and nowhere were the ideas of Goldman-Rakic on visuospatial working memory more energetically tested and challenged, than in the realm of functional brain imaging.

3.13.3.1 Functional Neuroimaging Studies of Working Memory

At about the same time at which Fuster and Alexander (1971) recorded neural activity in the monkey PFC during a working memory task, Ingvar and colleagues (Ingvar, 1977; Ingvar and Risberg, 1965) examined variation in regional cerebral blood flow (rCBF) during tasks requiring complex mental activity. Indeed, Risberg and Ingvar (1973), in the first functional neuroimaging study of STM, showed that during a backward digit span task, the largest increases in rCBF, compared with a resting baseline, were observed in prerolandic and anterior frontal cortex. It was not, however, until the emergence of PET and the development of the O-15 tracer that the mapping of brain activity during the exercise of higher mental functions would become genuinely

amenable to the evaluation of complex hypotheses about the neural basis of cognition. In the middle and late 1980s, technological advances in the PET technique, with its relatively high spatial resolution (approximately 1 cm^3), were accompanied by a critical conceptual innovation known as 'cognitive subtraction' that provided the inferential machinery needed to link regional variation in brain activity to experimental manipulations at the task or psychological level (Posner et al., 1988). Thus, for any set of hypothesized mental processes (*a,b,c*), if a task can be devised in which one condition recruits all of the processing components (Task $1_{a,b,c}$) and another condition recruits only a subset of the components (Task $2_{a,b}$), subtraction of the observed regional activity during Task 2 from that observed during Task 1 should reveal the excess neural activity due to the performance of Task 1, and thus is associated with the cognitive component *c*. The Working Memory model of Baddeley, with its discrete cognitive components (e.g., central executive, phonological loop, and visuospatial scratchpad) was an ideal model with which to test the power of cognitive subtraction using modern neuroimaging tools. Indeed, in the span of only 2 years, the landmark studies of Paulesu et al. (1993), Jonides et al. (1993), and D'Esposito (1995), had mapped all of the cognitive components of the Working Memory model onto specific regions of the cerebral cortex. The challenge in successive years was to go beyond this sort of 'psychoneural transcription' – which is necessarily a unidirectional mapping between the cognitive box and the cerebral convolution – and begin to develop models that generate hypotheses that refer directly to the brain regions and mechanisms that underlie working memory. In the following sections, we review how neuroimaging studies of STM and executive control used the Working Memory model to gain an initial neural foothold on which later studies were buttressed and that would lead to insights and advances in our understanding of working memory as it is implemented in the brain.

3.13.3.2 Visuospatial Working Memory

The first study of visuospatial working memory in PET was carried out by Jonides and colleagues in 1993, using the logic of cognitive subtraction to isolate mnemonic processes associated with the maintenance of visuospatial information, in a task very similar to those used by Goldman-Rakic and her colleagues with monkeys (Goldman-Rakic 1987; Funahashi et al., 1989). During 'memory' scans, subjects were shown an array of three dots appearing for 200 ms on the circumference of a 14-mm imaginary circle and instructed to maintain the items in memory during a 3-s retention interval. This was followed by a probe for location-memory consisting of a circular outline that either did or did not (with equal probability) enclose one of the previously memorized dots, and to which subjects responded with a yes/no decision. In 'perception' scans, the three dots and the probe outline were presented simultaneously, so that subjects did not have to retain the location of the items in memory during a delay, but instead simply had to decide whether the outline encircled one of the three displayed dots (see **Figure 5**).

Subtraction of the 'perception' scans from the 'memory' scans revealed a right-lateralized network of cortical regions that would become a hallmark of neuroimaging studies of visuospatial working memory: the posterior parietal lobe, dorsal premotor cortex, occipital cortex (Brodmann area 19), and PFC. In their interpretation of the findings, the

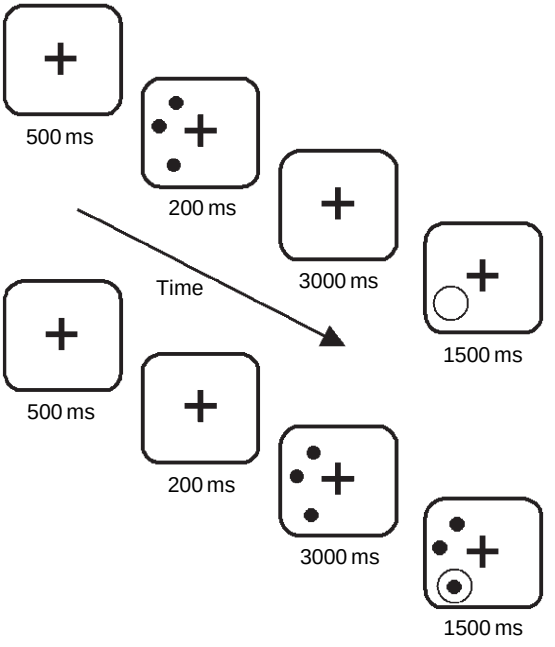

Figure 5 Schematic presentation of spatial memory task from Jonides J, Smith EE, Koeppe RA, Awh E, Minoshima S, and Mintun MA (1993) Spatial working memory in humans as revealed by PET. *Nature* 363: 623–625 and Smith EE, Jonides J, Koeppe RA, Awh E, Schumacher EH, and Minoshima S (1995) Spatial versus object working-memory – PET investigations. *J. Cogn. Neurosci.* 7: 337–356. Top panel shows example memory trial; bottom panel shows example perception trial.

authors suggested that the occipital activity reflected a role in the creation, but not necessarily the maintenance, of an internal visual image of the dot pattern, and that activity in the PFC might reflect one of two things: (1) the literal storage of a representation of the image in memory during the delay, or (2) the representation of a pointer or link to other brain circuitry, perhaps in the occipital or parietal lobe, that is actually responsible for maintaining the memory engram. These two explanations for the observation of prefrontal activity during working memory tasks, which in later years would often be pitted against each other, nicely frame the emerging debate on the division of labor among the cortical regions involved in the maintenance of information in working memory.

A major aim of many of the early neuroimaging studies of visuospatial working memory was to duplicate the canonical finding of Goldman-Rakic and colleagues of a dorsal-ventral dissociation in monkey PFC for spatial and object working memory. Studies by Petrides et al. (1993) and McCarthy et al. (1994) demonstrated with PET and functional MRI (fMRI), respectively, that middorsolateral PFC (Brodmann areas 9 and 46) shows increased activity during spatial working memory when compared with a control condition. An attempt to show a neuroanatomical double dissociation between spatial and object working memory was undertaken by Smith et al. (1995) in a PET study that used carefully controlled nonverbalizable object stimuli that were presented in both object and spatial task contexts. This study found distinct brain circuits for the storage of spatial and object information, with spatial working memory relying primarily on right-hemisphere regions in the prefrontal (BA 46) and parietal (BA 40) cortices, and object working memory involving only a left inferotemporal area. These results, however, only partially replicated the monkey study of Wilson et al. (1993), who had found distinct regions in PFC for spatial and object working memory. A similar pattern was found a year later in work by McCarthy et al. (1996), in which regional differences between object and spatial working memory were most pronounced across hemispheres rather than between dorsal and ventral divisions of the PFC. In a contemporaneous review and meta-analysis of all human neuroimaging studies of working memory, D'Esposito et al. (1998) showed that there was virtually no evidence for a neuroanatomical dissociation between spatial and object working memory. Indeed, establishing a correspondence between the functional neuroanatomy of visuospatial working memory in the monkey and human brains would prove remarkably difficult, leading to a protracted debate among and between monkey neurophysiologists and human neuroimaging researchers about the proper way to conceptualize the functional topography of working memory in the PFC (Goldman-Rakic, 2000; Miller, 2000). Increasingly, efforts were made to adapt human neuroimaging studies to resemble as closely as possible the kinds of tasks used in animal electrophysiology, such as the delayed match-to-sample procedure. The emergence of event-related fMRI, with its superior spatial and temporal resolution to O-15 PET, was critical to this new effort at cross-disciplinary synthesis and reconciliation and led to a number of fundamental insights on the brain basis of working memory, to the discussion of which we now turn.

Early PET studies of working memory relied exclusively on the logic of cognitive subtraction to isolate hypothesized components of a complex cognitive task. Thus, even for working memory tasks that consisted of a number of temporal phases within a given trial (e.g., stimulus presentation → memory maintenance → recognition decision), the low temporal resolution of PET prohibited separate statistical assessment of activity within a single task phase. Event-related fMRI, on the other hand, with its temporal resolution on the order of 2 to 4 s, could be used to examine functional activity in different portions of a multiphase trial, provided that each of the sequential task components was separated by approximately 4 s (Zarahn et al., 1997). This methodology permits the isolation of maintenance-related activity during the delay period of a match-to-sample procedure without relying on a complex cognitive subtraction (**Figure 6**).

Using event-related fMRI, Courtney et al. (1998) demonstrated a neuroanatomical dissociation between delay period activity during working memory maintenance for either the identity (object memory) or location (spatial memory) of a set of three face stimuli. Greater activity during the delay period on face identity trials was observed in the left inferior frontal gyrus, whereas greater activity during the delay period of the location task was observed in dorsal frontal cortex, a finding consistent with the spatial/object domain segregation thesis of Goldman-Rakic (1987). Unlike previous studies that had implicated human BA 46 – the presumed homologue to the monkey principal sulcus – in spatial working memory, Courtney observed enhanced delay-period activity for the location task, bilaterally, in the superior frontal sulcus, a region just anterior to the frontal eye fields.

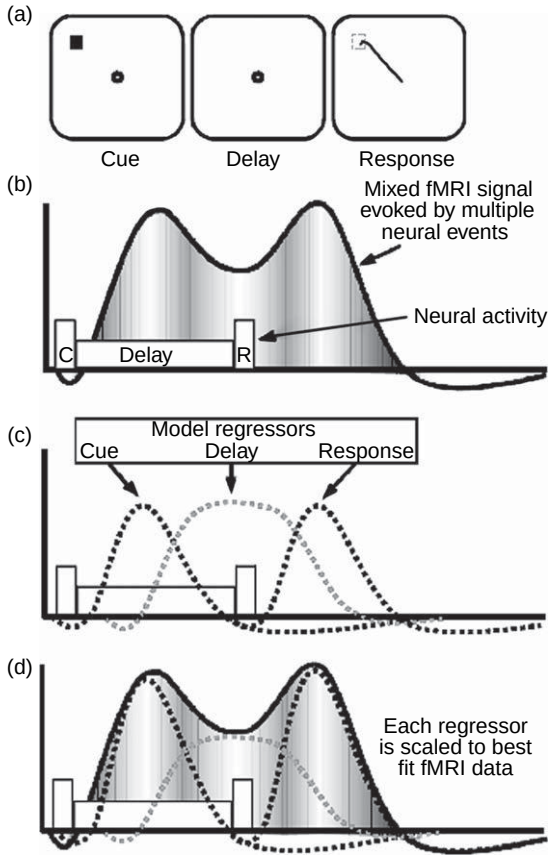

Figure 6 Delayed-response task and modeling with trial components of event-related fMRI data. (a) A prototypic spatial delayed-response task, like all delayed-response tasks, has three main epochs: a sample cue period where stimuli-to-be-remembered are presented, an unfilled delay period where stimuli are retained in memory, and finally a response period where a memory-guided response is required. (b) When multiple sequential neural events occur within a trial, the resulting fMRI response (R) is a mixture of signals arising from more than one time and more than one trial component. The gradient under the curve schematically represents the mixing or temporal overlap of the various signal components. For example, the white region at the peak of the first hump is evoked almost exclusively from neural processing during the cue phase of the task. However, just a few seconds later, in the darker portion just to the right, the signal is a mixture of processing at the cue phase and the beginning of the delay period. (c) In order to resolve the individual components of the mixed fMRI signal, separate regressors can be used to independently model the cue, delay, and response phases of the trial. (d) The magnitudes of the regressors scale with the degree to which they account for variance in the observed time series data. The magnitude of the delay regressor can be used as an index for maintenance-related activity.

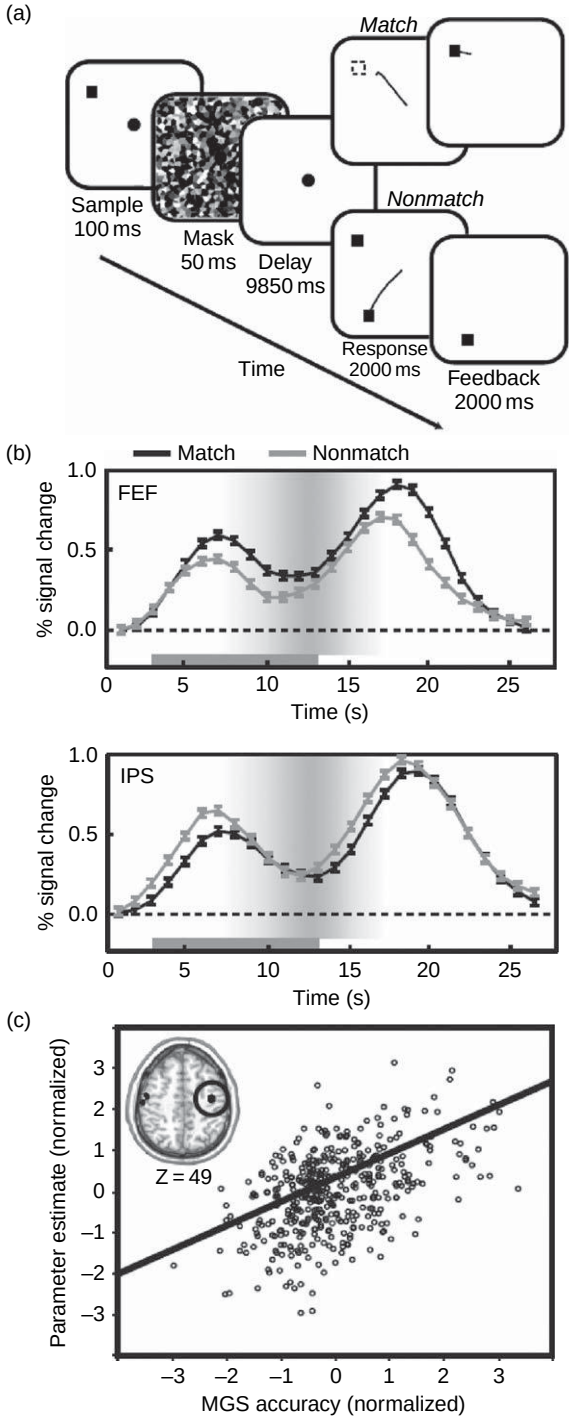
A control task requiring sensory guided eye movements was used to functionally delineate the frontal eye fields and thus distinguish them from regions with a specifically mnemonic function. They concluded that the localization of spatial working memory in the superior frontal sulcus (posterior and superior to BA 46) indicated an evolutionary displacement in the functional anatomy of the PFC, possibly due to the emergence of new cognitive abilities such as abstract reasoning, complex problem solving, and planning for the future. In short, then, this study was the first functional neuroimaging study to fully replicate the object versus spatial working memory dissociation shown by Goldman-Rakic and colleagues, insofar as one accepts their proposal that the human homologue to the monkey principal sulcus is located not in the middle frontal gyrus or BA 46, but rather in the superior frontal sulcus.

The study by Courtney represented a high water mark in the level of agreement between human neuroimaging and monkey electrophysiological studies of visuospatial working memory and their mutual correspondence to the Goldman-Rakic conception of a domain-segregated topography of prefrontal cortical function. Although several subsequent studies of spatial working memory offered support (Munk et al., 2002; Sala et al., 2003; Walter et al., 2003; Leung et al., 2004) for a specifically mnemonic role of the superior frontal sulcus in tasks of spatial working memory, other studies failed to replicate the finding (Postle and D'Esposito, 1999; Postle et al., 2000; Postle, 2006). The primary disagreement concerns not whether delay-period activity is found in the superior frontal sulcus during spatial working memory – it is – but rather whether such activity subserves an exclusively mnemonic or storage function. For instance, although Postle et al. (2000) observed delay-period activity in this region during a spatial working memory task, they also found it to be equally active during the generation of two-dimensional saccades, a task that required visuospatial attention and motor control but placed no demands on memory storage. In addition, the neural circuitry underlying spatial selective attention largely overlaps with that of spatial working memory (Corbetta et al., 2002), including the superior frontal sulcus, the frontal eye fields, and the intraparietal sulcus (IPS). Curtis et al. (2004) scanned subjects while they performed an oculomotor delayed-response task that required maintenance of the spatial position of a single dot of light over a delay period after which a memory-guided saccade was generated. Both frontal eye fields (FEF) and IPS delay-period activity showed activity that spanned the entire delay period (**Figure 7**). In addition, the magnitude of FEF and IPS delay-period activity predicted the accuracy of the memory-guided saccade generated after the

delay. This relationship suggests that the fidelity of the stored location is reflected in the delay-period activity. One interpretation of this result is that the persistent activity observed in the PFC reflects the operations of control processes that do not store information *per se*, but rather act to focus attention via top-down signals to posterior parietal cortex, toward particular locations in space.



3.13.3.3 Visual Object Working Memory

A number of studies have investigated the maintenance of objects, mostly visually presented faces, houses, and line drawings that are not easily verbalizable (e.g., Smith et al., 1995; Courtney et al., 1996, 1997; McCarthy et al., 1996; Belger et al., 1998; Postle and D'Esposito, 1999; Druzgal and D'Esposito, 2001, 2003; Rama et al., 2001; Mecklinger et al., 2002; Linden et al., 2003; Postle et al., 2003; Sala et al., 2003). Consistently, posterior cortical areas within the inferior temporal lobe that normally respond to the visual presentation of select objects also tend to activate during object working memory tasks. Therefore, the temporal lobe appears to play an important role in short-term storage of object features. For example, the fusiform gyrus, the ventral convexity surface of the temporal lobe, shows greater activation when a subject is shown pictures of faces than when other types of complex visual stimuli such as pictures of houses or scenes or household objects are presented (Kanwisher et al., 1997). Indeed, given its selective response properties, the fusiform gyrus has been termed the fusiform face area or FFA.

Four important findings indicate that posterior extrastriate cortical regions like the FFA play an important role in the mnemonic storage of object features. First, the FFA shows persistent delay-period activity (Druzgal and D'Esposito, 2001, 2003; Rama et al., 2001; Postle et al., 2003) during working memory tasks. Second, the activity in the FFA is somewhat selective for faces; it is greater during delays in which subjects are maintaining faces compared to with other objects (Sala et al., 2003). Third, as the number of faces that are being maintained increases, the magnitude of the delay-period activity increases in the FFA (Jha and McCarthy, 2000; Druzgal and D'Esposito, 2001, 2003). Such load effects strongly suggest a role in STS because, as the number of items that must be represented increases, so should the storage demands. Fourth, using a delayed paired associates task, Ranganath et al. (2004) have shown that the FFA responds during an unfilled delay interval following the presentation of a house that the subject has learned is associated with a certain face. Therefore, the delay-period FFA activity likely reflects the reactivated image of the associated face that was retrieved from LTM despite the fact that no face was actually presented before the delay. Together, these studies suggest that posterior regions of visual association cortex, like the FFA, participate in the internal storage of specific classes of visual object features. Most likely, the mechanisms used to create internal representations of objects that are no longer in our environment are similar to the mechanisms used to represent objects that exist in our external environment.

There have been several reports of delay-period-specific activations in the PFC during object working memory tasks as well (e.g., Courtney et al., 1998; Postle et al., 1999; Jha and McCarthy, 2000; Nystrom et al., 2000; Stern et al., 2000; Rama et al., 2001; Munk et al., 2002; Pessoa et al., 2002; Druzgal and D'Esposito, 2003; Ranganath et al., 2003; Sala et al., 2003). However, the localization of the delay-period activity appears varied across the dorsal, ventral, and medial portions of the PFC. The most consistent

Figure 7 Event-related study of spatial working memory by Curtis et al. (2004). (a) Schematic depiction of the oculomotor delayed-response tasks where subjects used the cue's location to make a memory-guided saccade. Both the matching-to-sample (top) and nonmatching-to-sample (bottom) tasks began with the brief presentation of a small. During matching trials, the subject made a memory-guided saccade (depicted by the thin black line) after the disappearance of the fixation cue marking the end of the delay. Feedback was provided by the representation of the cue. At this point, the subject corrected any errors by shifting gaze to the cue. The difference between the endpoint fixation after the memory-guided saccade and the fixation to acquire the feedback cue was used as an index of memory accuracy. During nonmatching trials, the subject made a saccade to the square that did not match the location of the sample cue. (b) Average (± S.E. bars) bold time series data for matching (black) and nonmatching-to-sample (gray) oculomotor delayed-response tasks. The solid gray bar represents the delay interval. The gray gradient in the background depicts the probability that the bold signal is emanating from the delay period, where darker indicates more probable. The frontal eye fields (FEF) show greater delay period activity during the matching task where an oculomotor strategy is efficient. The right intraparietal sulcus (IPS) shows greater delay period activity during the nonmatching task when subjects are biased from using such a strategy. (c) Scatter plot showing the correlation between memory-guided saccade (MGS) accuracy and the magnitude of the delay period parameter estimates in the right FEF. More accurate MGS were associated with greater delay period activity. From Curtis CE, Rao VY, and D'Esposito M (2004) Maintenance of spatial and motor codes during oculomotor delayed response tasks. *J. Neurosci.* 24: 3944–3952; used with permission.

finding in that regard may be a greater bias toward right hemisphere activation for object working memory compared with verbal working memory.

3.13.3.4 Verbal Working Memory

Research on the neural basis of verbal working memory has, for a number of reasons, taken a rather different course from corresponding work in the visuospatial domain. First, whereas in visual working memory many of the most influential ideas and concepts have derived from work in the monkey, verbal working memory is a uniquely human phenomenon and has therefore benefited from animal research only indirectly or by analogy with the visual system. Even research on the primary modality relevant to verbal working memory, that of audition, is surprisingly scarce in the monkey literature, owing to the difficulty in training nonhuman primates to perform delayed-response tasks with auditory stimuli, which can take upwards of 15 000 learning trials (see Fritz et al., 2005). On the other hand, an entirely different state of affairs prevails in the field of human cognitive psychology, where verbal short-term and working memory has over the last 40 years been studied extensively, almost to the exclusion of other modalities, resulting in thousands of published articles, a host of highly reliable and replicated behavioral phenomena, and dozens of sophisticated computational models. Finally, the study of aphasic patients has provided a wealth of information about the neural circuitry underlying language, and systematic neurological and neuropsychological inquiries into the impairments that accompany damage to the language system have yielded detailed neuroanatomical models. The aphasia literature notwithstanding, the study of the neural basis of verbal working memory has depended, to a much greater extent than has been the case in the visuospatial domain, on pure cognitive models of memory, in particular the phonological loop of Baddeley and colleagues. Not surprisingly as it turns out, there are notable similarities between working memory for visual and linguistic material, despite the absence of an exactly analogous capacity in nonhuman primates.

Early neurological investigations of patients with language disturbances or aphasia revealed that lesions to specific parts of the cerebral cortex could cause extremely selective deficits in language abilities. Thus, lesions to the inferior frontal gyrus are associated with Broca's aphasia, a disorder that causes severe impairments in speech production. Broca's aphasia is not, however, a disorder of peripheral motor coordination, such as the ability to move and control the tongue and mouth, but rather is a disorder of the ability to plan, program, and access the motor codes required for the production of speech (Goodglass, 1993). The functions of speech perception and comprehension in Broca's aphasia are generally preserved, however. Lesions to the posterior superior temporal gyrus and surrounding cortex, on the other hand, are associated with Wernicke's aphasia, a complex syndrome that is characterized by fluent, but error-filled, production and poor comprehension and perception of speech. A third, less-studied syndrome called conduction aphasia, typically caused by lesions in the posterior sylvian region (generally less extensive and relatively superior to lesions causing Wernicke's aphasia), is associated with preserved speech perception and comprehension, occasional errors in otherwise fluent spontaneous speech (e.g., phoneme substitutions), and severe difficulties with verbatim repetition of words and sentences (Damasio and Damasio, 1980). From the standpoint of verbal STM, a number of important points can be drawn from these three classic aphasic syndromes. First, the neural structures that underlie the perception and production of speech are partly dissociable. Thus, it appears that the brain retains at least two codes for the representation of speech: a sensory, or acoustic, code and an articulatory, or motor, code; the former is necessary for the perception of speech, and the latter is required for the production of speech. It is tempting to postulate that posterior temporal lesions primarily affect receptive language functions, whereas anterior lesions affect productive language functions – but this is not quite true; both Wernicke's aphasia and conduction aphasia are caused by posterior lesions, yet only the former is associated with a receptive language disturbance (Hickok and Poeppel, 2000). Second, all the aforementioned disorders affect basic aspects of language processing, such as the comprehension, production, and perception of speech. Even conduction aphasia, for which a deficit in repetition of speech is often emphasized, is characterized by speech errors that occur in the course of natural language production. Finally, the classical Wernicke-Lichteim-Geschwind (Geschwind, 1965) model of language explains each of these three syndromes as disruptions to components of a neuroanatomical network of areas, in the inferior frontal and superior temporal cortices, that subserve language function.

In the 1960s a handful of patients were described that did not fit nicely into the classic aphasiological rubric. Both Luria et al. (1967) and Warrington and

Shallice (1969) described patients with damage to the temporoparietal cortex who were severely impaired at repeating sequences of words or digits spoken aloud by the experimenter. Luria referred to the deficit as an acoustic-amnestic aphasia, whereas Warrington and Shallice (1969), who were perhaps more attuned to extant information-processing models in cognitive psychology, referred to the deficit as a "selective impairment of auditory-verbal short-term memory" (p. 885) In both of these cases, however, the memory impairment was accompanied by a deficit in ordinary speech production (i.e., word-finding difficulties, errors of speech, and reading difficulty), which was, in fact, consistent with the rather routine diagnosis of conduction aphasia, and therefore complicated the argument in favor of a pure memory impairment. Several years later, however, a patient (J. B.) (Shallice and Butterworth 1977), also with a temporoparietal lesion, was described who had a severely reduced auditory–verbal immediate memory span (one or two items) and yet was otherwise unimpaired in ordinary language use, including speech production and even long-term learning of supraspan lists of words. Several other such patients have since been described (for a review, see Shallice and Vallar, 1990), thus strengthening the case for the existence of an auditory–verbal storage component located in temporoparietal cortex.

The puzzle, of course, with respect to the classic neurological model of language discussed earlier, is how a lesion in the middle of the perisylvian speech center could produce a deficit in auditory–verbal immediate memory without any collateral deficit in basic language functioning. One possibility is that the precise location of the brain injury is determinative, so that a particularly focal and well-placed lesion in temporoparietal cortex might spare cortex critical for speech perception and production, while damaging a region dedicated to the storage of auditory–verbal information. However, the number of patients that have been described with a selective impairment to auditory–verbal STM is small, and the lesion locations that have been reported are comparable to those that might, in another patient, have led to conduction or Wernicke's aphasia (Damasio, 1992; Goodglass, 1993; Dronkers et al., 2004). This would seem, then, to be a question particularly well suited to high-resolution functional neuroimaging.

Systematic investigations of STM patients on tests of verbal working memory were essential to the logical development of the phonological loop (Vallar and Baddeley, 1984). For instance, the phonological store component – a passive buffer capable of storing approximately 2 s worth of speech-based information – is a descendant of the auditory–verbal store of Warrington and Shallice. Although Baddeley and colleagues considered neuropsychological investigations to be an extremely useful source of evidence for the development of an information-processing model of verbal working memory, they did not explicitly link the hypothesized components of the loop to regions of the brain. Thus, when the first functional neuroimaging studies of the neural correlates of the phonological loop were carried out, they were done without strong *a priori* neuroanatomical predictions – unlike the early PET studies of visuospatial working memory, which were guided by a large body of monkey literature.

Before we discuss these neuroimaging efforts, it is important to review in slightly more detail certain key aspects of the phonological loop. As has already been discussed in this chapter, the concept of a buffer or a memory store implies an independence from perceptual or motor processing. Thus, the storage component in the phonological loop – the phonological store – plays no direct role in the sensory analysis and processing of acoustic input. How, then, does information arrive to the phonological store? It turns out that information can enter the store in various ways. Verbal information that is presented visually must first be subvocalized, before it enters the store. Subvocalization (or silent speech) is necessary to recode a visual-orthographic stimulus into a phonological form. In contrast, acoustic information has direct and obligatory access to the phonological store. Despite this asymmetry in the manner in which auditory- and visual-verbal information enters the store, the representational code of the store is not modality specific, in the sense that it is not strictly tied to an acoustic input source. Once verbal material has entered the phonological store, it begins to decay rapidly. Phonological traces within the store can be refreshed, however, through the operation of the articulatory rehearsal process, which can cycle or loop through the contents of the store, serially reviving each of the decaying memory traces.

Faced with this more or less abstract model of the cognitive architecture of verbal working memory, the functional neuroimager must formulate some simple heuristics that can help constrain the neuroanatomical space in which to search for the various components of the phonological loop. For instance, the articulatory rehearsal process is wholly dependent on the brain circuit that underlies speech production, and

therefore one would expect that the operation of this component would rely to a large extent on the contribution of the inferior frontal gyrus, or Broca's area. Clearly, because acoustic information has obligatory access to the phonological store, one should expect to find its neural correlate in a region that activates during passive auditory stimulation (Becker et al., 1999; Chein and Fiez, 2001). In addition, because visual–verbal information enters the phonological store only by way of the articulatory rehearsal process, one should expect both silent reading (accompanied by subvocalization) and subvocal rehearsal to activate the phonological store. On the other hand, one should not expect to find the neural correlate of the phonological store in a region that is known to be critical for speech perception proper because of the model's explicit separation of perceptual and storage modules. The last heuristic is probably the most important and probably the most philosophically problematic: It has to be assumed that the modular organization of the phonological loop is reflected by a similarly modular organization in the brain – which is to say that one must stipulate that the same brain region cannot simultaneously fulfill the role of more than one component of the model. Thus, one must assume that the articulatory rehearsal process and the phonological store are not both located in the same brain region or set of regions. In fact, though, there is ample evidence from neuropsychological investigations that the articulatory rehearsal and phonological store components do not share a common neuroanatomical substrate (e.g., Vallar et al., 1997).

The first study that attempted to localize the components of phonological loop in the brain was that of Paulesu and colleagues (1993). In one task, English letters were visually presented on a monitor, and subjects were asked to remember them. In a second task, letters were presented, and rhyming judgments were made about them (press a button if letter rhymes with 'B'). In a baseline condition, Korean letters were visually presented, and subjects were asked to remember them using a visual code. According to the authors' logic, the first task would require the contribution of all the components of the phonological loop – subvocal rehearsal, phonological storage, and executive processes – whereas the second (rhyming) task would only require subvocal rehearsal and executive processes. This reasoning was based on previous research showing that when letters are presented visually (Vallar and Baddeley, 1984), rhyming decisions engage the subvocal rehearsal system, but not the phonological store. Thus, a subtraction of the rhyming condition from the letter-rehearsal condition should isolate the neural locus of the phonological store. First, results were presented for the two tasks requiring phonological processing with the baseline tasks (viewing Korean letters) that did not. Several areas were shown to be significantly more active in the phonological tasks, including (in all cases, bilaterally) Broca's area (BA44/45), the supplementary motor cortex (SMA), the insula, the cerebellum, Brodmann area 22/42, and Brodmann area 40. Subtracting the rhyming condition from the phonological STM condition left a single brain area: Brodmann area 40 (BA 40) – the neural correlate of the phonological store.

Not surprisingly the articulatory rehearsal process recruited a distributed neural circuit that included the inferior frontal gyrus. The implication of multiple brain regions during articulatory rehearsal is not surprising, given the complexity of the process and the variety of lesion sites associated with a speech-production deficit. On the other hand, the localization of the phonological store in a single brain region, BA 40 (or the supramarginal gyrus), comports with the idea of a solitary receptacle where phonological information is temporarily stored. A number of follow-up PET studies, using various tasks and design logic, generally replicated the basic finding of the Paulesu study, namely, a fronto-insular-cerebellar network associated with rehearsal processes and a parietal locus for the phonological store (Awh et al., 1996; Salmon et al., 1996; Schumacher et al., 1996; Jonides et al., 1998; Smith and Jonides, 1999).

In a perspicacious review of these premillennial PET studies of verbal working memory, Becker et al. (1999) questioned whether the localization of the phonological store in BA 40 of the parietal cortex could be reconciled with the logical architecture of the phonological loop. They noted that because auditory material has obligatory access to the store, its neural correlate ought to show robust activation during simple auditory perception. Functional neuroimaging studies of passive auditory listening, however, do not show activity in the parietal lobe, but are typically circumscribed to the superior temporal lobe (e.g., Binder et al., 2000). In addition, efforts to show verbal mnemonic specificity to the parietal lobe activation were uniformly unsuccessful, showing instead that working memory for words, visual objects, and spatial locations all activated the area (Nystrom et al., 2000; Zurowski et al., 2002). Thus, it would appear that if there were a true neural correlate to the phonological store, it must reside within the confines of the auditory cortical zone of the superior temporal cortex.

As was the case in the visuospatial domain, the emergence of event-related fMRI, with its ability to isolate delay-period activity during working memory, was an inferential boon to the study of verbal working memory. Postle et al. (1999) showed, with visual–verbal presentation of letter stimuli, that delay-period activity in single subjects was often localized in the posterior superior temporal cortex rather than in the parietal lobe. Buchsbaum et al. (2001) also used an event-related fMRI paradigm, in which, on each trial, subjects were presented with acoustic speech information that they then rehearsed subvocally for 27 s, followed by a rest period.

Analysis focused on identifying regions that were responsive both during the perceptual phase and the rehearsal phase of the trial. Activation occurred in two regions in the posterior superior temporal cortex, one in the posterior superior temporal sulcus (STS) bilaterally and one along the dorsal surface of the left posterior planum temporale, that is, in the Sylvian fissure at the parietal-temporal boundary (area Spt). Notably, although the parietal lobe did show delay-period activity, it was unresponsive during auditory stimulus presentation. In a follow-up study, Hickok (2003) showed that the same superior temporal regions (posterior STS and Spt) were active both during the perception and delay-period maintenance of short (5 s) musical melodies, suggesting that these posterior temporal storage sites are not restricted to speech-based, or phonological, information (**Figure 8**).

In addition, Stevens (2004) and Rama et al. (2004) have shown that memory for voice identity, independent of phonological content (i.e., matching speaker identity as opposed to word identity), selectively activates the mid-STS and the anterior STG of the superior temporal region, but not the more posterior and dorsally situated Spt region. Buchsbaum et al. (2005) have further shown that the mid-STS is more active when subjects recall verbal information that is acoustically presented than when the information is visually presented, whereas area Spt shows equally strong delay-period activity for both auditory and

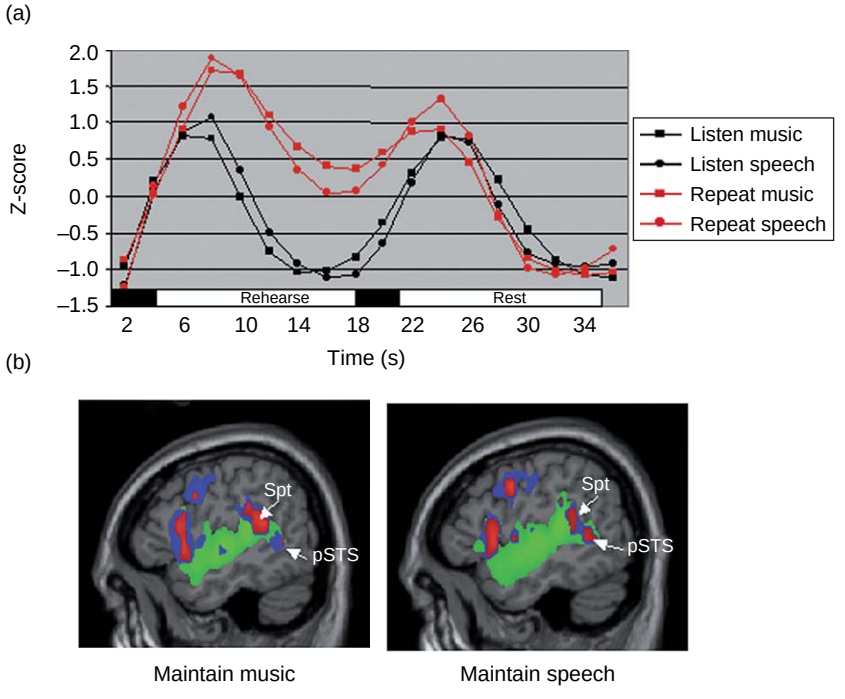


Figure 8 Main results from Hickok et al. (2003) study of verbal and musical working memory maintenance. (a) Averaged time course of activation over the course of a trial in area Spt for speech and music conditions. Timeline at bottom shows structure of each trial; black bars indicate auditory stimulus presentation. Red traces indicate activation during rehearsal trials, black traces indicate activity during listen-only trials in which subjects did not rehearse stimuli at all. (b) Activation maps of in the left hemisphere (sagittal slices) showing three response patterns for both music rehearsal (left) and speech rehearsal trials (right): auditory-only responses shown in green; delay-period responses shown in blue; and auditory + rehearsal responses shown in red. Arrows indicate the location of area Spt. pSTS, posterior superior temporal sulcus. From Hickok G, Buchsbaum B, Humphries C, and Muftuler T (2003) Auditory-motor interaction revealed by fMRI: Speech, music, and working memory in area Spt. *J. Cogn. Neurosci.* 15: 673–682; used with permission.

visual forms of input. Thus, it appears that different regions in the auditory association cortex of the superior temporal cortex are attuned to different qualities or features of a verbal stimulus, such as voice information, input modality, phonological content, and lexical status (e.g., Martin and Freedman, 2001) – and all these codes may play a role in the short-term maintenance of verbal information.

Additional support for a feature-based topography of auditory association cortex comes from neuroanatomical tract-tracing studies in the monkey that have revealed separate temporo-prefrontal pathways arising along the anterior–posterior axis of the superior temporal region (Romanski et al., 1999; Romanski, 2004). The posterior part of the STG projects to dorsolateral PFC (BA 46, 8), whereas neurons in the anterior STG are more strongly connected to the ventral PFC, including BA 12 and 47. Several authors have suggested, similar to the visual system, a dichotomy between ventral-going auditory-object and a dorsal-going auditory-spatial processing streams (Rauschecker and Tian, 2000; Tian et al., 2001). Thus, studies have shown that the neurons in the rostral STG show more selective responses to classes of complex sounds, such as vocalizations, whereas more caudally located regions show more spatial selectivity (Rauschecker and Tian, 2000; Tian et al., 2001). Hickok and Poeppel (2004, 2000) have proposed that human speech processing also proceeds along diverging auditory dorsal and ventral streams, although they emphasize the distinction between perception for action, or auditory-motor integration, in the dorsal stream and perception for comprehension in the ventral stream. Buchsbaum et al. (2005) have shown with fMRI time series data that, consistent with the monkey connectivity patterns, the most posterior and dorsal part of the superior temporal cortex, area Spt, shows the strongest functional connectivity with dorsolateral and posterior (premotor) parts of the PFC, whereas the midportion of the STS is most tightly coupled with BA 12 and 47 of the ventrolateral PFC (see **Figure 9**). Moreover, in a gross distinction between anterior (BA 47) and posterior (BA 44/6), parts of the PFC have been associated with conceptual-semantic and phonological-articulatory aspects of verbal processing (Poldrack et al., 1999; Wagner et al., 2001).

Earlier we posed the question of how a lesion in posterior sylvian cortex, an area of known importance for online language processing, could occasionally produce an impairment restricted to phonological STM. One solution to this puzzle is that subjects

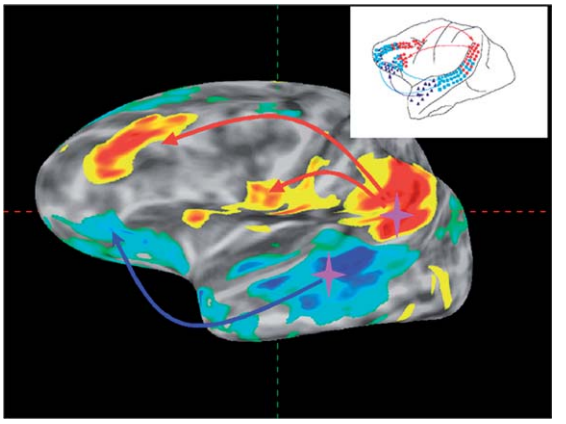

Figure 9 Map of functional connectivity delay-period maintenance of verbal stimuli from Buchsbaum et al. (2005). Seed regions for correlation analysis are denoted by stars located in area Spt and the middle part of the STS. Warm colors show areas more strongly correlated with Spt than with STS; cold colors show areas more strongly correlated with STS than Spt. Inset shows temporal-prefrontal connectivity in the monkey. From Buchsbaum BR, Olsen RK, Koch P, and Berman KF (2005) Human dorsal and ventral auditory streams subserve rehearsal-based and echoic processes during verbal working memory. *Neuron* 48: 687–697; used with permission. Inset from Scott SK and Johnsrude IS (2003) The neuroanatomical and functional organization of speech perception. *Trends Neurosci.* Feb; 26(2): 100–107; used with permission.

with selective verbal STM deficits from posterior temporal lesions retain their perceptual and comprehension abilities due to the sparing of the ventral stream pathways, whereas the preservation of speech production is due to an unusual capacity in these subjects for right-hemisphere control of speech. The STM deficit arises, then, from a selective deficit in auditory-motor integration – or the ability to translate between acoustic and articulatory speech codes – a function that is especially taxed during tests of repetition and STM (Hickok et al., 2003; Hickok and Poeppel, 2004).

The study of the neural basis of verbal working memory has proceeded from a large body of human neurological evidence pointing to the critical role of anterior regions (e.g., Broca's area) in speech production and posterior regions (e.g., temporoparietal cortex) in perceptual and mnemonic aspects of speech processing. This contrasts rather sharply with neurobiological investigations of spatial working memory, which was initially driven almost entirely by studies in the monkey and, in addition, posited a direct role for lateral PFC in mnemonic storage (Goldman-Rakic, 1987). Thus, for instance,

although there has been a great deal of debate as to whether the dorsolateral PFC stores information or whether it simply maintains pointers or links to posterior cortices where mnemonic representations are held (see Postle, 2006), there has, on the contrary, been little if any debate as to whether Broca's area is involved in verbal mnemonic storage *per se*, as it has generally been assumed that the inferior frontal region plays a specific role in motor-speech planning. Indeed, however, if we expand our conception of memory to include not just the percepts of the past, but the goals, plans, and intentions of the future – the "memory of the future" in David Ingvar's (1985) phrase – then the role of both dorsal and inferior frontal regions in spatial and verbal memory might relate to prospective operations that relate to objects held in working memory.

3.13.3.5 Models of Prefrontal Organization of Working Memory

Although there is strong support that the lateral PFC is critical for working memory maintenance processes, its precise role is still unclear. Goldman-Rakic and colleagues first proposed that different PFC regions are critical for active maintenance of different types of information. Based on monkey electrophysiological and lesion studies (Funahashi et al., 1989; Wilson et al., 1993), they theorized that persistent activity within the ventrolateral PFC would reflect the temporary maintenance of nonspatial codes (such as an object's color and shape), whereas dorsolateral PFC activity would reflect the maintenance of spatial codes (such as the location of an object in space). This hypothesis had the appeal of parsimony, as a similar organization exists in the visual system, which is segregated into what and where pathways (Ungerleider and Mishkin, 1982). Also, anatomical studies in monkeys have demonstrated that the parietal cortex (i.e., spatial vision regions) predominantly projects to a dorsal region of the lateral PFC (Cavada and Goldman-Rakic, 1989; Petrides and Pandya, 1984), whereas the temporal cortex (i.e., object vision regions) projects more ventrally within lateral PFC (Barbas, 1988).

Another possible axis along which the human lateral PFC may be organized is according to the type of operations performed on information being actively maintained, rather than the type of information being maintained. For example, Petrides proposed that there are two processing systems, one dorsal and the other ventral, within lateral PFC (Petrides and Pandya, 1994). It was proposed that ventral PFC (Brodmann's areas 45, 47) is the site where information is initially received from posterior association areas and where active comparisons of maintained information are made. In contrast, the dorsal PFC (areas 9, 46, 9/46) is recruited only when monitoring and manipulation of this information are required.

This model received initial support from an empirical PET study performed by Owen, Petrides, and colleagues (Owen et al., 1996) in which dorsal PFC activation was found during three spatial working memory tasks thought to require greater monitoring of remembered information than two other memory tasks that activated only the ventral PFC. We also tested this model of process-specific PFC organization using event-related fMRI (D'Esposito et al., 1999). In our study, subjects were presented two types of trials in random order in which they were required to either (1) maintain a sequence of letters across a delay period or (2) manipulate (alphabetize) this sequence during the delay to respond correctly to a probe. In every subject, delay-period activity was found in both dorsal and ventral PFC in both types of trials. However, dorsal PFC activity was greater in trials during which actively maintained information was manipulated. These findings suggest that the dorsal PFC may exhibit greater recruitment during conditions that require additional processing of actively maintained information, supporting a process-specific PFC organization.

On the surface, these two models of PFC organization seem incompatible, and to this day papers continue to be published pitting one against the other. However, a closer look at the empirical data from human functional imaging and monkey physiology studies over the past 10 years leads to the conclusion that both models accurately describe PFC organization. The persistence of the notion that these models are orthogonal to each other may result in part from a lack in precision of the anatomical definitions of the dorsal and ventral PFC that were being used. For example, as reviewed earlier, the principal evidence cited to support domain-specific PFC organization in humans (Leung et al., 2002) derives from studies by Courtney and colleagues, who found that the superior frontal sulcus (area 6/8) appears specific to spatial working memory, whereas regions within the inferior frontal gyrus (areas 45, 47) appear specific to nonspatial information (e.g., faces). Unquestionably, the superior frontal sulcus is anatomically dorsal to the inferior frontal gyrus. Thus, on the surface these data provide strong support for a dorsal-what versus a ventral-where,

domain-specific PFC organization. However, other data from monkey physiological and human functional imaging studies seem inconsistent with the domain-specific hypothesis because they provide evidence that certain dorsal and ventral PFC regions do not appear specific to one domain of information. For example, several single-unit recording studies during delayed-response tasks have found a mixed population of neurons throughout dorsal and ventral regions of lateral PFC that are not clearly segregated by the type of information (i.e., spatial vs. nonspatial) that is being stored (Rosenkilde et al., 1981; Fuster et al., 1982; Quintana et al., 1988; Rao et al., 1997). Also, cooling of PFC (Fuster and Bauer, 1974; Bauer and Fuster, 1976; Quintana and Fuster, 1993) and dorsal PFC lesions causes impairments on nonspatial working memory tasks (Mishkin et al., 1969; Petrides, 1995), and ventral PFC lesions cause spatial impairments (Iversen and Mishkin, 1970; Butters et al., 1973). Finally, another study found that ventral PFC lesions in monkeys did not lead to delay-dependent defects on a visual pattern-association task and color-matching task (Rushworth et al., 1997). Also, numerous human functional imaging studies have failed to find different patterns of PFC activation during spatial versus nonspatial working memory tasks (e.g., Owen et al., 1998; Postle and D'Esposito, 1999; Nystrom et al., 2000).

How can we reconcile all these findings? The answer emerges from a close examination of the particular PFC regions that do or do not exhibit persistent activity that is specific to a particular type of information. Thus, domain specificity may exist within the superior frontal sulcus (area 6/8) and portions of the inferior frontal gyrus (areas 44, 45, 47), but other lateral PFC regions such as middle frontal gyrus (areas 9, 46, 9/46) may not show domain specificity. A coarse subdivision of the PFC into dorsal and ventral regions fails to account for the possibility that both domain-specific and process-specific organization may exist. A hybrid model of PFC organization could accommodate the empirical findings (Postle et al., 2000). But a hybrid model may not be able to capture, in cognitive or neural terms, the specific type of processes that are being attributed to the middle frontal gyrus (areas 9, 46, 9/46). Are the processes attributed to this region (e.g., monitoring and manipulation) distinct from active maintenance processes? For example, one possibility is that monitoring and manipulation tasks recruit the middle frontal gyrus because they require active maintenance of more abstract relations (e.g., semantic, temporal) between items. In this view, the PFC is not organized by different types of processing modules, but by the abstractness of the representations being actively maintained. This organization could be hierarchic, ranging from features of an object (e.g., red), to more abstract dimensions (e.g., color), to superordinate representations such as goals or task context (e.g., color-naming task). Evidence from functional neuroimaging studies has begun to provide support for this idea.

A recent neuroimaging study has tested this model of hierarchical PFC organization, all within one set of experiments (Koechlin et al., 2003). In this fMRI study, the frequency of to-be-selected representations was manipulated in an effort to affect levels of PFC processing. Manipulation of the number of responses within a block primarily affected premotor cortex. Manipulation of the number of relevant stimulus dimensions within a block affected dorsolateral PFC. Finally, manipulation of the across-block frequency of cue-to-response or cue-to-dimension mappings affected PFC responses. Interestingly, structural equation modeling of the fMRI data revealed path coefficients from the PFC to the dorsal PFC to premotor cortex but not in the opposite direction, broadly consistent with a hierarchic organization. An important contribution from this study is that it considers the entire frontal cortex, from premotor regions to the most anterior portion of PFC (area 10), an area that has been relatively ignored in working memory research. This type of PFC organization is also consistent with data (O'Reilly et al., 2002), which demonstrated that a connectionist model possessing a concrete feature level and an abstract dimension level in its PFC could produce the double dissociations reported in the monkey data.

Miller and Cohen (2001) have presented a synthesis of empirical findings with a theoretical model regarding how basic maintenance processes subserved by the PFC can exert cognitive control. They propose that PFC delay activity is specific to those representations that are behaviorally relevant, enabling an animal or human to prospectively integrate across time when selecting an action. Automatic behaviors can be mediated by computations in posterior neocortices with little influence from internal goals maintained by the PFC. When bottom-up processes are insufficient for or in conflict with current goals, available cues may be insufficient to uniquely specify a response. Under such circumstances, the active maintenance of behaviorally relevant representations permits the appropriate selection for action.

The PFC has extensive reciprocal connections with most of the brain and is situated at the apex of mnemonic, affective, perceptual, and motor pathways arising from posterior and subcortical processors. Thus, it is in a privileged position to store behaviorally relevant representations and exert cognitive control. The frontal cortex appears hierarchically organized, not simply in a dorsal/ventral fashion, but in a posterior/anterior direction from premotor regions to frontopolar cortex. Future research must continue to determine the regional distinctions that define the functional topography of the frontal cortex and the principles by which these regions interact to produce controlled behavior.

In summary, goal-directed behavior, which is both intentional and flexible, requires the active maintenance of a broad range of perceptual, mnemonic, and motor representations. For example, imagine hitting a golf ball. If your ball is in the woods, you may need to maintain the location of the flag in the distance as you keep your eye on the ball. As you prepare to hit your ball, you also have to maintain the rules of the game because any movement of the ball as you address it may result in a penalty stroke. And finally, if you are playing poorly, it is important to maintain the original goal for taking up the game – to exercise and enjoy yourself.

3.13.4 Summary and Conclusions

Elucidation of the cognitive and neural architectures underlying STM has been an important focus of neuroscience research for much of the past two decades. The emergence of the concept of working memory, with its emphasis on the utilization of the objects stored in memory in the service of behavioral goals, has enlarged our understanding and broadened the scope of neuroscience research of STM. Data from numerous studies have been reviewed and have demonstrated that a network of brain regions, including the PFC, is critical for the active maintenance of internal representations. Moreover, it appears that the PFC has functional subdivisions that are organized according to the domain (verbal, spatial, object, etc.) of the topographical inputs arriving from posterior cortices. In addition, however, a level of representational abstractness is achieved through the integration of information converging in the PFC. Finally, working memory function is not localized to a single brain region but is rather an emergent property of the functional interactions between the PFC and other posterior neocortical regions. Numerous questions remain about the neural basis of this complex cognitive system, but studies such as those reviewed in this chapter should continue to provide converging evidence that may provide answers to the many residual questions.

3.14 Prefrontal Cortex and Memory

C. Ranganath and R. S. Blumenfeld, University of California at Davis, Davis, CA, USA

3.14.1 Introduction

Dating back at least to the work of Jacobsen (1935), researchers have been interested in characterizing the functional role of the lateral prefrontal cortex (PFC) in memory. In recent years, a wealth of evidence from neuropsychological, neurophysiological, and neuroimaging studies has accumulated, implicating the PFC in a wide variety of memory functions. Here, we will review this evidence and present a general framework for understanding the roles of different prefrontal regions in memory processing.

3.14.2 Anatomical Organization of the PFC

In order to understand how the PFC contributes to memory, it is useful to start by considering its anatomical characteristics. The PFC is situated in the frontal lobes, rostral to the premotor and motor cortices and, in humans, occupies approximately one third of the cortical mantle (Fuster, 1997). The lateral PFC consists of several highly interconnected subregions that can be distinguished based on cytoarchitectonic characteristics and anatomical connectivity. Many researchers (e.g., Goldman-Rakic, 1987; Petrides, 1994; Fuster, 1997) have proposed functional distinctions between mid-dorsolateral (DLPFC; Brodmann's areas [BA] 9 and 46) and ventrolateral (VLPFC; BA 44, 45, and 47) PFC. VLPFC is situated in the inferior convexity in the monkey brain and in the inferior frontal gyrus in humans. This region is highly connected to ventral posterior sensory areas, and especially to regions of the inferior and superior temporal lobe. DLPFC is situated in the cortex dorsal to the sulcus principalis in the monkey and in the middle frontal gyrus in the human brain. In contrast to VLPFC, DLPFC is more highly interconnected with dorsal stream regions (especially the posterior parietal cortex) and paralimbic cortical regions, including the retrosplenial and parahippocampal cortices.

Although little is known about more anterior regions of lateral PFC (APFC; BA 10), recent research suggests that these regions may be particularly critical for human cognition (Petrides, 1994; Fuster, 1997; Christoff and Gabrieli, 2000; D'Esposito et al., 2000; Koechlin et al., 2003; Ramnani and Owen, 2004). For example, recent comparative neuroanatomical work suggests a twofold increase in the size of APFC in humans relative to chimpanzees (Semendeferi et al., 2001), despite the fact that the relative size of the entire frontal lobe is similar between the two species (Semendeferi et al., 2002). As described in the following, VLPFC, DLPFC, and APFC have been implicated in human memory processes, and

there is some evidence that these regions may exhibit different functional characteristics (Wagner, 1999; Buckner and Wheeler, 2001; Fletcher and Henson, 2001; Rainer and Ranganath, 2002; Ranganath and Knight, 2003).

3.14.3 PFC and Working Memory

3.14.3.1 PFC Involvement in Working Memory: Short-Term Retention and Cognitive Control

Since the 1980s, a great deal of research has focused on the role of PFC in 'working memory' (WM) processes that support temporary retention and online processing of information. Much of this work has characterized the PFC as a global level, but more recent research has been devoted to specifying the different processes implemented by different subregions of PFC (Goldman-Rakic, 1987; Fuster, 1997; D'Esposito et al., 2000; Petrides, 2005). Psychological theories of WM generally distinguish between processes that support temporary retention of information across short delays (or what is now termed 'WM maintenance') and those that support attentional and cognitive control (Baddeley, 1986). The degree to which regions of PFC are necessary for maintenance versus control has been a topic of extensive debate in cognitive neuroscience.

The idea that PFC supports temporary retention of information has largely emerged from single-unit recording studies of monkeys performing the delayed response task, in which the monkey is shown a reward in one of two locations but must wait until after a delay before it can obtain the reward. The task is thought to require the monkey to maintain an internal representation of the remembered location or upcoming movement across the delay period. Critically, lateral prefrontal neurons exhibit persistent activity during the memory delay that is selective for the remembered location (Fuster and Alexander, 1971). This work was extended by Funahashi et al. (1989, 1990), who investigated prefrontal activity during an oculomotor delayed response task, in which a monkey is cued to make an eye movement to a spatial location, but it must wait until after a brief delay before making the saccade. Consistent with other studies of the delayed response task, lateral prefrontal neurons exhibited persistent activity during the memory delay that was specific to the spatial location that was to be remembered. Further research showed that PFC lesions in one hemisphere impaired memory performance specifically for locations in the contralateral hemifield (Funahashi et al., 1993). Based on these findings, it has often been assumed that lateral prefrontal neurons temporarily store information that is to be maintained across a delay (Goldman-Rakic, 1987).

Results from studies by Miller and Desimone seemed to further substantiate this idea by contrasting the activity of neurons in inferior temporal cortex (a region that is involved in visual object processing; cf. Miyashita and Hayashi, 2000) and PFC during a visual WM task. Their findings showed that both inferior temporal and prefrontal neurons showed persistent, stimulus-specific activity during memory delays (Miller et al., 1993, 1996). However, persistent delay period activity in inferior temporal neurons was abolished by the presentation of a distracting stimulus (Miller et al., 1993), whereas activity in PFC remained robust in the face of interference.

Many have interpreted Miller and Desimone's data to support the idea that short-term retention of information is supported by the PFC, rather than by posterior cortical areas that represent the information to be maintained. However, this interpretation rests on the assumption that persistent activity is the sole neural correlate of WM maintenance. This assumption was invalidated in a recent study, in which single-unit activity and local field potentials (LFPs) were recorded in occipital area V4 during a visual WM task (Lee et al., 2005). Unlike neurons in inferior temporal cortex, recordings from V4 did not reveal evidence of persistent, stimulus-specific activity during even an unfilled memory delay. However, results did reveal single-unit activity during the memory delay that was phase-locked to theta oscillations in the electroencephalogram. Critically, the phase-locking of single-unit activity and theta oscillations was selective to the remembered stimulus. These findings strongly suggest that posterior cortical regions can play important roles in WM maintenance even in the absence of overall changes in mean firing rate across the memory delay. Furthermore, converging lines of evidence now suggest that short-term retention of specific kinds of information is supported by activation of the posterior cortical areas that represent that information (*See* Chapter 3.13; Fuster, 1995; Miyashita and Hayashi, 2000; Lee et al., 2005; Ranganath and Blumenfeld, 2005; Ranganath and D'Esposito, 2005; Postle, 2006; Ranganath, 2006).

Results from lesion studies have additionally demonstrated that the PFC contributes to WM by

virtue of its role in cognitive control, rather than short-term retention (see D'Esposito and Postle, 1999; Curtis and D'Esposito, 2004; Postle, 2006, for detailed reviews of this topic). Jacobsen (1935) demonstrated that lateral prefrontal lesions caused impairments in the delayed response task, leading him to conclude that the PFC is critical for retaining information across short delays. However, this interpretation was later questioned by Malmo (1942), who demonstrated that prefrontal lesions only impaired monkeys' performance on the task if there was interference present between the instruction and the response. If the lights were turned off between the instruction and response (thus minimizing interference), performance was intact. Subsequent research in the 1960s substantiated the idea that monkeys with PFC lesions performed poorly because they were unable to suppress previously rewarded responses or because they could not maintain the appropriate task set (Mishkin, 1964; Pribram et al., 1964; Pribram and Tubbs, 1967; Nauta, 1971). For instance, Nauta (1971) noted that

> the initial impression that the 'frontal animal' suffers from a memory loss . . . has been effectively refuted, and it now seems certain that frontal-lobe ablation affects a response-guidance other than memory in the customary sense.

This impression has been supported by more recent lesion studies (Mishkin and Manning, 1978; Kowalska et al., 1991; Meunier et al., 1997; Rushworth et al., 1997; Petrides, 2000), as well as single-unit recording (Asaad et al., 2000; Lebedev et al., 2004) studies of monkeys and neuropsychological (Chao and Knight, 1995; D'Esposito and Postle, 1999; D'Esposito et al., 2006) and neuroimaging (Postle et al., 1999; Smith and Jonides, 1999) studies of humans. Indeed, consistent with the monkey literature, humans with prefrontal lesions do not exhibit significant impairments in short-term retention of information, but their performance is impaired on more complex tasks that involve inhibiting distraction and manipulating information (Chao and Knight, 1995, 1998; D'Esposito and Postle, 1999; Ranganath and Blumenfeld, 2005; D'Esposito et al., 2006).

How, then, does one explain the fact that prefrontal regions show persistent activity during WM maintenance? The most likely explanation is that prefrontal neurons do not temporarily store information that is to be maintained, but rather that they represent and maintain context-dependent rules or associations that dictate the kind of information that is currently goal relevant (Fuster, 1997; Miller, 2000). Indeed, this idea can explain not only why PFC neurons exhibit delay period activity, but also why they exhibit activity associated with virtually every relevant aspect of delayed-response tasks (Fuster, 1997). By representing context-dependent stimulus–response associations, PFC networks can use higher-order knowledge to guide behavior in novel situations and override prepotent responses. Because of its connections with posterior cortex, activation of prefrontal representations can increase or decrease the activation of posterior cortical representations, based on what is relevant for current or future goals. This view accords well with most theories of prefrontal function, which generally suggest a role for the PFC in the selection and maintenance of task-relevant information and the inhibition of irrelevant, distracting information (Pribram et al., 1964; Brutkowski, 1965; Luria, 1966a; Nauta, 1971; Stuss and Benson, 1986; Goldman-Rakic, 1987; Cohen and Servan-Schreiber, 1992; Cohen et al., 1996; Fuster, 1997; Knight et al., 1999; Miller, 2000; Shimamura, 2000; Miller and Cohen, 2001; Miller and D'Esposito, 2005).

3.14.3.2 Functional Imaging of Working Memory: Evidence for Functional Differentiation within PFC

Results from human neuroimaging studies of WM converge with the view described above, and these studies have also provided evidence for functional differentiations within PFC. Based on ideas outlined by Fuster (1997, 2004) and consideration of the available evidence, we suggest one such view, outlining a hierarchy of 'selection' processes implemented by different PFC subregions along the rostro–caudal and dorso–ventral axes (see **Figure 1**).

Anatomically, VLPFC subregions are well positioned to modulate activity in high-level auditory, visual, and multimodal association areas (Petrides and Pandya, 2002). Thus, the VLPFC may be a source of top-down signals that select (i.e., enhance or reduce the activation of) item representations in posterior cortical areas based on current task demands. Consistent with this idea, VLPFC activation is observed when a task requires inhibition of irrelevant or potentially distracting items (Konishi et al., 1999; Aron et al., 2004; Zhang et al., 2004), resolution of proactive interference (Jonides and Nee, 2006), resolution of competition among competing linguistic representations (Thompson-Schill

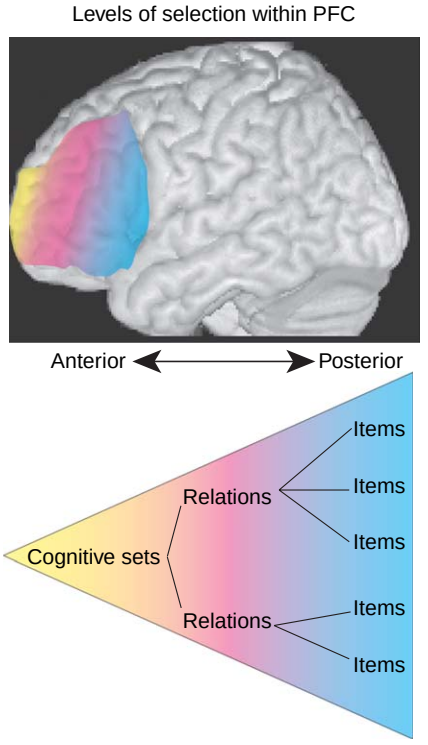

Figure 1 At top, a lateral view of the brain, with a gradient illustrating functional differentiation within the PFC along the rostro–caudal and dorso–ventral axes. At bottom, a hypothesized functional organization is depicted, such that regions in VLPFC (blue) may be involved in selecting relevant items, DLPFC (pink) may be involved in selecting relationships between items that are currently active, and APFC (yellow) may be involved in selecting cognitive sets that determine which items and relations are appropriate targets for selection.

et al., 1997; Wagner et al., 2001a), or activation of an item representation (i.e., WM maintenance; Curtis and D'Esposito, 2003). Furthermore, the topography of VLPFC activation in these studies is material dependent, such that tasks requiring selection, encoding, or maintenance of different kinds of items recruit different subregions of VLPFC (Schumacher et al., 1996; Kelley et al., 1998; Wagner et al., 1998; Poldrack et al., 1999; Wagner, 1999; Braver et al., 2001). In contrast, DLPFC and APFC activation is not material dependent, suggesting that these regions may act at a more abstract level (D'Esposito et al., 1998; Smith and Jonides, 1999; Wagner, 1999; Rainer and Ranganath, 2002; Ranganath and Knight, 2003; Ramnani and Owen, 2004).

Unlike VLPFC, DLPFC is not robustly recruited during tasks that solely require selection of task-relevant information. Instead, evidence from neuroimaging studies suggests that DLPFC is involved in using rules to activate, inhibit, or transform relationships among items that are active in WM. For example, DLPFC activation is reported in 'manipulation' tasks that involve sequencing of information that is being maintained in WM (D'Esposito et al., 1999; Postle et al., 1999; Wagner et al., 2001b; Barde and Thompson-Schill, 2002; Blumenfeld and Ranganath, 2006; Crone et al., 2006; Mohr et al., 2006) or monitoring of previous responses when selecting a future response (Owen, 1997; Owen et al., 1999). DLPFC activation has also been reported in 'chunking' studies which involve processing of relationships to build higher-level groupings among items that are active in memory (Bor et al., 2003, 2004; Bor and Owen, 2006). One parsimonious explanation for this diverse array of findings is that DLPFC may implement selection processes that accentuate or inhibit the activation of relationships among items that are active in memory.

Although APFC is not nearly as well characterized as DLPFC and VLPFC, available evidence is consistent with the idea that APFC is at the apex of the hierarchy of selection processes implemented by PFC. One way of conceptualizing this role is that APFC implements the selection of appropriate cognitive sets – that is, sets of goal-directed rules that determine which types of relations and items are appropriate for selection by DLPFC and VLPFC, respectively. Although virtually every type of task involves some kind of cognitive set, APFC recruitment specifically occurs during tasks that place demands on the *selection* of an appropriate cognitive set (Rogers and Monsell, 1995; Mayr and Kliegl, 2000; Rogers et al., 2000; Mayr, 2002). Consistent with this prediction, several functional magnetic resonance imaging (fMRI) studies have reported APFC activation using paradigms in which subjects must actively maintain a task set (Braver et al., 2003; Bunge et al., 2003; Sakai and Passingham, 2003) or hold a primary task set in mind while processing secondary subgoals (Koechlin et al., 1999; Braver and Bongiolatti, 2002; Koechlin et al., 2003; Kubler et al., 2003; Badre and Wagner, 2004). As we describe later, the role of APFC in selection and maintenance of cognitive sets might explain why APFC activation is routinely observed during long-term memory (LTM) retrieval tasks.

To summarize, it is clear that the PFC is involved in WM processes, but that role has been misinterpreted in recent years. Available evidence indicates that PFC is not necessary for short-term retention per se, and that it is more specifically critical for WM

control processes that guide behavior under a range of circumstances. These processes may emerge through prefrontal representations that use context information to select relevant information and inhibit irrelevant information. We suggest that this selection mechanism is common across prefrontal regions, and that different prefrontal regions act to select information at different levels (**Figure 1**). Specifically, VLPFC acts to activate or inhibit item representations, whereas DLPFC acts to activate or inhibit relationships between items that are actively selected or maintained through VLPFC operations. Finally, APFC may play a role in activating or inhibiting representations of cognitive sets that determine which types of items and relations are appropriate for selection (Bunge et al., 2003; Sakai and Passingham, 2003). As we will describe, this hypothesized division of labor corresponds well to the imaging literature on PFC and LTM processes (see also Fletcher and Henson, 2001, for a similar perspective).

3.14.4 Effects of Prefrontal Lesions on LTM Encoding and Retrieval

3.14.4.1 Neuropsychological Studies of Patients with Prefrontal Lesions

Clinicians have long noted that focal prefrontal lesions in humans produce subtle but noticeable memory deficits, and this impression accords well with results from neuropsychological studies (Stuss and Benson, 1986; Shimamura, 1995; Ranganath and Knight, 2003). In general, patients with PFC lesions show impairments on a wide range of memory tasks that tax executive control during encoding and/or retrieval (Stuss and Benson, 1986; Moscovitch, 1992; Shimamura, 1995; Ranganath and Knight, 2003). For instance, PFC patients exhibit impaired performance on unconstrained memory tests such as free-recall (Jetter et al., 1986; Janowsky et al., 1989a; Eslinger and Grattan, 1994; Gershberg and Shimamura, 1995; Wheeler et al., 1995; Dimitrov et al., 1999). In contrast to healthy control participants, PFC patients tend not to spontaneously cluster or group recall output according to semantic relationships within a categorized word list (Hirst and Volpe, 1988; Incisa della Rochetta and Milner, 1993; Stuss et al., 1994; Gershberg and Shimamura, 1995). Furthermore, when presented with several study-test trials with the same word list, healthy participants tend to recall items in the same order across recall trials, a phenomenon termed 'subjective organization.' Patients with prefrontal lesions, however, show less trial-to-trial consistency of recall output order compared to controls (Stuss et al., 1994; Gershberg and Shimamura, 1995; Alexander et al., 2003).

Patients with prefrontal lesions also exhibit impaired performance on tests of source memory (Janowsky et al., 1989c; Duarte et al., 2005), memory for temporal order (Shimamura et al., 1990; McAndrews and Milner, 1991; Butters et al., 1994; Kesner et al., 1994; Mangels, 1997), and judgments of frequency (Stanhope et al., 1998). Furthermore, PFC patients often fail to spontaneously use common memory strategies and lack insight into their own memory problems (Hirst and Volpe, 1988; Janowsky et al., 1989b; Moscovitch and Melo, 1997; Vilkki et al., 1998).

In contrast to these deficits, patients with prefrontal lesions can often perform at near-normal levels when given structured encoding tasks or tests that do not tax strategic retrieval processes. For instance, PFC patients perform better at cued recall compared to free recall and have only a mild impairment in item recognition (Wheeler et al., 1995). Moreover, patients can show marked improvements on a variety of recall measures if given sufficient practice or environmental support at encoding or retrieval (Hirst and Volpe, 1988; Incisa della Rochetta and Milner, 1993; Gershberg and Shimamura, 1994; Stuss et al., 1994).

3.14.4.2 Recollection and Familiarity in Patients with Prefrontal Lesions

As noted above, patients with prefrontal lesions tend to show only mild deficits in recognition memory performance. Behavioral research has supported the idea that item recognition can be supported either by the assessment of familiarity, or by the recollection of specific details associated with the item (Yonelinas, 2002). Some researchers have speculated that prefrontal damage may selectively affect the recollection process (Knowlton and Squire, 1995; Davidson and Glisky, 2002; Gold et al., 2006), based on reports of recollection deficits among the healthy elderly (Davidson and Glisky, 2002) and among amnesic patients with Korsakoff's syndrome (Knowlton and Squire, 1995) that may be correlated with performance on the Wisconsin card sorting task and other tasks thought to be dependent on PFC function. However, it is highly unlikely that performance on such

tests uniquely indexes the functioning of the PFC and no other brain region.

To directly test the role of PFC in recognition memory, it is necessary to directly assess recollection and familiarity in patients with focal prefrontal lesions. One methodological challenge in addressing this question is that prefrontal lesions are typically unilateral (due to stroke or tumor excision), and therefore patients might rely on the intact hemisphere to support performance. A recent study dealt with this issue by using a divided-field presentation method to specifically assess memory performance for information that was encoded in the visual field contralateral to the lesioned hemisphere ('contralesional') and the field ipsilateral to the lesioned hemisphere ('ipsilesional'). Thus, if PFC regions contribute to familiarity or recollection, one would expect deficits in these processes to be most substantial when objects were encoded in the contralesional visual field. Patients and controls were tested using the remember-know method, in which they decided whether each test object was shown during the study phase, and if so, whether they could recollect specific details about the study episode. These data were then used to create quantitative indices of familiarity and recollection for objects encoded in the contralesional and ipsilesional hemifields in each patient, and similar indices were created for each visual field in the corresponding age- and education-matched control participant. As shown in **Figure 2**, patients showed impaired familiarity for objects that were presented in the contralesional field at the time of encoding. Furthermore, although PFC patients did not exhibit deficits in subjective recollection, patients with left frontal lesions exhibited impairments in memory for the context in which each word was encountered (i.e., source memory).

Findings from this study demonstrate that, contrary to previous assertions, the PFC is necessary for normal familiarity-based recognition. Additionally, although patients with PFC lesions may have a subjective experience of recollection, they may still exhibit impairments in the ability to use recollected information to make source attributions (particularly following left frontal lesions – see the section titled 'Laterality of PFC activation during LTM encoding and retrieval' for more on this topic). This finding makes sense if one assumes that PFC damage affects control processes, rather than memory storage. That is, engagement of PFC-dependent control processes most likely impacts encoding of overall familiarity strength as well as encoding of distinctive contextual information that would support recollection (Ranganath et al., 2003b, 2005a; Blumenfeld and Ranganath, 2006). Furthermore, engagement of PFC-dependent control processes at retrieval most likely affect strategic search and decision processes that influence the retrieval and use of familiarity and recollective information (Ranganath et al., 2000, 2003a, 2007).

3.14.4.3 Theoretical Accounts of Memory Deficits Following Prefrontal Lesions

Theoretical accounts of memory deficits in patients with prefrontal lesions generally fall into two categories. Some theories emphasize the role of the PFC in selection processes that direct attention toward goal-relevant information and task-appropriate responses. Thus, memory deficits may arise in patients with prefrontal lesions because they are unable to select goal-relevant information or inhibit distracting or interfering items or responses during encoding or retrieval (Luria, 1966b; Perret, 1974; Shimamura, 1995). One finding consistent with this account comes from a study of paired associate learning in patients with focal PFC lesions and matched controls (Shimamura et al., 1995). In this study, participants learned a list of word pairs ('A–B') and then learned an overlapping list of word pairs ('A–C') across several trials. Recall success on the A–C list required subjects to inhibit the 'A–B' pairing and select the appropriate 'A–C' pairing. Critically, patients with PFC lesions showed a disproportionate decrease in recall performance between the first trial of A–B learning and the first trial of A–C learning (i.e., a measure of proactive interference), as compared to controls. Furthermore, during cued recall of the A–C list, PFC patients recalled significantly more intrusions from the A–B list. These finding suggest that patients with prefrontal lesions were unable to inhibit the influence of previously learned associations during encoding or retrieval of new associations.

The second category of theories to explain memory deficits following prefrontal lesions emphasizes the role of the PFC in guiding spontaneous organization of information (Milner et al., 1985; Hirst and Volpe, 1988; Incisa della Rochetta and Milner, 1993; Gershberg and Shimamura, 1995). In psychology, 'organization' refers to memory strategies that emphasize forming or utilizing relationships among items in a list during encoding and/or retrieval. Some common organizational strategies during encoding include

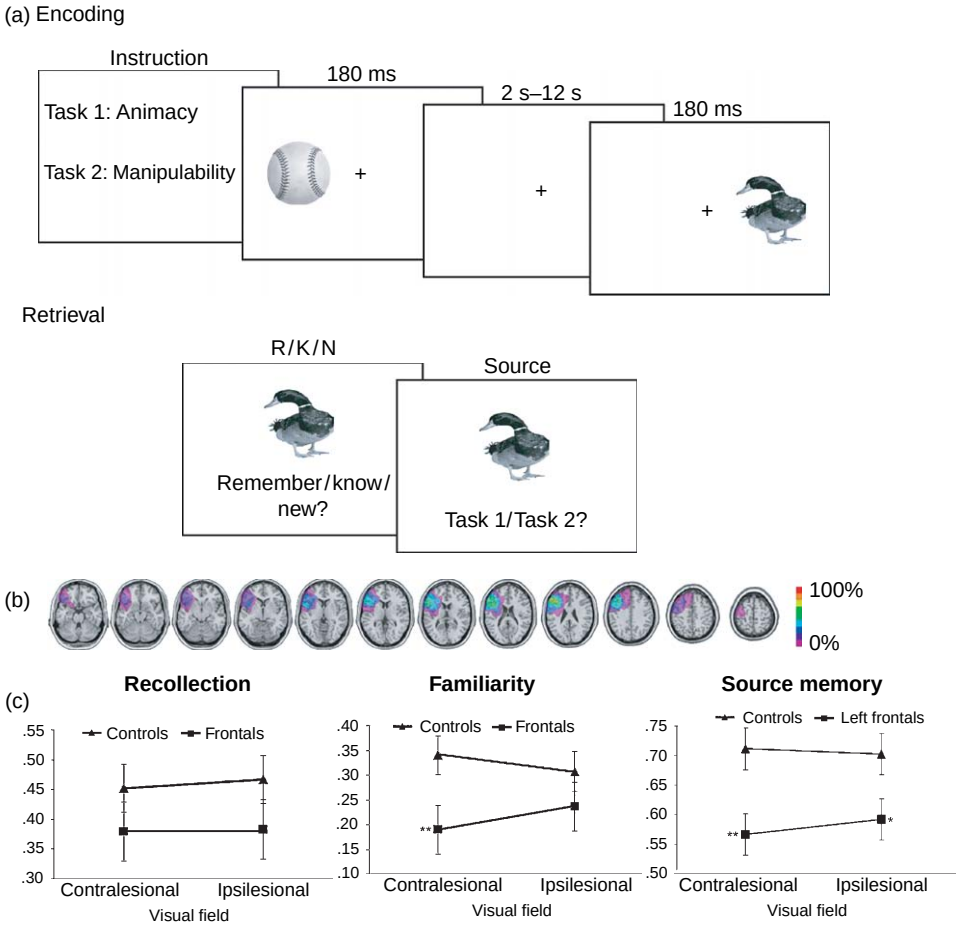

Figure 2 (a) Participants with lateral prefrontal lesions and controls encoded objects that were briefly flashed to the left or right hemifield, and then performed retrieval tests assessing memory for each item and the task that was performed during encoding. (b) Lesion overlap for patients. Right frontal lesions have been transcribed to the left hemisphere to determine the overlap across all patients. The color scale indicates the percentage of patients with lesions in a specific area. (c) Results showed that subjective measures of recollection (left) were relatively spared in the patients, whereas familiarity (middle) was impaired, particularly for objects encoded in the contralesional visual field. Source memory (right) performance was also impaired in patients with left frontal lesions. Experimental design and results from Duarte A, Ranganath C, and Knight RT (2005) Effects of unilateral prefrontal lesions on familiarity, recollection, and source memory. *J. Neurosci.* 25: 8333–8337.

categorizing words in a list according to semantic features, imagining two or more items interacting, or forming a sentence out of two or more words. Organizational processes do not facilitate LTM by enhancing features of specific items in memory, but rather by promoting memory for associations among items.

The organizational account described above can explain free recall deficits seen in patients with PFC lesions, because free recall is thought to rely heavily on organization of information in the study list. One study directly tested this hypothesis by comparing performance of patients with lateral prefrontal lesions and healthy controls on learning of lists of words that were either semantically related or unrelated (Gershberg and Shimamura, 1995). Patients with PFC lesions showed impaired recall of items from both related and unrelated lists. Furthermore, the patients failed to demonstrate normal levels of subjective organization and failed to show semantic clustering following study of semantically related lists, two indices of organizational processing during encoding. Interestingly, recall and clustering performance increased for semantically related word lists

when patients were explicitly asked to make a category judgment during encoding, when they were provided with the category names at test, or both. The same was not true for the healthy controls, who performed at similar levels regardless of whether they were given cues or instructions. This pattern of results suggests that patients were capable of using semantic information to guide encoding and retrieval, but that they lacked the ability to spontaneously use semantic organizational strategies. In contrast, controls were spontaneously using organizational strategies during encoding and/or retrieval. These findings, and others (Hirst and Volpe, 1988; Incisa della Rochetta and Milner, 1993; Stuss et al., 1994; Alexander et al., 2003) suggest that LTM deficits following prefrontal lesions may emerge partly from a failure to organize information during encoding and capitalize on organizational structure during retrieval.

Many researchers have suggested that both selection and organizational processes depend on the functioning of the PFC, and there are several studies that have found support for both the interference and organizational accounts in the same study (Hirst and Volpe, 1988; Stuss et al., 1994; Gershberg and Shimamura, 1995; Shimamura et al., 1995; Alexander et al., 2003). One question that cannot be addressed by the neuropsychological evidence is whether selection and organization depend upon the same regions of PFC, because these studies typically use subject groups that have significant heterogeneity in lesion size and location. However, in light of the evidence from imaging studies of WM control processes, it is possible that VLPFC is particularly critical for selection of relevant item information, whereas DLPFC is particularly critical for building of relationships between items in a manner that supports organization. As we will describe below, this hypothesis is consistent with results from neuroimaging studies of LTM encoding and retrieval.

3.14.5 Functional Neuroimaging of LTM Encoding and Retrieval

3.14.5.1 Subsequent Memory Effects and the PFC

Event-related fMRI studies have investigated LTM encoding by identifying 'subsequent memory' or 'Dm' (difference due to memory) effects (Paller and Wagner, 2002). In these paradigms, brain activity is monitored during the performance of an incidental encoding task (i.e., semantic processing of a single word). Following scanning, a surprise memory test is administered, and brain activation during encoding is analyzed as a function of later memory success or failure. For example, participants might be given a semantic encoding task in the scanner, and then once out of the scanner, they receive an item-recognition test on the items they studied. The results can then be used to contrast brain activity during successful versus unsuccessful encoding.

Results from studies using the subsequent memory paradigm have demonstrated significant pre-frontal involvement in LTM encoding. Inspection of the spatial distribution of activation peaks (or 'local maxima') from these studies, shown in **Figure 3**, reveals

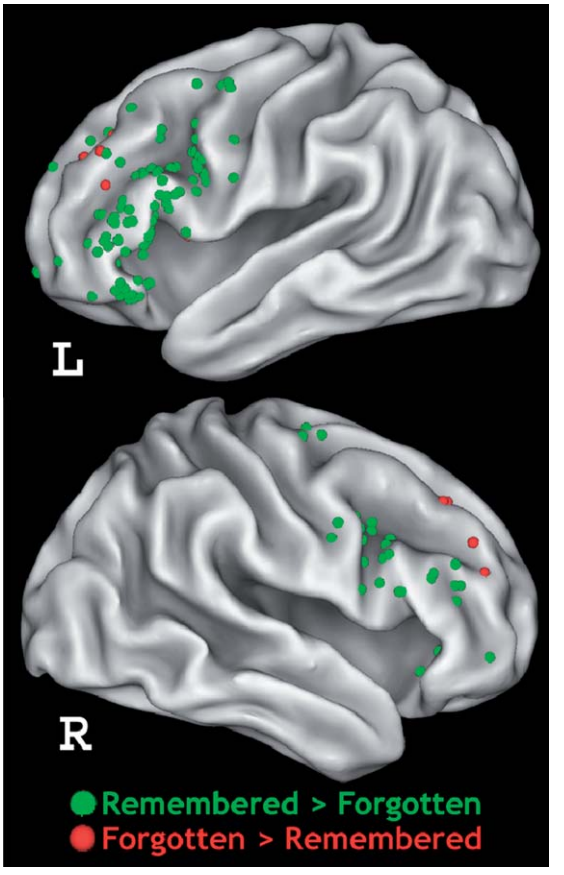

Figure 3 Activation peaks from fMRI studies investigating prefrontal activation during memory encoding. Each green dot represents an activation peak in an analysis that reported increased activation during encoding of items that were subsequently remembered, as compared with items that were subsequently forgotten (i.e., a 'subsequent memory effect'). Each red dot represents an activation peak in an analysis that reported increased activation during encoding of items that were subsequently forgotten, as compared with items that were subsequently remembered (i.e., 'a subsequent forgetting effect').

not only that PFC activation is routinely linked with successful LTM encoding, but also that the degree of involvement seems to differ between different PFC subregions. There is overwhelming support for the idea that VLPFC contributes to LTM formation. Out of 150 local maxima associated with subsequent memory, 132 fall within the VLPFC. Furthermore, 33 of the 35 studies that reported prefrontal subsequent memory effects find local maxima within the VLPFC. Given that the ability to select relevant item information is essential for many forms of goal-directed cognitive processing, including memory encoding, it makes sense that VLPFC should be strongly linked to memory encoding in a wide variety of behavioral contexts.

The imaging literature seems to tell a different story about the DLPFC. Out of 150 local maxima throughout the PFC, only 18 fall within the DLPFC. Furthermore, five studies have found increased DLPFC activation during processing of items that were subsequently forgotten, as compared with items that were subsequently remembered. Thus, based on the numbers alone, there does not appear to be much support for the idea that DLPFC contributes to LTM encoding. This pattern of findings could suggest either that DLPFC implements processes that do not contribute to successful LTM encoding, or that previous studies were insensitive to its role in LTM formation.

Relevant to the latter possibility, it is notable that imaging studies of WM have implicated DLPFC in processing of relationships between items, and that imaging studies of LTM encoding typically do not elicit relational processing. Most imaging studies have examined encoding of single items studied in isolation, using encoding tasks that orient attention toward specific attributes of a study item and away from relationships between items. In these studies, it is unlikely that participants would spontaneously process relationships among items in the study list, and engagement of relational processing might have even been deleterious to later memory performance (i.e., because allocating resources toward processing the relationships among items might take attentional resources away from processing the distinctive features of the items themselves). Accordingly, it is possible that the encoding conditions in many previous imaging studies were not conducive to revealing the contribution of DLPFC to successful LTM encoding. The retrieval tests used in subsequent memory paradigms might also be a relevant factor. Most imaging studies of encoding assess successful LTM formation with tests of item recognition memory. However, processing of relationships between items facilitates memory by enhancing interitem associations, and item recognition memory tests may not be sensitive to detecting these effects (Bower, 1970). Thus, sorting encoding activation by subsequent item recognition performance might mask the role of DLPFC in successful LTM encoding.

If DLPFC contributes to LTM encoding through its role in relational processing, the ability to detect this contribution may depend on the kinds of encoding and retrieval tasks that are used. Indeed, in imaging studies that used encoding tasks that encouraged relational processing or retrieval tests that are sensitive to memory for associations among items, DLPFC activity during encoding predicts subsequent memory (Addis and McAndrews, 2006; Blumenfeld and Ranganath, 2006; Staresina and Davachi, 2006; Summerfield et al., 2006). In one such study, we found evidence that DLPFC activation is related to successful LTM encoding specifically under conditions that emphasize processing of relationships between items (Blumenfeld and Ranganath, 2006). In this study, participants were scanned during the performance of two WM tasks (**Figure 4(a)**). On 'rehearse' trials, participants were presented with a set of three words and required to maintain the set across a 12-s delay period, in anticipation of a question probing memory for the identity and serial position of the items. On 'reorder' trials, participants were required to rearrange a set of three words based on the weight of the object that each word referred to. They maintained this information across a 12-s delay period in anticipation of a question probing memory for serial order of the items in the rearranged set. Although both rehearse and reorder trials required maintenance of the three-item set, reorder trials additionally required participants to compare the items in the set and transform the serial order of the items. Thus, reorder trials forced participants to actively process relationships between the items in the memory set, whereas rehearse trials simply required maintenance of the memory set across a delay. Analyses of subsequent recognition memory performance showed that there were significantly more reorder trials in which all three items were recollected than would be expected based on the overall item hit-rates alone (**Figure 4(b)**). The same was not true for memory for rehearse trials, for which the proportion of trials on which all three items were subsequently recollected was no different than would be expected by

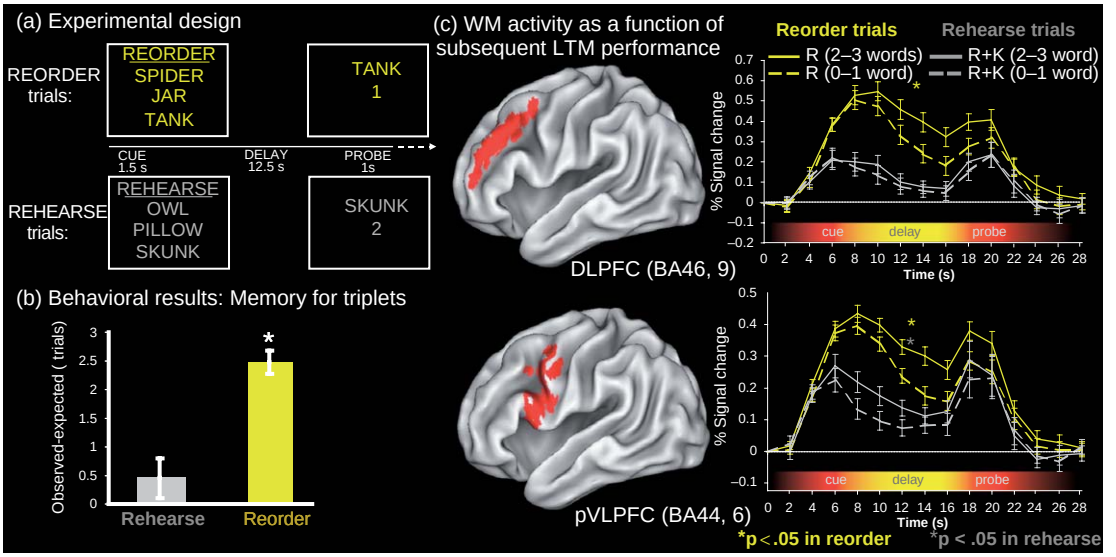

Figure 4 (a) Schematic depiction of the two tasks performed during fMRI scanning. (b) Behavioral results, showing that participants recalled significantly more triplets from each reorder trial (yellow) than would be expected based on the overall hit rate. This finding suggests that, on reorder trials, memory performance was supported by associations among the items in the memory set. (c) fMRI data showing that DLPFC (top) exhibited increased activation during the delay period of reorder trials for which 2–3 items were subsequently remembered (solid yellow), as compared with trials in which 0–1 items were remembered (dashed yellow). No such effect is seen on rehearse trials (gray lines). At bottom, activation in a region of posterior VLPFC (pVLPFC) is plotted, showing that delay period activation in this region during both rehearse and reorder trials was predictive of subsequent memory performance. Experimental design and results from Blumenfeld RS and Ranganath C (2006) Dorsolateral prefrontal cortex promotes long-term memory formation through its role in working memory organization. *J. Neurosci.* 26: 916–925.

the item hit-rates alone. These findings suggest that, on reorder trials, processing of the relationships among the items in each memory set resulted in successful encoding of the associations among these items.

Consistent with the idea that the DLPFC is involved in processing of relationships between items in WM, fMRI data revealed that DLPFC activation was increased during reorder trials, as compared with rehearse trials (**Figure 4(c)**). Furthermore, DLPFC activation during reorder but not rehearse trials was positively correlated with subsequent memory performance. Specifically, DLPFC activation was increased on reorder trials for which 2–3 items were later recollected, as compared with trials for which 1 or 0 items were later recollected. No such relationship was evident during rehearse trials. In contrast, activation in a posterior region of left VLPFC (BA 44/6) was correlated with subsequent memory performance on both rehearse and reorder trials. Thus, results from this study suggest that DLPFC and VLPFC may play dissociable roles in LTM encoding. DLPFC activation may specifically promote successful LTM formation through its role in processing of relationships among items, whereas VLPFC activation seems to promote LTM formation under a broader range of conditions.

Results from another recent study demonstrated the specific nature of DLPFC contributions to memory encoding by comparing the relationship between activation and subsequent performance on free recall and item recognition memory tests (Staresina and Davachi, 2006). As described earlier, item recognition tests are often insensitive to memory for inter-item associations in LTM, whereas recall performance is significantly influenced by encoding of interitem associations (Tulving, 1962). Consistent with a role for DLPFC in encoding inter-item associations, DLPFC activation was specifically enhanced during encoding of items that were recalled compared to those that were not. DLPFC activation was not correlated with subsequent item recognition performance. In contrast, encoding time activation in VLPFC was positively correlated with subsequent memory performance on both the recall and the recognition tests. These results are consistent with the idea that DLPFC activation will contribute to

subsequent LTM performance specifically under retrieval conditions that are sensitive to memory for associations among items.

The role of APFC in promoting LTM formation has not been well characterized in prior studies. We suspect that this is because activation in this region, like DLPFC, is not typically reported in studies of LTM encoding. Future work will be necessary to determine whether or how APFC contributes to successful LTM formation.

3.14.5.2 PFC Activation during LTM Retrieval

Numerous imaging studies have investigated the role of prefrontal regions in memory retrieval, showing that regions in DLPFC, VLPFC, and APFC are routinely activated during performance of such tasks (Fletcher and Henson, 2001; Ranganath et al., 2003a; Ranganath and Knight, 2003; Ranganath, 2004). Unlike studies of encoding, retrieval studies have not shown a consistent relationship between activation in any prefrontal region and successful retrieval. However, this is not surprising if PFC activation reflects control processes that are engaged during retrieval tasks even when retrieval fails (Ranganath et al., 2000, 2007; Dobbins et al., 2002; Simons et al., 2005a). If different prefrontal regions contribute to different control processes, then it may be more fruitful to compare and contrast activation between retrieval conditions that are more or less likely to engage these processes, rather than contrasting activation between successful and unsuccessful retrieval (Fletcher and Henson, 2001). Results from such studies have converged in many respects with results from studies of WM and LTM encoding in implicating VLPFC in item processing and DLPFC in relational processing.

One study conducted by Fletcher and colleagues is particularly relevant, in that they observed a double dissociation between the roles of VLPFC and DLPFC across two LTM retrieval tasks. In this study, positron emission tomography was used to measure prefrontal activation during two different retrieval tests. In one condition, the study lists were structured lists of 16 single words that were organized according to an overall theme and then broken down into four subcategories. For these lists, participants were given a free recall test, with the instruction to use the organizational structure of the list to guide retrieval. In the other condition, the study lists consisted of 16 category–exemplar word pairs (e.g., 'fruit–banana'). For these lists, participants performed a cued recall test, in which they had to recall the appropriate exemplar in response to each category name (e.g., 'fruit–?'). These two retrieval conditions differed in terms of the control processes that should be engaged during retrieval. In the free recall condition, participants were encouraged to use relational processing in order to generate appropriate retrieval cues, whereas in the cued recall condition, the specific cue was already provided. However, in the cued recall condition, presentation of a category name would presumably activate many semantic associations, and therefore, item-based selection processes would be required to resolve this conflict (Thompson-Schill et al., 1997; Wagner et al., 2001a). Critically, the authors found a double dissociation between activation within the PFC, such that DLPFC activation (BA 46) was increased during the free recall condition, whereas VLPFC activation (BA 44) was increased during the cued recall condition. This finding is consistent with findings from WM and LTM encoding studies suggesting that VLPFC regions implement processes that modulate activation of item representations, whereas DLPFC regions implement processes that activate representations of relationships among items.

In addition to more lateral regions of PFC, anterior prefrontal regions (BA 10) are also routinely activated in studies of LTM retrieval, and particularly during source memory tasks that require retrieval of detailed information (Nolde et al., 1998; Fletcher and Henson, 2001; Ranganath and Knight, 2003). An interesting finding to emerge from many of these studies is that APFC activation is often not contingent on successful retrieval, or even on the difficulty of the retrieval decision (Henson et al., 1999; Rugg et al., 1999; Ranganath et al., 2000, 2007; Dobbins et al., 2002, 2003; Simons et al., 2005a,b). As noted earlier, APFC activation during WM tasks tends to be associated with the demand to select or maintain a cognitive set that dictates what information is relevant for selection. Cognitive models of memory retrieval suggest that this may be particularly relevant for accurate performance on source memory tasks (Johnson et al., 1993, 1997a; Mather et al., 1997; Norman and Schacter, 1997; Marsh and Hicks, 1998). This is because episodic memories are complex and consist of multiple characteristics (e.g., records of perceptual information in multiple modalities, cognitive operations, actions, affective reactions; Johnson et al., 1993). In many instances, a potential retrieval cue can activate several potential memories, including information that is irrelevant to a particular source decision (Koriat and Goldsmith, 1996;

Johnson, 1997; Koriat et al., 2000). Source memory decisions therefore demand the selection of an appropriate cognitive set in order to constrain retrieval of information associated with a cue and to narrow down the criteria for subsequent decision processes (Johnson et al., 1993; Mather et al., 1997; Norman and Schacter, 1997; Marsh and Hicks, 1998). This set would be initiated in response to a retrieval cue in order to constrain retrieval of information associated with the cue and narrow down the criteria for subsequent decision processes (Johnson et al., 1993; Johnson and Raye, 1998; Rugg and Wilding, 2000). This process has been described as setting 'decision criteria,' 'feature weights,' or a 'retrieval orientation.' We hypothesize that APFC is critical for selecting cognitive sets, and that source memory decisions constitute an example of when this process must be engaged.

One way of testing this idea is to contrast APFC activation between retrieval tasks that vary in terms of the specificity of the memory decision that is to be made (Ranganath et al., 2000, 2007). In one such study (Ranganath et al., 2000), brain activity was contrasted between a retrieval task that required participants to make a general item recognition decision versus a retrieval task that required participants to make a recognition decision specifically based on the match between the visual features of test items relative to studied items (**Figure 5**). Not surprisingly, participants were slower and less accurate at making responses to previously studied items in the more specific test condition. However, for unstudied items, accuracy and reaction times were comparable across the two test conditions. Results showed that activation in left APFC was increased during the more specific test, as compared with the more general test. What is more remarkable, however, is that activation during specific test trials was also increased for new items that

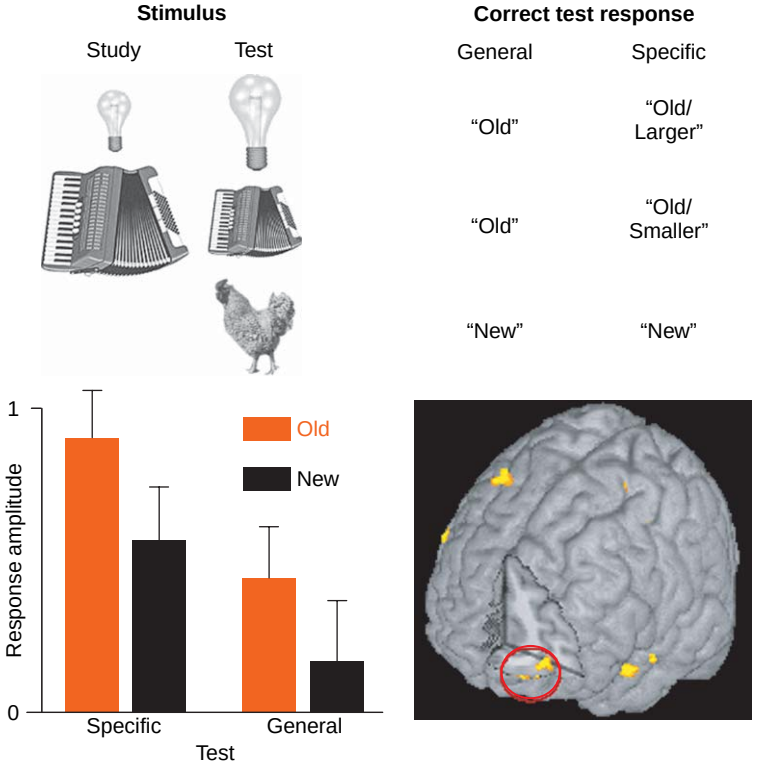

Figure 5 Participants studied objects that were shown in a large or small size, and then at test were shown objects that were either larger or smaller than the studied objects. In the 'General' test condition, participants were instructed to make a decision as to whether each object was studied, whereas on specific test trials, participants were additionally instructed to decide whether each test object was larger or smaller than the studied objects. In a region of left APFC, shown in the lower right panel, activation was increased for both old and new items in the specific test, as compared with the more general test condition (lower left panel). Experimental design and results from Ranganath C, Johnson MK, and D'Esposito M (2000) Left anterior prefrontal activation increases with demands to recall specific perceptual information. *J. Neurosci.* 20: RC108: 1–5.

were not seen during the study phase, despite the fact that behavioral performance was the same across the two test conditions. Thus, APFC activation during specific test trials reflected the need to constrain retrieval of information associated with each test item and to narrow down the criteria for subsequent decision processes. In this sense, APFC activation in source memory tasks might be analogous to activations in WM tasks in which one must select and maintain sets of rules that dictate the items or relationships that are currently relevant (Braver et al., 2003; Bunge et al., 2003; Sakai and Passingham, 2003).

Relevant to this idea, some researchers have suggested that APFC may be involved in maintaining an 'episodic retrieval mode' – a cognitive set which ensures that stimuli will be treated as cues for episodic retrieval (Lepage et al., 2000; Rugg and Wilding, 2000; Buckner, 2003). This view is supported by recent functional imaging studies showing sustained anterior prefrontal activity during episodic retrieval tasks, sometimes extending across multiple retrieval trials (Duzel et al., 1999; Lepage et al., 2000; Velanova et al., 2003). Additionally, retrieval mode-related activation in APFC appears to depend on the degree of control that is required in a given episodic memory test (Velanova et al., 2003). These findings are consistent with the idea that APFC is more generally involved in selection and maintenance of cognitive sets that support accurate episodic retrieval and source monitoring.

3.14.5.3 Laterality of PFC Activation during LTM Encoding and Retrieval

Another issue of interest that emerged from imaging studies of LTM retrieval concerns hemispheric asymmetries in the PFC. The question emerged from results of positron emission tomography studies of verbal memory that repeatedly observed left prefrontal activation during semantic decision tasks and right-lateralized prefrontal activation during tasks that engaged episodic retrieval processes (Tulving et al., 1994). Reviewing these findings, Tulving and his colleagues proposed the hemispheric encoding retrieval asymmetry (HERA) model, in which the left PFC was proposed to play a disproportionate role in episodic encoding (via its role in semantic processing) and the right PFC was proposed to play a disproportionate role in episodic retrieval (Tulving et al., 1994; Nyberg et al., 1996).

Shortly after its introduction, HERA was criticized, based on findings showing that left and right VLPFC are typically recruited during both encoding and retrieval tasks, and that the relative laterality of these effects is more dependent on the types of material that are being processed than on the type of memory operation (encoding or retrieval) being performed (Kelley et al., 1998; Wagner et al., 1998; McDermott et al., 1999; Golby et al., 2001). In response to this criticism, Habib et al. (2003) have argued that such findings

> . . . have no relevance to HERA. They provide good evidence in support of material-specific hemispheric asymmetry, but, because encoding and retrieval processes were not systematically varied and their interaction with hemispheres was not examined in these studies, the data are neutral with respect to HERA.

Another criticism of HERA is that, in focusing on left–right asymmetries, the model failed to account for perhaps more compelling functional differences along the rostro–caudal and dorsal–ventral axes (Buckner, 1996). Furthermore, laterality effects in DLPFC and APFC remain difficult to characterize. Laterality effects in these regions have typically not varied according to material, but also have not strictly followed predictions of the HERA model (Nolde et al., 1998; Ranganath and Knight, 2003; Ranganath, 2004).

Following up on the HERA model, Cabeza and colleagues (2003) recently proposed that the left PFC is engaged by tasks requiring semantically guided generation of information, whereas the right PFC is engaged by tasks requiring monitoring and checking of retrieved information. Another idea that has been proposed is that that left PFC is more engaged during the monitoring of specific memory characteristics, whereas right PFC is more engaged during the monitoring of undifferentiated information (Mitchell et al., 2004). A related idea is that the left PFC may disproportionately contribute to the use of specific contextual information to make a memory decision, whereas the right PFC may disproportionately contribute to the use of familiarity to make a memory decision (Dobbins et al., 2004). Like the HERA model, these accounts also do not specify whether the proposed hemispheric asymmetries would be expected to be constant across different subregions of PFC (e.g., DLPFC, VLPFC, APFC). At present, it is unclear if any of these models can fully account

for patterns of hemispheric asymmetry in PFC activation during LTM retrieval, but this is in part due to the fact that the models have not been directly contrasted in many studies (Ranganath, 2004).

3.14.6 Conclusions and Future Prospects

Converging evidence from neuropsychology and neuroimaging supports the idea that prefrontal regions play an important role in WM and LTM encoding and retrieval. Research on WM has shown that the PFC is not necessary for short-term retention of information per se, and instead that prefrontal regions contribute to WM performance by using goals and prior knowledge to guide activation of mnemonic representations. For example, regions in VLPFC may be more involved in modulating the activation of relevant items, whereas DLPFC may be more involved in modulating the activation of relationships between items that are currently being processed. Regions in APFC may be involved in selecting sets of rules that determine which items and relations are appropriate for selection.

Studies of LTM converge with the findings described earlier by demonstrating a role for the PFC in control processes that support encoding and retrieval. Neuropsychological research has shown that PFC regions may support LTM encoding by subserving controlled selection of attention toward goal-relevant items and by building or assessing relationships between relevant items. Imaging studies have shown that VLPFC may support LTM encoding by enhancing the strength and distinctiveness of memory for item information, whereas DLPFC may support encoding by building associations among items. During retrieval, VLPFC may support the ability to resolve competition in order to retrieve relevant items from memory, whereas DLPFC may support the ability to use relational information to guide successful retrieval and to inhibit previously learned associations. Additionally, some evidence suggests that APFC may support the selection of rules to determine the dimensions on which a retrieval cue and retrieved information should be processed.

Although our model can explain the extant evidence, future research will be needed to more extensively test it and to specify some important and currently unresolved issues. One important question is the nature of functional interactions within the PFC, and between different prefrontal and posterior cortical regions. Given the functional role for APFC suggested above, it would seem that APFC should modulate activation in corresponding regions of DLPFC and VLPFC, depending on the task set that is to be implemented (Sakai and Passingham, 2003). Furthermore, to the extent that VLPFC implements processes that select features of relevant items, one might expect that VLPFC should show increased connectivity with posterior areas that represent those features (Gazzaley et al., 2004). DLPFC regions, however, might process relational information in a number of ways. For instance, it is possible that DLPFC processes relational information by directly modulating activation in posterior cortical areas (Summerfield et al., 2006), perhaps by modulating the relative timing of neural firing within and across different areas (Shastri, 1996). Another possibility is that the posterior parietal cortex maintains dynamic relational bindings on line (Vogel et al., 2001), and that DLPFC can alter these bindings through its interconnections with parietal regions (Wendelken, 2001). A third possibility is that the DLPFC might modulate activation of relationships between items through its interactions with VLPFC (Blumenfeld and Ranganath, unpublished observations). Of course, none of the three accounts are mutually exclusive, and much more research needs to be done to address this fundamental question.

Another critical question for future research is to understand the role of orbitofrontal cortex (BA 11, on the ventromedial surface of the PFC) in memory processes. Research on orbitofrontal cortex and WM has generally focused on its role in integrating emotional and cognitive influences on behavior. However, given the extensive connectivity between the orbitofrontal cortex and medial temporal regions (perirhinal and entorhinal cortex) that are critical for LTM, it is reasonable think that orbitofrontal cortex should play an important role in LTM (Ranganath et al., 2005b). Evidence from patients with orbitofrontal lesions (due to anterior communicating artery aneurysms) is consistent with this idea (Rapcsak et al., 1996, 1999; Johnson et al., 1997b; Moscovitch and Melo, 1997; Schnider and Ptak, 1999; Schnider, 2000).

In conclusion, human neuropsychology and neuroimaging research has revealed significant insights into the roles of different regions of PFC in different kinds of memory processes. We have presented an

integrative framework to characterize these roles, but further research needs to be done to flesh out this framework and to address several important, and as yet unresolved, questions. Given the fact that disturbances in memory and prefrontal functioning are associated with normal aging (Tisserand and Jolles, 2003), cerebrovascular disease (Wu et al., 2002; Nordahl et al., 2005, 2006), and psychiatric (Cohen and Servan-Schreiber, 1992; Glahn et al., 2005) and neurological (Elliott, 2003; Levin and Hanten, 2005; Neary et al., 2005) conditions, addressing these questions will be of fundamental importance.

3.15 Basal Forebrain and Memory

A. A. Chiba and L. K. Quinn, University of California San Diego, La Jolla, CA, USA

3.15.1 Introduction

The basal forebrain is an aggregate of heterogeneous structures coursing along the ventral rostrocaudal extent of the brain. The anatomical connectivity of this collective allows it access to virtually the entire cortical mantle and to other subcortical structures thought to be essential to learning and memory. Often characterized by its large cholinergic projection neurons, the basal forebrain is home to a host of cell types and is regulated by a rich neurochemical background. The link between the basal forebrain and memory is frequently based on the decline of this structure in Alzheimer's disease. Yet, as in the medial temporal lobe system, there exists a characteristic amnestic syndrome associated with widespread damage to the basal forebrain. Animal models have been extensively used in an attempt to determine the role of this collective or of its subdivisions in memory and in other cognitive and behavioral functions. Further, the electrophysiological and rhythmic properties of the subdivisions of the basal forebrain are indicative of its extensive potential to function in a neuromodulatory capacity. Whereas analyses of the differential contribution of anatomical subdivisions of the basal forebrain to memory have been fruitful, further understanding of the organizational principles and functional properties of this region is likely to reveal additional clues to its role in memory and cognition.

3.15.2 Basal Forebrain Amnesia

A diversity of amnestic syndromes has been observed following insults to numerous loci in the neural system. As a result, a variety of neural circuits have been heavily implicated in underlying different aspects of memory, mostly indicated by the form of amnesia following disruption of the circuit. The circuits to which damage is traditionally observed to result in an amnestic syndrome are those including the prefrontal cortex, the cingulate cortices, the hippocampus, the rhinal cortices, multimodal cortical regions, and diencephalic regions (see Tranel et al., 2002; Milner, 2005; Frankland and Bontempi, 2006, for

review). Subregions of the basal forebrain share projections with each of these regions and are known for their neuromodulatory influence on these sites. Thus, not surprisingly, discrete lesions of the basal forebrain have also been observed to result in a profound amnestic syndrome. This basal forebrain amnestic syndrome shares many common features of the various forms of amnesia induced by damage to its projection sites.

Still, the manifestation of basal forebrain amnesia is dissociable from other amnestic syndromes based on a few hallmark features. In patients with basal forebrain lesions, severe anterograde amnesia for episodic memory is described as roughly equivalent to that of medial temporal and diencephalic patients. Yet, in basal forebrain amnesics, recognition of those episodic memories remains intact, demonstrating preserved function relative to medial temporal patients (Wais et al., 2006). This is illustrated by a case study, of patient JS, in which discrete damage to the basal forebrain resulted in a form of profound amnesia (Osimani et al., 2006). JS demonstrated severe anterograde amnesia, including diminished new learning and rapid forgetting, with relatively preserved recognition of episodic information. Also observed was temporally graded retrograde amnesia for episodic memory spanning several years in the face of preserved semantic and procedural memory. The general form of the amnestic syndrome described for patient JS thus overlaps with that of hippocampal and diencephalic amnesiacs who show impaired capacity for new declarative memory but preserved semantic and procedural memory. While each form of amnesia includes temporally graded retrograde amnesia, the temporal span of the retrograde amnesia in patient JS appears intermediate to that of medial temporal amnesiacs and diencephalic amnesiacs.

A further distinction between basal forebrain amnesiacs and medial temporal amnesiacs is a disproportionate deficit in their ability to determine the temporal distribution of episodic memories relative to their memories for those events. A study examining memory for episodes in contrast to memory for episodic timelines concluded that basal forebrain–damaged patients possess an equivalent deficit to medial temporal patients in knowing 'what' or retrieving information from autobiographical memories, but they have a disproportionate deficit in knowing 'when' or appropriate chronological placement of autobiographical memories (Tranel and Jones, 2006). Temporal knowledge is also disproportionately impaired in amnesiacs with retrosplenial or posterior cingulate damage who demonstrate profound impairments in the ability to remember the temporal order of recent events yet show spared order memory of remote events (Valenstein et al., 1987; Bowers et al., 1988). Thus, basal forebrain amnesiacs share the temporal disorientation of those enduring damage to cingulate cortices.

The most common source of basal forebrain damage is rupture and repair of aneurysms of the anterior communicating, the anterior cerebral, or the pericallosal artery (Myers et al., 2002). A comparison of subjects with basal forebrain damage resulting from anterior communicating artery aneurysms with those with hippocampal/medial temporal damage resulting from hypoxia demonstrated a double dissociation between medial temporal amnesics and basal forebrain amnesics in the ability to perform and reverse a conditional discrimination. The discrimination was a simple conditioning task in which subjects learned to associate a correct directional response (right or left) with a particular background color (light or dark). Hippocampal amnesiacs learned this conditional discrimination far better than did basal forebrain amnesiacs. When subjects were required to reverse the associations (direction to background color) in order to achieve a correct response, basal forebrain amnesiacs were able to reverse the contingencies, whereas hippocampal amnesiacs were rigid in their inability to perform such reversals (Myers et al., 2005). Thus, some of the most visible dissociations between medial temporal lobe amnesiacs and basal forebrain amnesiacs emerge in nondeclarative memory tasks (Myers et al., 2002).

The results put forth in this section reveal that there is a distinct amnestic syndrome that arises from damage to the basal forebrain. However, basal forebrain amnesia generally shares features of amnestic phenomena involved in damage to many other cortical and subcortical brain regions. This is most likely due to the vast anatomical connectivity in which the basal forebrain participates. The widespread influence of the basal forebrain on other regions involved in mnemonic processing suggests an integrated role of the basal forebrain and its associated structures in the determination of distinct memory dysfunction.

3.15.3 The Basal Forebrain and Alzheimer's Disease

The primary source of a role for the basal forebrain in memory is derived from years of research on

Alzheimer's disease (AD) (Perry et al., 1978; Bartus et al., 1982; Wenk, 1997; Francis, 2005). The cognitive signature of AD is progressive memory decline, whereas a striking neuroanatomical marker of AD is degeneration of the magnocellular cholinergic neurons in the basal forebrain (Wu et al., 2005; Wenk, 2006). In general, the observed deficits in AD parallel those of basal forebrain amnesia. There exists a deficit in explicit memory, a partial deficit for implicit memory, and preserved procedural memory (for review see Carlesimo and Oscar-Berman, 1992). An additional common feature is the recent finding of relatively preserved familiarity-based recognition memory in AD patients and intact familiarity-based recognition memory in patients with mild cognitive impairment (MCI) (Westerberg et al., 2006).

Pathology of the cholinergic basal forebrain is likely to occur in early stages of AD (Bowen et al., 1982), as is hypofunction of particular cortical target regions, including the posterior cingulate and entorhinal cortices (Huang et al., 2002; deToledo-Morrell et al., 2004; Pennanen et al., 2004; Borroni et al., 2006). Concomitant with posterior cingulate hypofunction in patients with MCI and in those with AD is a temporal disorientation that is manifested by temporal order or sequential processing problems (Hirono et al., 1998; deToledo-Morrell et al., 2001; Nestor et al., 2003). Entorhinal cortex hypofunction correlates with MCI, whereas the addition of further hippocampal dysfunction best correlates with a progression to AD (Pennanen et al., 2004). A postmortem study of individuals with AD and those with MCI demonstrates a reduction in (both groups) of P75 neurotrophin receptor (NTR) binding in the basal forebrain, indicating a reduced functional presence of the basal forebrain cholinergic neurons that bear this receptor in the brains of these individuals. This reduction is of particular interest, as the number of P75 (NTR) immunoreactive neurons in the basal forebrain is significantly correlated with tests of working memory and attention (Mufson et al., 2002). Thus, early indicators of memory decline include the basal forebrain and its projection sites. A recent clinical effort is aimed toward preserving the basal forebrain in an attempt to arrest the cognitive decline associated with AD. This effort involved the implantation of autologous fibroblasts genetically modified to express NGF directly into the basal forebrain of patients with early AD. The results are promising, as implanted patients show widespread increases in brain metabolism and markedly slower rates of cognitive decline (Tuszynski et al., 2005).

Despite the preponderance of research aimed at the cholinergic system, other transmitter systems demonstrate altered function in AD and may shed light on the role of the basal forebrain and its constituent circuits in memory (Gsell et al., 2004). For example, successful therapeutic efforts are currently being targeted at excitatory amino acid neurotransmission (for review see Wenk, 2006; also see Francis, 2005). Capitalizing on more recent anatomical findings that GABAergic neurons in the basal forebrain follow similar trajectories as cholinergic neurons may also provide an opportunity for delineating the status of GABAergic neurons in the basal forebrain of AD patients and their role in memory (McKinney and Jacksonville, 2005).

3.15.4 Basal Forebrain Anatomy

The basal forebrain is a group of heterogeneous clusters whose anatomical complexity and organization are constantly unraveling as new techniques are developed and applied to its study (for review see Zaborszky, 2002; also see Zahm et al., 2006). The basal forebrain is parsed into groups of functional anatomical subdivisions based on projection patterns, cell types, and transmitter content (for review see Alheid and Heimer, 1988). Historically, the striking loss of cholinergic function in AD led to extensive study of the basal forebrain cholinergic system and its role in memory. Thus, a large number of the anatomical subdivisions of this system are based on the distribution of cholinergic projection neurons. More recent investigations indicate that GABAergic and perhaps glutamatergic projection neurons also comprise this structure (Jones and Mühlethaler, 1999; Zaborszky et al., 1999).

The basal forebrain neurons are generally organized along a rostrocaudal axis, such that cholinergic nuclei are somewhat contiguous in nature (Semba et al., 1988; Zaborszky et al., 2005; see **Figure 1**). The majority of behavioral and anatomical studies subdivide the basal forebrain into primary subdivisions based on their differential projection systems. The differential projection patterns show a large degree of conservation from primate to rodent and have, thus, been heavily examined across multiple species.

The human basal forebrain has been subdivided and mapped according to the magnocellular projection neurons that reside as groups within the aggregate. The designation of subdivisions is based on cholinergic projection neurons, and the

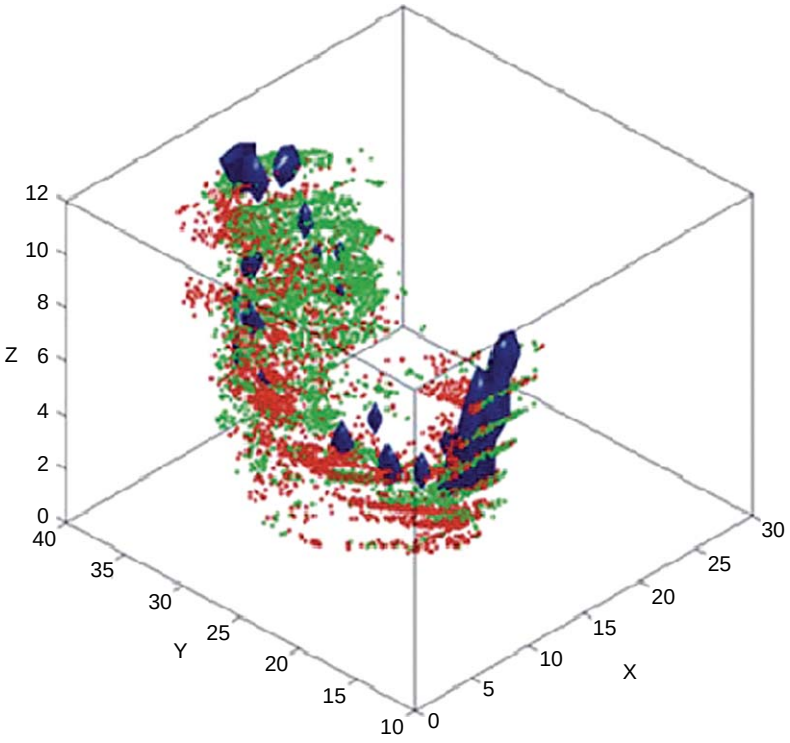

Figure 1 Scatter plots of both cholinergic (red) and parvalbumin (green) cells superimposed on the iso-relational surface (gradient of density changes) shows the relative cell density of the two neuronal types. From Zaborszky L (2002) The modular organization of brain systems. Basal forebrain: the last frontier. *Prog. Brain Res.* 136: 359–372.

subdivisions are referred to as Ch1-4 (for reviews see Mesulam et al., 2004; also see Zaborszky et al., 1999). These Ch subdivisions correspond to designated anatomical subdivisions in the rodent and primate. The Ch1 and Ch2 regions in the human correspond to the medial septum and ventral diagonal band complex (MS/VDB). The Ch3 region corresponds to the horizontal limb of the diagonal band of Broca (HDB), and the Ch4 region corresponds to the nucleus basalis of Meynert (nBM). Ch4 can be subdivided into six spatially distinct regions: Ch4am (anteromedial), Ch4ai (anterointermediate), Ch4id (intermediodorsal), Ch4al (anterolateral), Ch4iv (intermedioventral), and Ch4p (posterior). The Ch1 and Ch2 (MS/VDB) neurons provide the primary cholinergic input to the hippocampus. The Ch3 (HDB) neurons provide primary input to the olfactory bulb. The Ch4am provides the primary cholinergic input to medial cortical areas including the cingulate gyrus, whereas the Ch4al provides the primary input to frontoparietal, opercular areas, and the amygdala. Ch4i provides projections to lateral, frontal, posterior parietal, peristriate, inferotemporal, parahippocampal, and orbitoinsular regions, whereas Ch4p provides input to superior temporal and temporopolar regions (see Mesulam, 2004, for review; also see Zaborszky et al., 1999).

Much of the basal forebrain anatomy has been conserved in the rodent, and the bulk of recent anatomy has focused on the rodent system. Three primary subdivisions are most often referred to as the functional components of the basal forebrain: the medial septal nucleus in combination with the vertical limb of the diagonal band of Broca (MS/VDB), the horizontal limb of the diagonal band of Broca in combination with portions of the magnocellular preoptic area (HDB/MCPOA), and the corticopetal basal forebrain including the nucleus basalis magnocellularis (NBM), the substantia innominata (SI), and portions of the ventral pallidum (hereafter included in NMB/SI). Neurons within the MS/VDB complex provide the major cholinergic innervation of the hippocampus, cingulate cortex, and subiculum, with a projection to the entorhinal cortex. Cells within the HDB/MCPOA project primarily to the olfactory bulb and entorhinal cortex, with additional projections to the occipital cortex and the amygdala. The NBM/SI contains a continuum of

projection neurons that provides the major source of cholinergic input and some noncholinergic input (mostly GABAergic) to nearly all neocortical regions. Additionally, it provides a primary input to the basolateral amygdala and to the reticular nucleus of the thalamus (for a detailed review see Zaborszky, 2002).

The NBM/SI region serves to regulate cortex and, at the same time, receives input from nonisocortical paralimbic cortical areas (orbitofrontal-prefrontal, temporopolar, insular, parahippocampal, and cingulate), the amygdala, the hypothalamus, and various brain stem cell groups. As there is no evidence of direct thalamic projections to the basal forebrain, sensory information must reach the basal forebrain through either the prefrontal cortex or the central nucleus of the amygdala, although other unreported pathways cannot be discarded. Additionally, the basal forebrain makes reciprocal connections with the central nucleus of the amygdala, ventral tegmental area, locus ceruleus, and pedunculopontine tegmental nucleus (PPT) (a brainstem cholinergic nucleus that also projects to the thalamus).

By virtue of a convergence of afferent brainstem projections to the basal forebrain, diverse neurochemical systems can heavily modulate the basal forebrain and its constituent cortical targets. Dopaminergic influence can occur through projections arising from the ventral tegmental area (VTA) or by projections arising directly from the substantia nigra pars compacta, substantia nigra pars reticulata, or retrorubral field (Semba et al., 1988). Serotonergic influence gains access to the basal forebrain by way of dense projections arising from the dorsal raphe nucleus, lighter projections from the median raphe nucleus, or sparse projections directly from the raphe magnus (Semba et al., 1988; Gasbarri et al., 1999). The basal forebrain can receive noradrenergic influence either from the locus ceruleus or from the nucleus of the solitary tract (Semba et al., 1988; Espana and Berridge, 2006). Finally, the brain stem cholinergic system, which is also referred to as the pontomesencephalic cholinergic system (Shute and Lewis, 1967; Woolf, 1991), provides cholinergic input to the basal forebrain primarily by receipt of projections from the laterodorsal tegmental nucleus (LDT) (Satoh and Fibiger, 1986; Woolf and Butcher, 1986; Semba et al., 1988) and also from the PPT (Semba et al., 1988).

Thus, the NBM/SI corticopetal region is well positioned to exert influence on the cortex, providing a primary source of acetylcholine and other neurotransmitters in a regionally independent manner and in the service of other neural systems. Such a system is well suited to play a role in a variety of cognitive functions, including memory.

3.15.5 Basal Forebrain Cell Types

The ability to produce selective neurotoxic lesions of only the cholinergic neurons within the basal forebrain has led to a strong emphasis being placed on discovering the function of these cells, especially given their role in AD and in attentional processing. However, the cholinergic cells constitute only a portion of the cell population in the region. Several other cell types, including GABAergic, peptidergic, and most likely glutamatergic cells also reside within the basal forebrain (Jones and Mühlethaler, 1999; Zaborszky et al., 1999).The characterization of these noncholinergic cell populations is an important route of exploration. While the precise role of these other cell types is unknown, the anatomical localization of these cells within the cholinergic basal forebrain system and their projection patterns indicate that they provide a very important contribution to the functionality of the basal forebrain.

In an elegant series of studies, Zaborszky's group (Zaborszky, 2002; Gritti et al., 2003; Zaborszky et al., 2005) has found noncholinergic cells that contain the different calcium-binding proteins – calbindin, calretinin, and parvalbumin – and has determined the three-dimensional structure and clustering patterns of the four cell types within the entirety of the basal forebrain. These neuronal types form sheets or bands that are twisted and attached to each other and that are not randomly distributed but show location-dependent density profiles (see **Figure 1**). In almost all basal forebrain regions that contain large cholinergic neurons, the other cell types are interspersed in this manner.

There has been some discrepancy on the percentage of basal forebrain neurons that are cholinergic as opposed to containing other neurotransmitters. Zaborszky et al. (2005) found high ratios of GABAergic to cholinergic cells that varied according to structure, with higher ratios in the globus pallidus and SI than in the MS/VDB, HDB, ventral pallidum, and the internal capsule. While it is unclear what proportion of these GABAergic cells are cortically projecting, other studies (Gritti et al., 1997; Sarter and Bruno, 2002) found that there are roughly equal amounts of GABAergic and cholinergic cells that project to cortex. Additionally, Jones

and colleagues (Manns et al., 2001, 2003) found a large subset of cells that were neither GABAergic nor cholinergic but, rather, putatively glutamatergic. These cells also project to cortical regions. In a new study by this group using unbiased stereological estimates in rat, it was found that only a small minority of cells within the BF (5%) are capable of synthesizing acetylcholine, while 35% are capable of synthesizing GABA, and a vast majority (90%) are capable of synthesizing glutamate (Gritti et al., 2006).

The heterogeneity of cell types, and the interesting structural patterning they manifest, reveals a rich organization within the basal forebrain. The structure may consist of functionally distinct circuits constituted by basal forebrain subsections and their connected cortical regions. Further understanding of the organizational principles of this system and the role of GABAergic and glutamatergic, in addition to cholinergic, cells is likely to provide clues regarding the way in which the system may subserve aspects of cognition and memory.

3.15.6 Medial Septum/Vertical Limb of the Diagonal Band Electrophysiology and Memory

The MS/VDB is most well known for its role in the generation and maintenance of hippocampal oscillatory activity, especially the theta and gamma rhythms found therein (Petsche and Stumpf, 1962; Stewart and Fox, 1990a,b; Vinogradova, 1995). Initial evidence for this role came from studies that showed that lesions of the MS/VDB result in abolition of the hippocampal theta rhythm, whereas stimulation of the MS/VDB produces theta in the hippocampus (Lee et al., 1994; Jackson and Bland, 2006). Additionally, cells in the MS/VDB show oscillatory activity that correlates with the hippocampal theta rhythm. Ford et al. (1989) found that the majority of cells in the MS/VDB were theta-related and classified them as theta-on or theta-off cells. Dragoi et al. (1999) also found several types of theta-related neurons in the MS/VDB: rhythmic neurons phase-locked to theta, nonrhythmic but phase-locked cells, and a smaller group of cells that were neither rhythmic nor phase-locked to the hippocampal theta oscillation (see also Gaztelu and Buno, 1982; Alonso et al., 1987; King et al., 1998). The determination of which type of cells these were was not undertaken, and there is still some controversy over the role of different types of MS/VDB neurons on hippocampal theta. Given that there is a strong reciprocal connection from hippocampal interneurons to MS/VDB GABAergic neurons, and that hippocampal cells also show intrinsic theta rhythmic firing, it may be important to think of theta generation as a system-wide phenomenon involving several cell types and depending upon the reciprocal interrelationship between the MS/VDB and hippocampus.

Evidence for a role in hippocampal theta generation and maintenance by cholinergic MS/VDB cells is mainly indirect. Selective lesions of the cholinergic cells in the MS/VDB lead to a severe reduction of rhythmically bursting neurons within the MS/VDB (Apartis et al., 1998). Additionally, Lee et al. (1994) selectively lesioned the cholinergic MS/VDB cells and found a reduction in theta power in the hippocampus. However, a definite theta peak during active wake and rapid eye movement (REM) sleep remains in the face of an absence of cholinergic input, leading to the suggestion that GABAergic neurons could play a prominent role in theta rhythm generation. In a study in which only the noncholinergic cells in the MS/VDB were lesioned (Yoder and Pang, 2005), an attenuation of hippocampal theta was found, confirming this hypothesis. Additionally, juxtacellular labeling techniques have revealed parvalbumin (PV)-positive neurons exhibiting highly regular bursting activity correlated to either the peak or trough of hippocampal theta waves. Subsequent studies have shown that MS/VDB GABAergic cells have the intrinsic propensity to oscillate at theta frequency (Serafin et al., 1996). Furthermore, some of these neurons had an intraburst frequency in the gamma range (Manns et al., 2000a,b; Borhegyi et al., 2004), allowing for entraining of both theta and gamma rhythmicity in the hippocampus. These findings indicate that the septohippocampal GABAergic projection may be sufficient to maintain some hippocampal theta activity, while the cholinergic cells may have a role in determining the magnitude of hippocampal theta.

The MS/VDB's role in memory may be mainly through its role in theta generation, as there is considerable evidence that theta rhythm plays a vital role in information processing and memory formation (Winson, 1972; Givens and Olton, 1994; O'Keefe and Burgess, 1999; Seager et al., 2002). The role of theta in learning and memory has been a topic of interest since the finding that MS/VDB lesions that eliminated theta in the hippocampus produced severe memory deficits (Winson, 1978). A plausible mechanism by which theta rhythmicity could affect

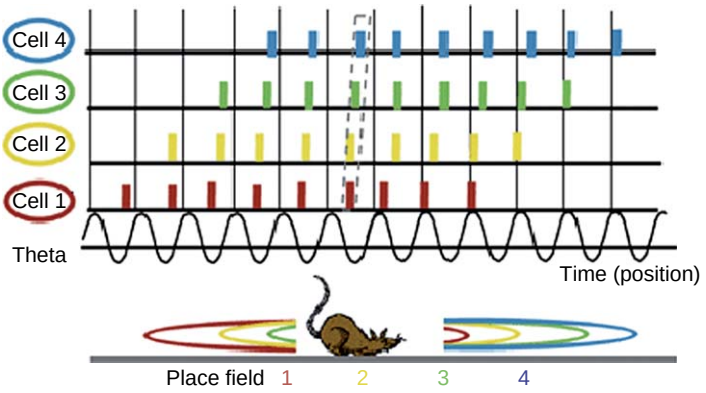

Figure 2 Theta phase precession observed in the place cells of the rat hippocampus. When the rat runs to the right, the phase shift in firing within each theta rhythm cycle occurs in place cells 1–4, which are activated sequentially. The phase is arranged in order of firing within one phase cycle (an example is represented by gray lines). The rat running environment is expressed in compressed form in each theta cycle. From Dr. Yoko Yamaguchi, Laboratory for Dynamics of Emergent Intelligence.

information-processing and memory is for it to act as a substrate for long-term potentiation (LTP) and long-term depotentiation (LTD). In fact, studies have indicated a faster decay of LTP with MS/VDB lesions and prolonged LTP maintenance with MS/VDB stimulation (Rashidy-Pour et al., 1996; Frey et al., 2003). While the role of LTP and LTD in learning and memory is still incompletely understood, there is mounting evidence for such a role (Moser et al., 1993; Rogan et al., 1997; Wilson and Tonegawa, 1997; but see Barnes, 1995, for a critique of this view). It is revealing that several studies have indicated that LTP occurs at the peak of the theta rhythm (Pavlides et al., 1988) and that stimulation at the peak of theta induces LTP, while stimulation at the negative phase of theta rhythm depotentiates previously potentiated synapses (Holscher et al., 1997). These findings have led to the construction of a model in which the two phases, the peak and trough of local theta, correspond to memory encoding and retrieval, respectively (Hasselmo et al., 2002).

Adding to the general idea that theta has a role in memory through its action on LTP and LTD is an intriguing finding concerning the nature of place-specific cells and their firing patterns with respect to the theta rhythm. Principal (pyramidal) cells in the hippocampus show location-specific discharge during exploration (place fields). O'Keefe and Recce (1993) found that the phase of the theta cycle at which such cells fire advances gradually as the animal passes through the cell's place field; that is, the initial spiking occurs at a particular phase of theta, but each successive spike moves to an earlier location on the theta wave (see **Figure 2**). This phenomenon has been called phase precession and has been postulated to result in the compression of temporal sequences of place cell firing, which could facilitate synaptic plasticity (Skaggs et al., 1996) and perhaps act as a neural substrate of path integration and episodic memory (Dragoi and Buzsaki, 2006).

The MS/VDB's effect on hippocampal rhythmicity is thus a well-studied and robust phenomenon. Additionally, through its effect on synaptic plasticity in the form of LTP and LTD, the MS/VDB can strongly affect the way in which hippocampal processes underlying learning and memory function.

3.15.7 The Nucleus Basalis Magnocellularis/Substantia Innominata Electrophysiology and Memory

The NBM/SI possesses interesting electrophysiological properties that render it highly important for cortical processing. It is involved in the general role of activation or desynchronization of cortex but also plays a more specific role in learning and memory, as single-unit, field potential, and stimulation studies have revealed. While some progress has been made in determining the electrophysiological properties of NBM/SI neurons and their role in learning and memory, there is still much to be done to fully explicate these properties.

There is an abundance of evidence indicating that the NBM/SI region of the basal forebrain is involved

in the activation or desynchronization of the cortical EEG, a state that corresponds to active, exploratory, and attentive behaviors. This capacity is dependent upon both cholinergic and GABAergic projections to cortex, although much of the initial evidence for this role came from studies on acetylcholine and its role in cortical activity. The first such study (Longo, 1966) blocked cortical acetylcholine through a muscarinic receptor antagonist, which resulted in an increase in slow-wave activity much like that found in non-REM sleep. Since this initial study, many others have corroborated a role for acetylcholine on the activation of cortex (Dringenberg and Vanderwolf, 1997; McCormick and Bal, 1997; Detari et al., 1999; Cape et al., 2000; Detari, 2000; Manns et al., 2000a; Linster and Hasselmo, 2001).

Further studies showed that lesions of the NBM/SI result in a marked reduction of cortical activation, leading to the conclusion the NBM/SI is necessary for such activation. While there is some evidence that selectively lesioning just the cholinergic cells in the NBM/SI results in an attenuation of cortical desynchrony (Berntson et al., 2002), more evidence points to a combinatorial action, with GABAergic and other transmitter types such as glutamate also being involved in this capacity. Given that an equal number of GABAergic and cholinergic neurons within the NBM/SI project to cortex (Walker et al., 1989; Gritti et al., 1997; Zaborszky et al., 1999), this is not surprising. Furthermore, as stimulation of NBM/SI GABAergic corticopetal projection neurons inhibits cortical GABAergic interneurons, this can in turn increase cortical disinhibition, resulting in increased cortical activation (Jones and Mühlethaler, 1999; Manns et al., 2001; Sarter and Bruno, 2002).

Single-unit studies have provided further evidence that the NBM/SI is involved in activating cortex. For example, enhancement of single-unit responses in the cortex occurs through stimulation of cholinergic cells (Metherate and Ashe, 1993; Herron and Schweitzer, 2000; Berntson et al., 2003). Additionally, many basal forebrain neurons show elevated discharge rates and a bursting pattern of firing during active wake and REM sleep (Cape et al., 2000; Manns et al., 2000a; Szymusiak et al., 2000). While many of these cells increase their firing rates during cortical desynchronization, some decrease their firing rates during this time. By utilizing simultaneous labeling and recording studies, Duque et al. (2000) discovered that both cholinergic and PV-labeled (GABAergic) neurons increased activity with cortical activation, while those that were labeled as neuropeptide Y (NPY), which are most likely local interneurons, decreased rates. These data lend support for a major GABAergic component to cortical activation. It is clear from the above that the basal forebrain has a complex effect on the cortex, with different neuronal types contributing differently to activation or desynchrony.

While the effect on cortical arousal is interesting in itself, there is also neurophysiological evidence supporting a more specific role for NBM/SI activity in learning and memory. This evidence originated with Kanai and Szerbs' work in 1965 on acetylcholine release in the cortex (Kanai and Szerb, 1965). They found that there were two distinct mechanisms of release in the cortex, one related to general arousal and another, more specific, function related to sensory stimuli that have obtained significance for the animal. Later work showed that stimulation of the NBM/SI increases the responsiveness of cortical neurons to sensory stimuli (Metherate and Ashe, 1991) and that Ach applied to cortical sensory neurons increases responses to sensory stimuli (Sillito and Kemp, 1983; Metherate et al., 1987), while lesions reduce the responsiveness of neurons in visual cortex to visual stimuli (Sato et al., 1987).

In addition to general increases in responsiveness, several studies have shown that NBM/SI neurons respond to particular associations formed during learning, as they respond to the learned significance of task events as well as to the novelty, familiarity, or recency of presentation of stimuli (Wilson and Rolls, 1990a,b; Whalen et al., 1994; Wilson, and Ma, 2004). Many studies have shown that stimulation of basal forebrain neurons also results in changes in the cortex that correspond to improvements in learning and increased plasticity (Metherate and Ashe, 1991; Edeline et al., 1994; Kilgard and Merzenich, 1998; Weinberger and Bakin, 1998; Rasmusson, 2000; Miasnikov et al., 2001; Kilgard, 2003). Conversely, lesions of the NBM/SI result in a reduction in such learning and plasticity (Conner et al., 2003, 2005). These changes may be subserved by the long-term enhancement of evoked potentials and the facilitation of multiunit activity that is also seen with stimulation of the region. One major remaining question is the determination of cell types that respond in these ways. To date, no study on the responses of NBM/SI neurons during behavioral tasks has determined the neurotransmitter type (cholinergic, GABAergic, or other) of the cells that have been recorded.

Cortical oscillations in the theta, beta, and gamma ranges are implicated in learning and memory.

Several studies have shown that cells within the NBM/SI are intrinsically oscillatory and that the NBM/SI can induce oscillatory activity in the cortex. Lee et al. (2004) showed that cholinergic neurons within the NBM/SI discharge in bursts at maximal rates during active waking and REM sleep, which is correlated with theta oscillations. They also found that subgroups of GABAergic neurons had very regular high-frequency tonic spiking within a gamma EEG frequency range and rhythmic bursting at theta-frequency range during cortical activation. In addition to these single-unit studies on oscillatory activity, Quinn et al. (2002) showed that local field potential recordings within the NBM/SI of freely behaving animals reveal rhythmic activity at the theta, beta, and gamma frequency ranges. Given its wide projection pattern to numerous cortical regions, oscillatory activity in the BF can have wide-ranging effects on the patterning of activity in cortex.

3.15.8 Animal Models of Memory

A characterization of the role of the basal forebrain and its subregions in memory has been provided through the utilization of primate and rodent models in which all or part of the basal forebrain has been removed and the resultant behavioral capabilities of the animal analyzed. A variety of techniques have been used for removal of this region, including electrolytic lesions, neurotoxic lesions, and more recently, immunotoxic lesions. Historically, observed deficits following removal of the basal forebrain were attributed to the cholinergic denervation of target structures of the basal forebrain, but with the advent of an immunolesion technique, reinterpretation of these results became necessary.

Direct investigation of the role of cholinergic neurons in memory became possible in the early 1990s, when a new immunotoxin, 192 IgG-saporin, was developed (Wiley et al., 1991). Delivery of 192 IgG-saporin directly into the basal forebrain results in selective destruction of cholinergic neurons, whereas neighboring noncholinergic neurons are left intact. This selective destruction is accomplished by taking advantage of the receptor profile of basal forebrain cholinergic neurons. Cholinergic neurons bear the P75 neurotrophin receptor that is absent from neighboring neurons. Preferentially binding to the P75 receptor, 192 IgG is an immunoglobulin that effectively delivers a cytotoxin (saporin) to the cell body, accomplishing selective destruction of the cholinergic neurons in the basal forebrain. Here it is important to note that a small subpopulation of neurons in the cholinergic basal forebrain do not bear the P75 neurotrophin receptor. This subpopulation of neurons projects primarily to amygdaloid nuclei, resulting in residual cholinergic innervation of various amygdaloid nuclei (including the basolateral nucleus) (Hecker and Mesulam, 1994).

A large body of work using this immunolesion technique has served to revise the role of the basal forebrain cholinergic system in various aspects of memory, as many of the deficits found with complete lesions have not been found with targeted removal of only cholinergic neurons. (see Baxter, 2001, for review). The basal forebrain contains several other neuromodulatory cell types, including GABAergic and glutamatergic cells, which together comprise a high percentage of the totality of neurons found in the region. Understanding the role of these and other neuromodulators is of great importance to fully explicate the role of the basal forebrain in memory.

3.15.9 The Medial Septum/Vertical Limb of the Diagonal Band and Memory

Total removal of MS/VDB neurons in rodents leads to profound deficits in spatial learning and memory tasks alongside an increase in reactive behavior (Gage and Olton, 1975; Mitchel et al., 1982; Dunnett et al., 1987; Hagan et al., 1988; Kelsey and Landry, 1988; Kesner et al., 1988). For example, on several spatial memory tasks that are classically disrupted by hippocampal lesions, including the Morris water maze and radial eight-arm maze, deficits in the ability to recall spatial locations following full lesions of the MS/VDB are robust. Additionally, temporary inactivation of the MS/VDB results in drastic memory deficits along with a reduction in hippocampal theta rhythm, which is important for memory (Mizumori et al., 1990; Givens and Olton, 1994; Hasselmo et al., 2002) Thus, historically, such deficits were thought to be a result of cholinergic denervation of the hippocampus and other structures to which the intact MS/VDB provides cholinergic input, building on a cholinergic hypothesis of memory. However, with the advent of selective lesioning techniques, the cholinergic basis of these deficits has been called into question.

3.15.10 Selective Cholinergic and GABAergic Lesions of the Medial Septum/Vertical Limb of the Diagonal Band: Implications for Attention, Learning, and Memory

A more recent body of work, in which discrete removal of the cholinergic neurons is accomplished by direct infusion of 192IgG-saporin into the MS/VDB complex, demonstrates that rodents maintain the ability to do standard spatial memory tasks, including various versions of the Morris water maze (Baxter et al., 1995, 1999a); McMahan et al., 1997). Rats with these lesions are also able to perform a standard radial maze task, even when long delays are inserted between training and testing (Chappell et al., 1998). Interestingly, selective lesions of just GABAergic cells within the MS/VDB also do not affect rats' ability to perform normally on the same tasks (Pang et al., 2001). Since neither type of lesion alone results in impairments on standard spatial memory tasks, it may be concluded that most spatial memory impairments found with lesions of the MS/VDB require at the least a depletion of both the cholinergic and GABAergic neurons within the region.

Whereas impairments in spatial memory are either mild or absent in rats who have sustained selective cholinergic lesions of the MS/VDB, a separate body of work indicates that these rats have memory deficits in tasks that emphasize other behavioral or sensory domains. Rats with selective cholinergic MS/VDB lesions demonstrate impairments on a social transmission of food preference task, a task that is dependent on olfactory associative memory (Berger-Sweeney et al., 2001; Vale-Martinez et al., 2002). Specifically, these rats demonstrate a deficit in delayed recall of a food preference learned prior to surgery, indicating a retrograde memory deficit. These data are taken to mean that the cholinergic projection to the hippocampus is involved in retrieval of social memories related to food preference.

Another arena in which rats with selective lesions of the MS/VDB demonstrate memory deficits is when they are presented with more than one potentially relevant feature. Rats were tested on a conditional associative learning task, termed environment-spatial conditional learning. In this task, the correct location of a spatial response depended on the array of local environmental cues. Rats with cholinergic lesions of the MS/VDB were impaired when the two parts of the conditional problem were presented concurrently, but not when one spatial environment was learned prior to the other. (Janisiewicz and Baxter, 2003).

These same lesions reliably produced impairments in tasks requiring that the rat learn to decrement attention to irrelevant stimuli, indicating that this system is critical for reducing attention to irrelevant stimuli and perhaps to reducing interference from irrelevant features in the environment. Although these functions do not directly address memory functions, they certainly come to bear on effective learning and memory. (Baxter et al., 1997, 1999b). Such changes in attentional processing are also evident in selective lesions of projection sites of the MS/VDB area. Discrete cholinergic denervation of the anterior cingulate, a projection region of this system, led to an increase in interference from distracting background flashes in a target detection task. This same manipulation also reduced a characteristic increase in the firing rate of medial prefrontal neurons to the distracting flashes (Gill et al., 2000), indicating that such firing works in the service of reducing processing of the flash and allowing salient information to be processed and remembered.

Discrete cholinergic lesions of the MS/VDB also impair various tasks that involve strategy selection or adaptively changing strategies or behavioral sets across both spatial (Cahill and Baxter, 2001; Bizon et al., 2003) and nonspatial (Baxter, 2001) memory tasks. This function of learning enables optimal performance in learning and memory tasks.

Selective cholinergic lesions of the MS/VDB produce domain-specific deficits in learning and memory that are insufficient to account for the sort of amnesia observed in humans but are sufficient to hamper the sort of optimal learning on which memory relies. Additionally, some very convincing studies have emphasized the importance of the GABAergic system not just as a modulator of the cholinergic system but as another primary projection system of the basal forebrain. Combined cholinergic and GABAergic lesions lead to global spatial memory impairments. This is a strong indicator that the conjoint activity of the system is essential to memory function.

3.15.11 The Nucleus Basalis Magnocellularis/Substantia Innominata and Memory

Complete lesions of the nucleus basalis/substantia innominata (NBM/SI) region of the basal forebrain

reveals similar learning and memory deficits to those of the MS/VDB region, despite the very different projection patterns of the two regions. Lesioning either region leads to difficulty on spatial discrimination tasks (Hepler et al., 1985) and spatial working memory tasks, including standard water maze and radial maze tasks (Bartus et al., 1985; Connor et al., 1991; Matsuoka et al., 1991). Thus, earlier studies viewed these two basal forebrain systems as having somewhat redundant memory functions while emphasizing a role for the total system in working rather than reference memory (Knowlton et al., 1985).

On nonspatial tasks, investigations have revealed differential disturbances of temporal memory between the MS/VDB and the NBM, indicating that rats with NBM lesions share deficits in temporal memory with those having frontal cortex lesions, rather than with those having MS/VDB lesions (Meck et al., 1987). The role of the NBM in aspects of temporal memory has also been explored through direct comparisons of the performance of rodents with NBM lesions to that of patients with AD on order memory tasks. Such comparisons revealed that complete lesions of the NBM result in order memory deficits that parallel those observed in patients with AD (Kesner et al., 1987).

With the development of a broader variety of neurotoxic lesion techniques, further studies indicated that, as with the MS/VDB, the substantive spatial working memory deficits observed in rodents with NBM lesions were most highly correlated with maximal destruction of basal forebrain neurons, but not with maximal depletion of acetylcholine (Wenk et al., 1989; Markowska et al., 1990). A direct comparison of different types of memory tasks across different neurotoxic lesions of the NBM indicated that maximal destruction of the NBM (in the absence of maximal depletion of cortical acetylcholine) led to spatial working memory deficits in the water maze and delayed match-to-position tasks. These lesions also impaired an attention-based serial reaction time and a passive avoidance task.

NBM lesions that maximally depleted cortical acetylcholine resulted in preserved performance on spatial working memory tasks. However, cortical acetylcholine depletion did result in impaired performance on the serial reaction task (Dunnett et al., 1990). These findings combined with contemporary findings from pharmacological studies, led to the proposal that the NBM may be preferentially involved in attentional processes rather than memory processes (Dunnett et al., 1990; Muir et al., 1993; Pang et al., 1993). One hypothesis set forth to explain the stark behavioral contrast between the substantive working memory deficits following total destruction of the NBM as opposed to the absent or mild working memory deficits following partial destruction of the NBM was the idea that the substantive memory deficits were a result of damage to the globus pallidus that included disruption of corticostriatal output pathways (for review see Dunnett et al., 1990; Muir et al., 1993). Alternatively, the mild deficits were taken to be a result of depleting cortical acetylcholine and thereby disrupting basic attentional processes (for review see Muir et al., 1993).

3.15.12 Selective Cholinergic Lesions of the Nucleus Basalis Magnocellularis/Substantia Innominata: Implications for Attention, Learning, and Memory

The advent of a selective immunolesion technique (192-IgG saporin) has allowed a thorough assessment of the necessity of the SI/NBM corticopetal cholinergic system in various aspects of attention as well as memory.

Behavioral and neurobiological data concur that cholinergic neurons in the basal forebrain help to fluidly and appropriately regulate attention to relevant stimuli (for review see Baxter and Chiba, 1999; McGaughy et al., 2000). The integrity of NBM/SI cholinergic neurons is also required for the typical facilitation in processing stimuli whose outcomes are uncertain (Chiba et al., 1995; Bucci et al., 1998), a strategy that has been proposed to underlie the learning of effective predictive associations between stimuli (Pearce and Hall, 1980; Holland and Gallagher, 1993). This facilitated learning of, or increasing of attention to, surprising events that are typical of intact rats but are absent in rats with NBM/SI cholinergic lesions. In addition, the integrity of NBM/SI cholinergic neurons has been found to contribute to the fluid allocation of visuospatial attention, perhaps by reducing the behavioral influence of misleading stimulus expectations from visuospatial cues. This was revealed in an experiment in which rats with NBM/SI cholinergic lesions demonstrated poorer performance than control rats on trials in which misleading cues were presented (Chiba et al., 1999). The integrity of the NBM/SI cholinergic system may also be essential for adequate detection, selection, vigilance, and processing of stimulus associations, in

addition to the proper allocation of processing to these attentional functions. This is indicated by a large literature in which NBM/SI cholinergic lesions selectively impair aspects of these functions. (for review see Sarter et al., 1999; McGaughy et al., 2000, 2002; Baxter, 2001).

Many of the described attentional deficits have been replicated by utilizing cortical infusions of 192IgG saporin to remove only those NBM/SI neurons that innervate particular cortical sites involved in these aspects of attention. Specifically, vigilance or sustained attention deficits have been replicated in animals with frontoparietal deafferentation (McGaughy et al., 1998), whereas failure to increase attention to surprising events and deficits in conditioned responding were replicated by posterior parietal deafferentation (Bucci et al., 1998; Bucci and Chess, 2005). Thus, there exists a large body of literature, based on this selective immunolesion technique, implying a role for the cholinergic NBM/SI and its cortical targets in various aspects of attention.

A large number of studies indicate that the classic working memory deficits observed in rats with total NBM/SI lesions are not observed in rats with selective cholinergic lesions of this system (for review see Baxter and Gallagher, 1996; Everitt and Robbins, 1997; Wenk, 1997; Baxter and Chiba, 1999; Baxter, 2001). For example, neither a deficit in water maze performance nor a deficit in radial maze performance (even with very long delays) was evident in these rats (Baxter et al., 1995; Chappell et al., 1998; Galani et al., 2002). Additionally, neither passive avoidance nor delayed alternation was impaired in rats with these lesions (Wenk et al., 1994). In order to eliminate the possibility that the MS/VDB neurons exert a compensatory function when the NBM/SI is lesioned, it was also important to examine the behavioral effects of combined lesions of the MS/VDB and NBM/SI cholinergic neurons on behavior. An investigation utilizing a cholinergic immunotoxin to create a combined lesion of MS/VDB, SI/NBM, and HDB indicated that, even in the face of removing this entire system, spatial working memory (as measured by performance in a standard water maze task) remained intact (Vuckovich et al., 2004). The aggregate of the NBM neurotoxic lesion work and the large body of work utilizing the selective cholinergic immunotoxin, 192 IgG saporin, refuted the long-standing hypothesis that basal forebrain cholinergic projections to the cortical mantle are essential to support classic working memory tasks.

Here it is important to note that the NBM/SI provides cholinergic innervation to the cortical mantle and also to the amygdala. The cholinergic immunotoxin, 192 IgG saporin, depletes the preponderance of cortical acetylcholine while sparing a large portion of the cholinergic innervation of the amygdala. Selected studies examining the importance of the NBM/SI projections to amygdala in memory highlight the potential importance of this basal forebrain axis in subserving aspects of memory. If the NMB/SI cholinergic neurons are lesioned simultaneously with either lesioning or cholinergic blockade of the amygdala, substantive working memory and/or emotional memory deficits are incurred, including aspects of memory consolidation and enhancement of emotional memory (see Beninger et al., 2001; Power et al., 2002). Further examination of the basal forebrain amygdalopetal pathway is likely to provide insight regarding an important role for basal forebrain cholinergic neurons in additional aspects of memory.

In light of the reliance of many of the classic working memory tasks on spatial information, a further set of studies set out to examine the role of the NBM/SI cholinergic projections in supporting forms of associative memory that rely on nonspatial sensory associations. The studies revealed that NBM/SI cholinergic lesions produce a deficit in social transmission of food preference on both immediate and 24-h retention intervals (Berger-Sweeney et al., 2000; Vale-Martinez et al., 2002), indicating a deficit in encoding new sensory associations. Another study assessing a form of configural associative memory, negative patterning, indicates that rats with NBM/SI cholinergic lesions demonstrated a deficit in this form of sensory associative learning (lights and tones) (Butt et al., 2002). These results were taken to indicate that the rats either were unable to attend to multiple sensory stimuli concurrently or were unable to cope with the different response strategies required by the task. In order to address the potential issue of cognitive flexibility, an additional study examined the ability of NBM/SI cholinergic lesioned rats to learn and reverse sensory associations. The results of this study indicate that NBM/SI lesioned rats were able to learn a simple discrimination (between two stimuli of different sensory modalities) but that they were impaired at learning multiple reversals (Cabrera et al., 2006). This is indicative of a general lack of cognitive flexibility, a function that is also impaired in primates with similar lesions. Thus, the NBM/SI appears to

play an important role in the learning, memory, and flexible use of sensory associations. Further clarity of this role will arise from additional investigation (*See* Chapter 3.11).

3.15.13 The Role of the Basal Forebrain in Regulating Cortical Targets

Behavioral learning and memory that depend on the formation and utilization of complex sensory associations have been shown to rely upon intact basal forebrain cholinergic projections to cortical regions. This is consistent with a large body of literature indicating that cortically projecting cholinergic neurons in the basal forebrain promote activity and plasticity in the cortex in response to sensory stimuli or actions that predict significant events in the environment (Wilson and Rolls, 1990a; Whalen et al., 1994; Bakin and Weinberger, 1996; Kilgard and Merzenich, 1998; Mercado et al., 2001; Conner et al., 2003, 2005; Oldford et al., 2003; Berg et al., 2005). The ability of the NBM/SI to promote plasticity in very restricted cortical regions (see Weinberger, 2003; Kilgard, 2003, for review) provides anatomical support for the idea that such associative learning deficits may rely on the basal forebrain cholinergic projections to the cortical targets that preferentially support a particular type of learning.

Further support for this hypothesis comes from studies showing that selective removal of only those cholinergic neurons that project to a particular target cortical region disrupts aspects of sensory learning or memory. For example, selective removal of the cholinergic innervation of the orbitofrontal cortex (OFC) in rats is sufficient to replicate the learning and memory deficits in social transmission of food preference observed in NBM/SI lesioned rats (Ross et al., 2005). This finding is in accordance with the strong anatomical olfactory inputs to OFC and the importance of the OFC in supporting various aspects of olfactory learning and memory (see Eichenbaum, 1998, for review). Removal of the HDB cholinergic neurons eliminated acetylcholine in the olfactory system (including cortical targets and the olfactory bulb), thereby decreasing a rat's ability to discriminate between perceptually similar odorants (Linster et al., 2001).

Whereas the aforementioned studies focus on the role of acetylcholine in permitting sensory associations and discriminations, other studies examining selective destruction of basal forebrain cholinergic neurons that project to multimodal cortical regions indicate that such lesions disrupt learning and memory of novel stimuli, but not familiar stimuli. For example, cholinergic deafferentation of the entorhinal cortex results in impaired working memory, as measured by a delayed nonmatch-to-sample task, for novel but not for familiar odorants (McGaughy et al., 2005). Cholinergic deafferentation of the perirhinal cortex disrupts object recognition memory for novel objects, a process that is also disrupted by complete lesions of the perirhinal cortex (Winters and Bussey, 2005). Interestingly, these cortical target structures receive cholinergic information from two or more of the basal forebrain regions, indicating redundancy of cholinergic input and an opportunity for convergence of basal forebrain input at these cortical sites. Taken together, investigations utilizing selective cortical deafferentation indicate that these selective lesions replicate impairments incurred by lesions to their cortical regions. This indicates that basal forebrain cholinergic modulation is basic to effective cortical function under conditions of learning, memory, and attention.

3.15.14 The Effects of Basal Forebrain Lesions in the Nonhuman Primate

The effect of basal forebrain lesions on learning and memory delineated above was gleaned primarily from rodent studies. Nonhuman primate studies utilizing neurotoxic lesion techniques that removed the majority of NBM cell bodies have revealed selective performance deficits that differ somewhat from those found in rodents. In general, unlike complete lesions in rodents, only mild or transient memory deficits ensued, whereas, as in the rodent studies, impairments in learning and attention persisted. A study of monkeys with restricted NBM lesions found a lack of memory impairment on a recognition memory test (Aigner et al., 1987). A study of visual discrimination learning in marmoset monkeys with neurotoxic lesions of the nucleus basalis indicated a transient impairment for retention (lasting only 1 week after lesion), with a persistent impairment in new learning (Roberts et al., 1990). An additional study, testing other aspects of learning and memory, demonstrated that marmoset monkeys were able to selectively attend to stimulus features in an intra- and extradimensional set shifting task. Still, they demonstrated a

transient impairment for new learning and were incapable of serial reversal learning, demonstrating a sort of cognitive inflexibility (Roberts et al., 1992). An additional study, examining the role of the basal forebrain in cynomolgus monkeys, employed neurotoxic lesion techniques targeted at both MS/VDB and NBM (with the end result being substantial damage to the NBM with lesser damage to the MS/VDB). These basal forebrain lesioned monkeys were tested on a variety of memory tasks and on aspects of attention such as orienting and target detection. The resultant data strongly indicate a role for this region in allocating visuospatial attention, in the absence of any distinct memory impairments (Voytko et al., 1994).

An immunotoxin (with similar action to 192-IgG saporin, described above) targeting cholinergic neurons in the primate was used to independently lesion the projections to hippocampus (MS/VDB) and to the majority of cortex (NBM) in the marmoset monkey. Monkeys with MS/VDB cholinergic lesions demonstrate intact performance on a simple visual discrimination task, with a persistent deficit in a visuospatial conditional discrimination task. Monkeys with NBM cholinergic lesions demonstrate intact visuospatial conditional discrimination learning, with a transient deficit in simple visuospatial learning (Ridley et al., 1999a).

Further studies indicate that combined cholinergic lesions of the MS/VDB and NBM led to persistent deficits in both of these tasks (Ridley et al., 1999b, 2005). Thus, cholinergic depletion of the primate basal forebrain appears to produce a persistent effect on new learning.

3.15.15 Behavior Summary

Certainly, the variety of work done on the basal forebrain indicates that it plays an important role in aspects of attention and in aspects of learning and memory. The role of the system in memory may rely, in part, on the fact that the integrity of the basal forebrain is essential in order for experience to exert change on fundamental stimulus representations (*See* Chapter 3.11). Although this sort of memory is distinct from the classic form of declarative memory to which people typically refer when discussing memory deficits, it remains a form of memory that can substantively affect many aspects of cognition, including working memory. Another way in which the system may play a role in memory is through facilitating acquisition and encoding of selected aspects of memories (see Hasselmo, 2006, for review). Thus, the basal forebrain is an essential structure in allowing new information to be fully sustained and flexibly used by the neural system.

3.15.16 A Comment on Theoretical Models of Basal Forebrain Function

A multitude of experiments across behavioral domains and species have been conducted in order to shed light on the essential role of the basal forebrain and memory. Anatomical work provides the rich neurochemical landscape and potential of this region to regulate target structures and serve as a pathway to cortical modulation. Electrophysiological recording provides clues to the timing functions of this structure, in addition to its potential to modulate brain dynamics under various behavioral states. Animal models present the potential for this structure to subserve various aspects of learning, memory, and attention. Disease states provide clues to the impoverished world in which subjects with damaged basal forebrains must exist. Despite the convergent evidence that multiple fields of study lend to the behavioral function of this region, reconstruction of this work into a unified framework has posed a difficult problem. Promising attempts to unify and concatenate these data into a formal structure have recently been attempted through theoretical modeling.

The important, but often contested, roles of the basal forebrain in supporting learning and memory have inspired formal theories of the computations performed by this region and the role of such computations in regulating aspects of neuromodulation and/or neural transmission in target structures. These theories hold promise in that they provide testable hypotheses and a means by which a multitude of data can be reconstructed into a larger theoretical framework. Of the many computational models that exist, those of Hasselmo and colleagues (see Hasselmo, 2006, for review; Linster and Hasselmo, 2001) and those of Dayan, Yu, and colleagues (Yu and Dayan, 2005) are particularly relevant to the behavioral work presented in this chapter. Among other things, models by Hasselmo and colleagues provide an account of how encoding might be enhanced in various target structures of basal forebrain neurons. Models by Dayan, Yu, and colleagues provide an account of how learning is

facilitated by basal forebrain influences on cortex, revealing the way in which stimulus uncertainty augments cortical processing according to prior expectations. Full explication of such models is beyond the scope of this chapter but bears high relevance to the role of the basal forebrain in learning and memory and provides a compelling direction for future investigation.

3.15.17 Conclusion

Given its widespread anatomical connectivity and provocative neurophysiological properties, the sphere of influence enjoyed by the basal forebrain is undoubtedly extensive. Accessing nearly all regions of cortex and subcortex through distinct subregions, each holding a rich and diverse compilation of cells and neurochemicals, the basal forebrain is in a position to affect neuronal function across the brain. The complexities and intricacies of this heterogeneous region have only begun to be discovered, but the knowledge already gleaned has provided us with insight into some of its functions. Many of the structures to which the basal forebrain is most highly connected are essential to learning and memory, and thus the basal forebrain is naturally positioned to have a large effect on mnemonic function. Evidence provided through behavioral, lesional, and electrophysiological methods has revealed just such an effect. Through further examination of the entirety of the basal forebrain, including the different cell types and their neuromodulatory action, and through continuing examination of the vast nexus of connectivity to cortical and subcortical areas involved in memory, subtleties concerning the exact role in mnemonic processing will most likely be revealed.

3.16 Ascending Systems Controlling Attentional Functions

M. Sarter and E. Demeter, University of Michigan, Ann Arbor, MI, USA

3.16.1 Introduction: Attention in Learning and Memory

Neurobiological research has often attempted to differentiate between brain systems mediating learning and memory and attention. Indeed, the modulatory functions of brainstem and basal forebrain ascending systems, particularly the noradrenergic and cholinergic cortical projections, traditionally have been described in terms of contributing to 'arousal,' the 'gating' of cortical information processing, or to the general readiness of forebrain systems for input processing. In contrast, a role of these modulatory systems in learning and memory has remained a less salient subject (but *See* Chapter 3.26; McGaughy et al., 2005; Hasselmo and Stern, 2006). Some authors even rejected the hypothesis that these systems modulate learning and memory altogether (for a critical discussion of the evidence that supported such a dissociation see Sarter et al., 2003).

Perspectives concerning the relationships between attentional functions and capacities and learning and memory range from complete conceptual and experimental separation between the two cognitive domains, particularly in the context of theories that focus on storage mechanisms, to theories that consider the attentional processing of a stimulus as an integral variable for effective encoding (e.g., Craik and Lockhart, 1972). These latter theories question the degree to which brain systems subserving learning and memory and attention, respectively, can be dissociated (e.g., Gaffan, 2005). Contemporary connectionist views generally embrace this perspective and suggest that the attentional modulation of a cue represents an inherent function of a learning process during which outcome errors result in the redistribution of attentional resources to cues present (e.g., Kruschke, 2003).

The wide range of states and processes subsumed under the construct of 'attention' and the sometimes undefined use of this term have together complicated the theoretical development of relationships between attentional functions and learning and memory (*See* Chapters 1.13, 2.02). However, the grouping of attentional functions into basic, selective, and executive components readily gives rise to testable hypotheses about the role of attention in learning. First, at the most basic level, vigilance or alertness, that is, the ability to sustain attention to exteroceptive input sources, underlies all higher forms of attention. A general readiness for input processing, as opposed to a state of drowsiness or hyperarousal, presents a necessary condition for effective learning. Second, the ability to direct attentional resources to selected inputs is crucial for learning. This may be as a function of stimulus salience (often termed bottom-up

control of attention) or practice, knowledge, and expectation (top-down control of attention). Third, the management of attentional resources available for competing stimuli and tasks and in response to challenges to attentional performance (by, for example, distractors, extended time-on-task, sleepiness; see Sarter et al., 2006) concerns the most executive aspects of attentional functions.

The relationships between demands on attention and demands on memory are bidirectional. Attention to stimuli facilitates learning, and memories assist in allocating attentional resources to a particular location and/or modality, or away from distractors (Nissen and Bullemer, 1987; Summerfield et al., 2006; Turk-Browne et al., 2006). Attention-based rehearsal plays an active role in spatial working memory. If subjects' ability to direct their attention toward a memorized location is hindered, memory accuracy for location declines (Smyth and Scholey, 1994). Performance of a secondary task that requires shifts of attention also impairs memory performance on a primary task (Awh et al., 1998), supporting the idea that spatial attention has a functional role in the maintenance of location information. Furthermore, excessive demands on perceptual and attentional processes degrade learning rates and the performance of tasks involving previously learned rules. Conversely, high demands on working memory disrupt distractor filtering, reflecting that the attentional resources normally available for effective filtering were consumed by the demands on working memory task (e.g., Lavie, 2005; see **Figure 1**).

The role of attention in retrieval is less clear and has rarely been studied (e.g., Craik et al., 1996; Fernandes and Moscovitch, 2000). A common fronto-parietal-cingulate-thalamic network has been found for both visual attention and episodic retrieval, suggesting a role for attentional processes in episodic retrieval (Cabeza et al., 2003). It could be speculated that retrieval and reconsolidation mechanisms are influenced by attentional states and capacities, similar to the role of such states and capacities in the original encoding of stimuli (Craik and Lockhart, 1972).

Thus, it is not only appropriate but perhaps necessary to discuss brain systems controlling attentional

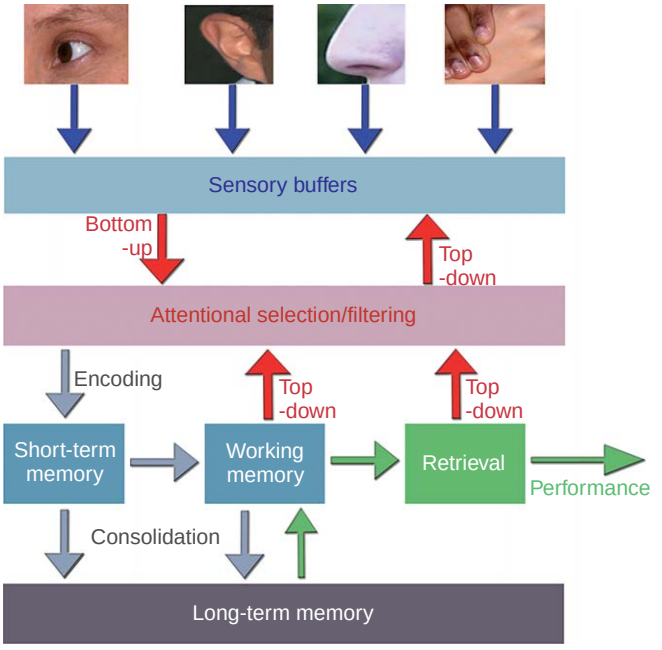

Figure 1 Schematic illustration of the role of attentional functions and capacities in learning and memory. Stimuli are selected for further processing, either as a result of their salience (bottom-up) or based on expectations, practice, and memory (top-down). Such top-down mechanisms include biasing of receptive fields toward stimulus shape, location, and modality, and perhaps also the suppression of the processing of irrelevant modalities and shapes (for examples see Table 1 in Sarter et al., 2006). Impairments in attentional processing weaken stimulus selection and detection (as defined by Posner et al., 1980) and therefore the effective formation of memories involving relevant stimuli. Conversely, excessive demands on working memory consume the attentional resources available for stimulus selection and detection, as indicated by the breakdown of 'noise'-filtering under such conditions (for more discussion see Sarter et al., 2003).

functions in a synopsis on learning and memory. As will be discussed in this chapter, recent evidence on the role of ascending noradrenergic and cholinergic projections in attention increasingly indicates that, in addition to mechanisms supporting the more traditional hypotheses about modulation of arousal and alertness, these systems modulate and indeed initiate defined cognitive operations. In other words, noradrenergic and cholinergic projections may not only modulate forebrain information processing, but 'decide' whether a stimulus will be integrated into the processing stream. The noradrenergic and cholinergic systems may therefore control the behavioral outcome, or whether an outcome is capable of redistributing the attentional resources toward stimuli and cognitive operations that optimize performance.

This evidence, discussed below, forces a departure from the conventional interpretation of effects of neuromodulators strictly in terms of 'alerting' and 'orienting' systems (Raz and Buhle, 2006). Rather, ascending modulator systems are integral components of distributed forebrain circuits mediating discrete cognitive functions. These cognitive functions range from the augmentation of sensory input processing to cue detection and outcome processing, thus constituting elementary stages of learning. Consequently, ascending neuromodulator systems play a necessary role in learning as well as the memory-based performance of tasks involving the detection, selection, and processing of stimuli that control motivated behavior.

In this chapter, we will focus on the regulation and functions of the noradrenergic projection system arising from the locus coeruleus (LC) and the basal forebrain (BF) cholinergic system. We will stress the organizational and functional similarities between these systems as well as the evidence indicating that cholinergic and noradrenergic projections mediate different aspects of attentional operations. As relatively little is known about the attentional functions of other brainstem ascending projections, including the serotonergic projections to the forebrain, these systems will not be discussed. Likewise, although the functions of dopaminergic systems in error detection and reward mechanisms are of relevance for attentional processes (Small et al., 2005; Sarter et al., 2006) and such mechanisms may be difficult to differentiate from attentional processes (Maunsell, 2004), the discussion of dopaminergic systems will be restricted to evidence on the dopaminergic modulation of the forebrain cholinergic system in the context of the mediation of attentional effort (defined in the section 'Acetylcholine').

3.16.2 Commonalities and Differences in the Organization of Noradrenergic and Cholinergic Systems

Noradrenergic and cholinergic systems exhibit several fundamental differences in their anatomical organization. Nonetheless, there are also important commonalities between the two systems, particularly with regard to the position of the locus coeruleus and basal forebrain within larger circuits including the prefrontal cortex.

Located in the dorsorostral pons, the LC represents the primary source of noradrenaline (NA) in forebrain, particularly in the cortex and basal forebrain. The LC contains a relatively small number of neurons (<50,000 in humans) but exerts immense influence over forebrain circuits, in part as a result of the extensive collateralization, or highly divergent efferents, of the noradrenergic projection system (Berridge and Waterhouse, 2003; Aston-Jones and Cohen, 2005b). In addition to collateralization, there is also substantial evidence that noradrenaline exerts widespread effects via extrasynaptic or 'volume transmission' (Seguela et al., 1990).

The cholinergic projections to hippocampus and cortex arise mainly from the septal nucleus, the vertical limb of the diagonal band of Broca, the nucleus basalis of Meynert (nbM), the substantia innominata (SI), the horizontal limb of the diagonal band (HDB), and the preoptic region (species-specific differences in the organization of these projection systems are discussed elsewhere, e.g., Mesulam et al., 1983; Woolf, 1991; Zahm, 2006. As little remains known about the regulation and functions of the septo-hippocampal cholinergic system, the cholinergic projections from the more lateral-dorsal basal forebrain regions to the cortex will be the focus of the present review on the role of ascending systems in the regulation of attention.

In contrast to the noradrenergic system, the degree to which the cholinergic projections from the nBM, SI, and HDB are collateralized remains disputed. However, several studies suggested that an individual cholinergic, cortically projecting neuron, if at all showing axonal collaterals, does not innervate multiple cortical areas (Price and Stern, 1983; Walker et al., 1985; Koliatsos et al., 1988). The view that individual cholinergic neurons have restricted terminal fields corresponds with the assumption that acetylcholine (ACh) is not transmitted extrasynaptically, although

this issue also remains controversial (Descarries and Mechawar, 2000; Mechawar et al., 2000; Turrini et al., 2001). The presence of a highly potent metabolizing enzyme, acetylcholinesterase (AChE) further challenges the degree to which ACh can reach distant, extrasynaptic receptors.

Finally, anatomical and functional considerations have formed the basis for a description of the cortical cholinergic input system in terms of consisting of modular, functionally distinct subcomponents (Zaborszky, 2002; Golmayo et al., 2003; see **Figure 2**). Evidence is not available to support such a conceptualization with respect to the noradrenergic projections to telencephalic regions (Saper, 1987). However, it should also be noted that earlier descriptions of a diffuse noradrenergic projection system were rejected on the basis of evidence indicating that noradrenergic innervation patterns differ between cortical target regions (Parnavelas and Papadopoulos, 1989; Papadopoulos and Parnavelas, 1991).

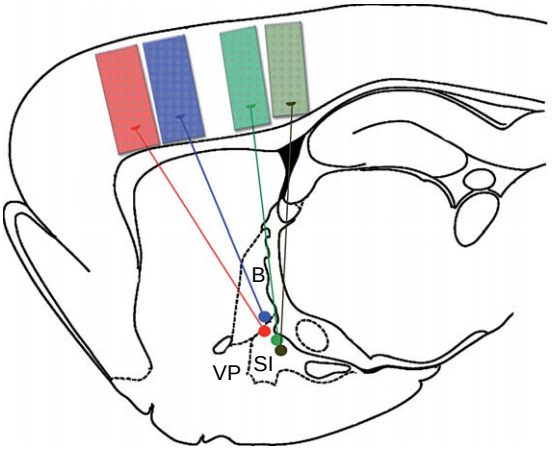

Figure 2 Schematic illustration of the organization of a modular basal forebrain cholinergic projection system to the cortex (Zaborszky et al., 1999; see also Zaborszky, 2002). Cholinergic inputs to cortical regions are thought to be activated in a modality-, cortical region-, and perhaps even column-selective manner. Although cholinergic projections follow a limited topographic organization and have been suggested to be arranged in longitudinally oriented, segregated projection bands, the selectivity of the recruitment pattern is also based on the hypothesis that prefrontal projections to the basal forebrain carry, for example, modality-specific information to cortical projection neurons (see also Golmayo et al., 2003). Although noradrenergic innervation patterns differ by cortical region, there is little evidence that would suggest the presence of similarly segregated projection bundle in the LC projection system. B, nucleus basalis; VP, ventral pallidum; SI, substantia innominata. Adapted and modified from Figure 13 in Zaborszky L, Pang K, Somogyi J, Nadasdy Z, and Kallo I (1999) The basal forebrain corticopetal system revisited. *Ann. N. Y. Acad. Sci.* 877: 339–367, with permission from Elsevier.

Thus, the anatomical organization of the two ascending modulator systems exhibits fundamental differences. The presence of a stricter topographic organization of cholinergic projections to the cortex (Luiten et al., 1987), combined with a very limited collateralization of axonal projections and the possibility that volume transmission does not apply to, or only to a very limited degree, ACh, collectively indicate a system that influences its target regions in a more specialized, differentiated manner when compared with noradrenergic projections. As we will see further, these contrasts between the two neuromodulator systems are not completely matched by analogous contrasts in their functions. However, we need to reiterate that the available evidence remains extremely incomplete and therefore limits direct, functional comparisons between the systems.

Furthermore, despite an anatomical description of these two systems that emphasizes organizational differences, several anatomical features suggest important commonalities between the noradrenergic and cholinergic systems. This is particularly true with respect to the position of the LC and the cholinergic BF within larger neuronal circuits involving the prefrontal cortex. Both the LC and the BF receive projections from prefrontal regions (Gaykema et al., 1991; Zaborszky et al., 1997; Jodo et al., 1998), and therefore, prefrontal operations can feed back and control the excitability of BF as well as LC neurons. Moreover, despite the morphological differences emphasized earlier, both systems can influence prefrontal as well as practically all other cortical regions. Assuming ACh, at least under certain conditions or in certain regions, is volume transmitted, both the noradrenergic and the cholinergic systems may support synaptic, rapidly changing (or phasic) as well as slower, extrasynaptic (or tonic) components of neurotransmission. In other words, both neuromodulator systems may support global mechanisms that can be described in terms of changes in arousal or readiness for input processing, as well as modulating highly defined, target area–specific cognitive operations. As will be discussed further, such dual modes of neurotransmission have emerged as a common theme in research on both the noradrenergic as well as the cholinergic system.

The possibility that commonalities in the basic operations of the two systems render any contrasts in their anatomical organization to be of secondary

importance is further supported by evidence demonstrating, anatomically and functionally, the significance of noradrenergic contacts with basal forebrain neurons (Chang, 1989; Zaborszky et al., 1993; Smiley and Mesulam, 1999; Smiley et al., 1999; Espana and Berridge, 2006). Noradrenergic neurons recruit the cholinergic cell bodies in this region primarily via α_1-receptors (Fort et al., 1995). We previously demonstrated that this LC–BF link is largely responsible for the modulation of cortical evoked potentials in response to activation of the noradrenergic system (Berntson et al., 2003; Knox et al., 2004). Thus, the available evidence, while remaining limited, strongly supports the general view that the effects of increases in activity in the ascending noradrenergic system on cortical information processing are mediated via stimulation of basal forebrain cholinergic neurons (see also Berridge, 2006).

3.16.3 Effects of Noradrenaline and Acetylcholine on Cortical Neuronal Excitability

NA and ACh are referred to as neuromodulators, meaning rather than directly producing direct excitatory or inhibitory effects on postsynaptic neurons, NA and ACh modulate the effects produced by other neurotransmitters like glutamate and gamma-aminobutyric acid (GABA). Numerous experiments determine the effects of local administration of NA or ACh on the excitability of cortical neurons. Based on these studies, the functions of both systems have often been described in terms of 'increasing signal-to-noise ratio,' with spontaneous activity being typically considered as 'noise' (Murphy and Sillito, 1991). Although some studies supported that, similar to ACh, NA enhances the responses of cortical neurons to sensory stimuli, there is also substantial evidence that, particularly as the activity of the LC or local cortical concentration of NA increases, NA suppresses such responses, (Foote and Aston-Jones, 1995; Edeline, 2003; Hurley et al., 2004).

3.16.3.1 Noradrenaline

The effects of cortically locally administered NA or stimulation of the LC on cortical neuronal activity can be summarized as follows:

1. Increases in noradrenergic activity enhance the response of cortical neurons to sensory stimuli (e.g., Waterhouse and Woodward, 1980; Waterhouse et al., 1990, 1998).
2. Further increases in the levels of LC stimulation suppress the sensory responsiveness of cortical target neurons in accordance with either a monotonic or bell-shaped function (Devilbiss and Waterhouse, 2004).
3. Paired noradrenergic and sensory stimulation preferentially attenuated the response to the sensory stimulus, indicating that brief increases in NA can modify the tuning curves of cortical neurons (Manunta and Edeline, 2004). These modifications in the tuning curves typically oppose those seen with ACh.

3.16.3.2 Acetylcholine

The evidence on the effects of local cortical administration of ACh or basal forebrain stimulation on cortical neuronal activity and cortical information processing is extensive and can be summarized as follows:

1. ACh suppresses intracortical or associational processing while amplifying thalamic input and enhancing intralaminar processing (e.g., Sato et al., 1987; Hasselmo and Bower, 1992; Xiang et al., 1998; Kimura et al., 1999; Oldford and Castro-Alamancos, 2003; Roberts et al., 2005).
2. ACh promotes synchronization of responses to sensory inputs (e.g., Rodriguez et al., 2004).
3. Paired cholinergic and sensory stimulation enhances the response to the sensory stimulus. Furthermore, the cortical area representing the stimulus is enlarged as a result of such pairings (e.g., Rasmusson and Dykes, 1988; Delacour et al., 1990; Metherate and Weinberger, 1990; Tremblay et al., 1990; Webster et al., 1991; Hars et al., 1993; Kilgard and Merzenich, 1998; Mercado et al., 2001; Kilgard et al., 2002; Penschuck et al., 2002; Weinberger, 2003; Ma and Suga, 2005). ACh appears to promote such neuroplasticity via cortical muscarinic M1 receptors (Zhang et al., 2006). However, cholinergic stimulation may not be necessary for such neuroplasticity to occur, as plasticity in the adult primary auditory cortex has been seen after removal of cholinergic inputs (Kamke et al., 2005). Thus, rather than acting as a gate on cortical plasticity, in this context the cholinergic system seems to act more as a gain control mechanism.

4. ACh preferentially suppresses previously potentiated fibers, therefore promoting the formation of new memories (Linster et al., 2003).

5. High levels of ACh suppress the 'signal-to-noise' ratio, suggesting a disruption of information flow under this condition (Zinke et al., 2006).

Although this evidence remains limited, particularly with respect to the effects of different levels of cholinergic stimulation, the two modulators produce overlapping as well as diverging effects on cortical target neurons. Furthermore, there is very little evidence on the effects of coactivation or coadministration of the two modulators, and the evidence described indicates that a prediction of such effects might be very difficult (Ahissar et al., 1996). Moreover, the physiological significance with respect to concentration and patterning of local administration of ACh and NA remains debated. Therefore, experiments that assess the effects of combined stimulation of noradrenergic and cholinergic projections on cortical target neurons (Florin-Lechner et al., 1996; Van Gaalen et al., 1997; Berridge and Abercrombie, 1999; Pudovkina et al., 2001) might generate particularly informative results. However, the interpretation of the results from such experiments is further complicated by evidence suggesting that local cortical mechanisms mutually influence the release of ACh and NA (e.g., Beani et al., 1986; Rao et al., 2003). Clearly, there is a pressing need for studies on the combined modulatory effects of ACh and NA on cortical neuronal responsivity and information processing.

3.16.4 Behavioral and Cognitive Functions Deduced from Neurophysiological Recordings in the Locus Coeruleus and Basal Forebrain

Contemporary theories about the cognitive functions modulated by LC projections to the forebrain are largely based on neurophsyiological recordings in the LC of task-performing animals. In contrast, there is a paucity of such recordings in the cholinergic basal forebrain, due in part to the challenges associated with the identification and recording from cholinergic neurons (Duque et al., 2000; Lee et al., 2004).

Recordings in the BF of primates indicated that neurons in this region encode the conditioned outcome of sensory stimuli (Richardson and DeLong, 1990; Wilson and Rolls, 1990). As will be discussed further in this chapter, such evidence corresponds with the more recent demonstration of transient increases in prefrontal ACh release in response to the detection of cues that predict reward. Therefore, the results from prior neurophysiological studies may be interpreted in terms of indicating that changes in BF neuronal activity reflect the enhanced attentional processing of behaviorally significant stimuli. Indeed, earlier suggestions that the phasic changes in activity in BF neurons reflect brief changes in arousal (Richardson and DeLong, 1990) correspond with the more specific hypothesis that such brief increases in cholinergic activity in prefrontal regions mediate the incorporation of attended signals into ongoing behavior and cognitive activity.

These early studies also suggested that telencephalic projections to the BF serve as a critical source for the convergence of sensory and reward information in the BF. Recently, we expanded this circuit to include prefrontal–nucleus accumbens–BF projections (Neigh et al., 2004; Sarter et al., 2006; see **Figure 3**). The nucleus accumbens is believed to serve as a link between reward information and generating behavior or behavioral change (see Robbins and Everitt, 1996, for a review). Based on the subject's motivation, the nucleus accumbens is capable of activating top-down effects to maintain the attentional performance needed to obtain the relevant reward (Sarter et al., 2006). The nucleus accumbens may thus activate the neuronal circuitry mediating the effects of increased attentional effort.

The general hypothesis that the BF encodes the learning of behaviorally significant stimuli likewise dominated the interpretation of earlier LC recording studies in monkeys and rats performing operant procedures (*See* Chapter 3.15), as the conditioned responses of LC neurons are alterable by changes in stimulus meaning (e.g., Sara et al., 1994; Aston-Jones et al., 1997). Extracellular recordings of LC noradrenergic neurons in primates performing a visual discrimination task revealed these neurons responded selectively to target stimuli (Aston-Jones et al., 1997). Upon reversal of task contingency, these neurons stopped responding to the initial stimulus and began responding to the new target stimulus. This reversal preceded any reversal in the behavioral responses. LC neurons' response to the new target increased in latency, and this increase was mirrored in an increased latency of behavioral responses as well, indicating these neuronal responses reflect stimulus meaning

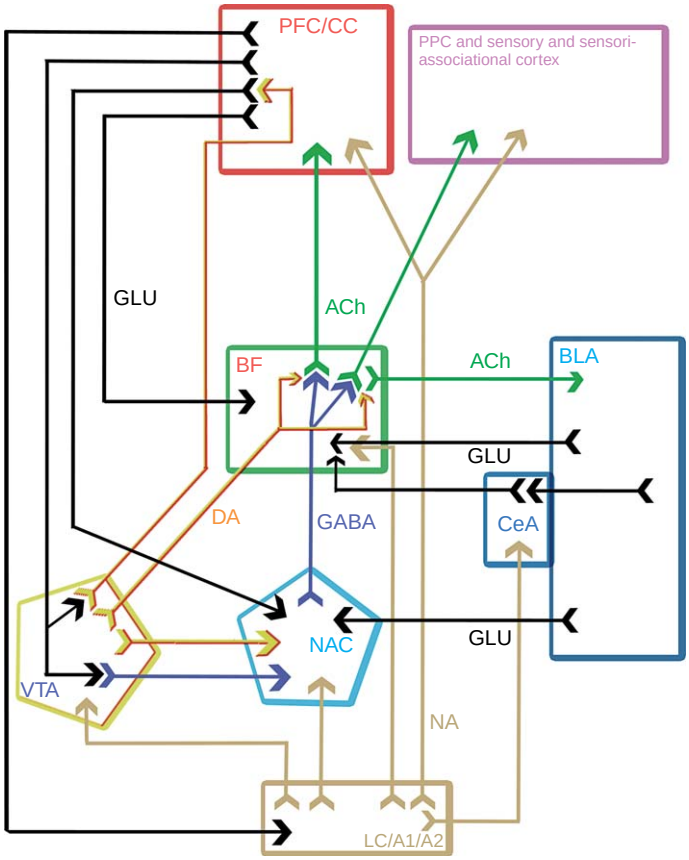

Figure 3 Schematic illustration of the neuronal network regulating the basal forebrain (BF) cholinergic system during attentional performance (Sarter et al., 2006). The figure describes connections and synaptic contacts selected on the basis of anatomical evidence and functional significance. During standard attentional performance, cholinergic neurons projecting to prefrontal and cingulated cortex (PFC/CC) contribute to the activation of the anterior attention system. Projections to sensory and posterior associational regions serve to amplify thalamic inputs while suppressing associational processing and synchronize the attentional operations maintained by prefrontal-posterior parietal cortex (PPC) circuits (e.g., Gill et al., 2000; Broussard et al., 2006). Information indicating performance decline (error detection, including prediction errors, reward loss) is generated on the basis of interactions between prefrontal (PFC) and anterior cingulate (ACC) circuits. Via glutamatergic (GLU) projections to midbrain dopamine (DA) cell groups, particularly the ventral tegmental area (VTA) and the nucleus accumbens (NAC), indicators of performance decline are integrated with incentive information. The VTA, directly and indirectly via projections to the NAC, activates cholinergic projections to the cortex. Activation of cholinergic projections to prefrontal regions under conditions that challenge attentional performance is hypothesized to further activate the anterior attention system and thereby initiate the top-down mechanisms designed to stabilize and perhaps recover attentional performance (Sarter et al., 2006). Based in part on prefrontal projections to the BF, cholinergic activation of the posterior cortex in response to performance challenges contributes to such top-down effects. The combined effects of increased cholinergic activity in the PFC/CC and posterior cortex are to enhance the detection and discrimination of target stimuli and to suppress the effects of distractors, thereby stemming further decline in attentional performance and fostering performance recovery. The attentional effects of changes in activity in ascending noradrenergic (NA) projections originating primarily from the locus coeruleus (LC) and the catecholaminergic cell groups in the medulla (A1/A2) are mediated in part via noradrenergic projections to BF cholinergic neurons (see text). Finally, glutamatergic (GLU) projections from the basolateral (BLA) amygdala, in part via the central amygdaloid nucleus (CeA), regulate the basal forebrain system. This circuit appears to be involved in the recruitment of attentional mechanisms during fear conditioning and, perhaps more generally, in situations involving the processing of salient affective stimuli (e.g., Power et al., 2002; Holland and Gallagher, 2006). Adapted and modified from Figure 3 in Sarter M, Gehring WJ, and Kozak R (2006) More attention must be paid: The neurobiology of attentional effort. *Brain Res. Rev.* 51: 145–160, with permission from Elsevier.

rather than being driven by physical attributes of the stimulus. Subsequent research by Foote and Aston-Jones and their coworkers identified phasic (bursts of LC activity) and tonic (elevation of LC baseline activity, absence of phasic bursts) changes in LC activity and proposed that intermediate levels of tonic LC activity promote selective responding to stimuli and thus practiced task performance. Intense LC activity, in contrast, may promote a shift in vigilance in situations characterized by new events or unexpected outcomes (Aston-Jones et al., 1991; Foote et al., 1991; Usher et al., 1999). Phasic activation of LC neurons was evoked by conditioned stimuli in monkeys performing an attention task, suggesting this phasic activation contributes to the enhanced attentional processing of such stimuli (Aston-Jones et al., 1994). More recent evidence further broadened the role of LC neurons in cognitive performance by demonstrating that they also encode the outcome of responses, thereby maintaining and facilitating performance (Clayton et al., 2004). Importantly, tonic and phasic LC activity do not represent distinct modes but are both part of a continuum: an inverted U-shaped relationship between LC activity and attentional task performance. Performance is poor with either low or high tonic LC activity, reflecting states of either too little or too much arousal, respectively. Attentional task performance is optimal at moderate levels of tonic LC activity, when there are also high levels of phasic LC activation following goal-relevant stimuli (phasic mode; Aston-Jones and Cohen, 2005a). We will come back to this conceptualization in the context of phasic ACh release in the prefrontal cortex below.

The studies by Aston-Jones and colleagues generated a detailed and perhaps unexpectedly sophisticated model of LC function. Within this model, phasic activity takes advantage of known reward sources by facilitating behavioral responses to task outcomes and filtering responses to distractors (Aston-Jones and Cohen, 2005b). Changes in tonic activity facilitate disengagement from task-related processes and exploration of the environment for other reward sources. These functions are implemented via NA's neuromodulatory effects on cortical targets, modifying the responsivity of processing in the cortical circuitry mediating task performance. This model may be interpreted as breaking the traditional boundaries of the role of a neuromodulator by attributing the processing of specific cognition operations to LC activity, or by considering the ability of the LC to modulate forebrain-based cognitive operations in a temporally highly specific, stimulus- and outcome-bound fashion. As little is known about the degree to which the functional specificity of LC activity translates into spatially and temporally constrained NA release in the forebrain, and as the high degree of collateralization predicts a fairly low spatial resolution of changes in noradrenaline release in the forebrain, it remains appropriate to continue discussing LC projections as a rather globally acting attentional modulator system (Aston-Jones and Cohen, 2005b; see also **Figure 3**). However, it is also clear that the stimulus- and outcome-based attentional modulation of forebrain cognitive operations by LC projections renders the more traditional and less defined description of noradrenergic 'arousal' functions no longer particularly useful.

It is unfortunate that corresponding analyses of performance-associated neuronal activity are not available with respect to BF (cholinergic) neuronal activity. However, given the available evidence on NA and the ACh release data to be discussed further, it is not difficult to predict that such research would generate a model describing BF neuronal activity in terms that correspond well with the contemporary conceptualization of LC activity.

3.16.5 Tonic Noradrenaline and Acetylcholine Release in Task-Performing Animals

In the past, the analysis of neuromodulator functions on the basis of the demonstration of changes in synaptic release was restricted largely to studies using microdialysis, a technique that allows monitoring of the neurochemistry of the extracellular space *in vivo*. The relatively low temporal resolution of evidence generated by microdialysis (typically at the order of minutes) indicates that this method mostly monitors tonic changes in release. However, measurements of neurotransmitter release in task-performing animals, including comparisons with release data from control tasks stripped of demands on cognitive, particularly attentional operations, yielded specific hypotheses about the functions of neuromodulators, especially the cortical cholinergic input system (Sarter et al., 2005, 2006).

3.16.5.1 Noradrenaline

The evidence relating telencephalic NA release with defined cognitive operations or, specifically, attentional performance has remained scarce. The majority of experiments demonstrated that cortical NA release increases in response to stressors or novelty (e.g., Dalley et al., 1996; McQuade et al., 1999). The study by Dalley et al. (2001) is of particular interest, as they demonstrated that NA release was not systematically elevated in association with attentional task performance, but robustly increased in response to changes in the stimulus-response contingencies. This supports the hypothesis that the attentional role of the noradrenergic system is a function of response outcome. A similar conclusion was drawn from the results of an experiment that measured noradrenaline release in animals performing a working memory task (Rossetti and Carboni, 2005). Although it will be important to exclude the possibility that these results are not merely reflecting unspecific arousal effects, it is noteworthy that these studies' interpretational focus on the mediation of the effects of response outcome on ongoing task performance corresponds with major aspects of the model by Aston-Jones discussed earlier.

3.16.5.2 Acetylcholine

Contrasting with the microdialysis evidence on NA, the functional significance of ACh release is better understood. While increases in cortical ACh release have been observed in numerous behavioral contexts and in relation to locomotor activity and sensory stimulation, the interpretation of evidence from several of these earlier experiments is confounded by uncontrolled variables, including stress brought by the experimental procedures and novelty (for review see Pepeu and Giovannini, 2004). However, a substantial number of experiments indicated that the performance of a task taxing attentional processes is selectively associated with increases in cortical ACh release. In contrast, during tasks that involved, for example, extremely high rates of operant responses, variable reward rates, and noncontingent stimuli and, generally, assessed basic components of operant performance, cortical ACh did not significantly increase over baseline, or the increases remained quite limited when compared with attentional task-performing animals (e.g., 30–50% increases in rats performing an operant schedule of reinforcement vs. 120–150% increases in attentional task-performing animals; Himmelheber et al., 1997, 2000; Passetti et al., 2000; Dalley et al., 2001; Arnold et al., 2002; McGaughy et al., 2002).

More recent experimental results further defined the variables responsible for performance-associated increases in ACh release, specifically in the prefrontal cortex. Behavioral or pharmacological challenges on attentional performance result in transient performance impairments that, in motivated subjects, subsequently stabilize or recover. However, despite impaired attentional performance relative to standard task levels, augmentation of task-associated increases in prefrontal ACh release was observed (Himmelheber et al., 2001; Kozak et al., 2006a,b). This augmented ACh release above levels seen during standard task performance is hypothesized to reflect increases in attentional effort (Sarter et al., 2006). Attentional effort is defined as cognitive incentive. In motivated individuals, increases in attentional effort are thought to activate top-down mechanisms to counteract performance declines following a challenge to attention. Examples of challenges to attention include distractors, increased time on task, sickness, and sleepiness.

These data support the broader view that the basal forebrain cholinergic projections to prefrontal regions, on account of their afferent connections with prefrontal, mesolimbic, and limbic regions (**Figure 3**), contribute to the activation of the anterior attention system believed to underlie effortful control capabilities in order to combat performance decline. Clearly, this hypothesis combines motivational and attentional mechanisms, as increases in attentional effort are a function of the subjects' motivation to maintain performance under challenging conditions. Therefore, such augmented increases in prefrontal ACh release observed in response to performance challenges are thought to be mediated primarily via prefrontal–mesolimbic circuits converging on BF neurons and recruiting these neurons in response to prediction errors and reward loss (Sarter et al., 2006). It is noteworthy in this context that glutamatergic manipulations in the nucleus accumbens exclusively affect ACh release in the prefrontal cortex (Zmarowski et al., 2005, 2007), confirming the view that reward-related information is selectively influencing cholinergic activity to this region.

Furthermore, evidence suggests that the cholinergic projections to the more posterior cortical regions

are a component of the prefrontal projection system that mediates top-down effects, such as enhanced input processing in order to combat challenge-provoked performance decline (Kozak et al., 2006a,b). These results support the conceptualization of a two-tiered cortical cholinergic input system, consisting of prefrontal inputs that contribute to the activation of the anterior attention system as a function of demands on attentional effort, and cholinergic projections to sensory and posterior associational regions that contribute to the mediation of top-down mechanisms in order to combat further performance decline following performance challenges (Sarter et al., 2006).

Collectively, the evidence from microdialysis studies on the role of NA and ACh release in attentional performance remains underdeveloped, particularly with respect to the demonstration of specific functional correlates of NA release. However, the available microdialysis evidence supports a potential dissociation between the functions of ACh versus NA release suggested by other experimental approaches. Specifically, increases in cholinergic activity are directly related to demands on attentional processing, particularly in response to challenging conditions. In contrast, increases in NA appear to be more directly related to the maintenance of ongoing task performance as a function of response outcome. Such a hypothesis, if corroborated by additional evidence, would yield a useful complementary scenario describing the combined, synergistic and antagonistic roles of ACh and NA in the mediation of attentional performance. Together, the two modulators span the full range of components of attentional performance, from general increases in arousal and readiness for cortical input processing (ACh and NA) to cue detection and regulation of attentional effort (ACh) and optimization of task performance as a function of response outcome (NA).

3.16.6 Phasic and Tonic Prefrontal Cortical Acetylcholine Release Mediates Cue Detection

Given the extensive evidence on the importance of phasic noradrenergic activity for optimal task performance, the development of a similar line of understanding in the cholinergic system is imperative. However, while techniques to monitor phasic activity of noradrenergic neurons have been available for years, analogous methods for the cholinergic system have been developed only recently. The recoding of brief, transient, or phasic changes in ACh release, at a subsecond level of temporal resolution, has become possible on the basis of an amperometric method. This method utilizes enzyme-selective microelectrodes to detect choline generated by hydrolysis of newly released ACh. Details about this technology as well as evidence in support of the fundamental assumption that choline signals recorded with this methods reflect ACh release have been previously reported (Parikh et al., 2004; Parikh and Sarter, 2006).

We recorded cholinergic activity using this method in the prefrontal cortex and, as a control region, in the motor cortex of rats performing a cued appetitive response task (Parikh et al., 2006). A trial consisted of the presentation of a light cue for 1 s that indicated the delivery of food reward 6 ± 2 s later at one out of two food ports (randomly selected). Importantly, the intertrial interval (ITI) was relatively long (90 ± 30 s), allowing the animals to disengage from performance and resume task-independent behavioral activities like grooming. Following the presentation of the cue, animals disengaged from ongoing behavior and oriented to and monitored the food ports. This effect of a cue is termed 'cue detection' (Posner et al., 1980). In 30–40% of trials, this behavior was not elicited by the cue, and therefore the cue was missed. Importantly, in trials involving missed cues, food reward delivery elicited port approach and reward retrieval. As would be expected, the latencies between reward presentation and pickup were longer in trials involving missed cues.

In the prefrontal cortex, transient increases in cholinergic activity were evoked by detected cues but not by missed cues (**Figure 4**). Port approach and reward retrieval did not elicit cholinergic activity. The increases in detected cue-evoked cholinergic activity coincided in time with the cue-evoked disengagement from ongoing behavior and orientation to the ports. Importantly, such disengagement and orientation to the ports was also elicited by food reward delivery in trials involving missed cues, but did not generate phasic increases in cholinergic activity in motor cortex.

Additional evidence supported the conclusions that these transient increases in cholinergic activity in the prefrontal cortex mediate the detection of cues, as opposed to reflecting the sensory properties of a perceived stimulus. First, the interval between the

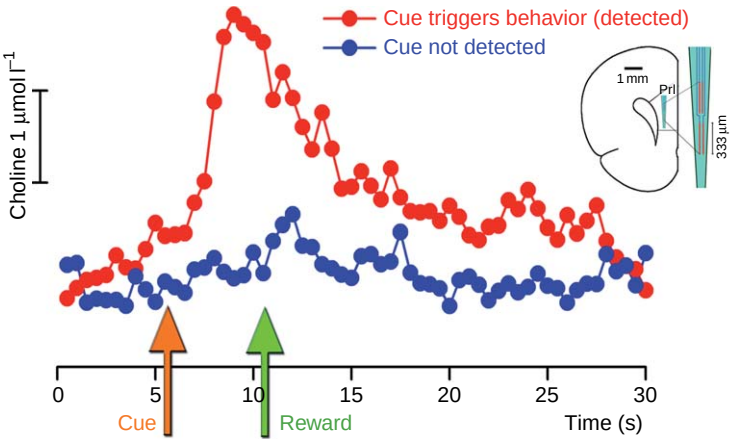

Figure 4 Representative traces depicting changes in cholinergic activity recorded by using enzyme-selective microelectrodes for the amperometric detection of changes in extracellular choline concentrations as a result of hydrolysis of newly released acetylcholine (ACh). The inset on the right depicts the four platinum recording sites on the ceramic-based microelectrode and the approximate placement of the electrode in the prelimbic cortex (Prl). Technical details and evidence in support of the reliability and validity of this method are described elsewhere (Parikh et al., 2004; Parikh and Sarter, 2006). In animals trained to perform a cued appetitive response task (see text for details), cues that triggered disengagement from ongoing behavior and orientation to, and monitoring of, the food ports ('detection') elicited a transient increase in cholinergic activity. Cues that failed to elicit such behavior did not produce such cholinergic spikes. Importantly, when animals missed the cue, food reward delivery still triggered food port approach, reward pickup, and consumption, but this was not associated with a cholinergic spike (see arrow depicting reward presentation). Moreover, a shortening of the interval between the cue and reward delivery resulted in a left shift of the timing of the peak amplitude of the cholinergic signal, indicating that this signal did not merely reflect sensory–perceptual mechanisms but the cognitive operation that were evoked by the cue. Finally, bilateral removal of cholinergic inputs to the prefrontal cortex decreased the cue detection rate, supporting the hypothesis that the phasic increase in cholinergic activity is necessary for cue detection (Parikh et al., 2006).

presentation of the cue and reward presentation was shortened to 2 ± 1 s, requiring the detection process to be moved closer to the actual presentation of the cue. This manipulation resulted in a significant left shift of the timing of the peak amplitude of the choline signal. The demonstration of this left shift indicates that the choline signal reflects a cognitive operation rather than the sensory processing of the cue. Second, the onset of the behavioral response to the cue correlated highly with the timing of a 25% increase in choline signal level. Third, bilateral removal of cholinergic projections to the medial prefrontal cortex resulted in a significant increase in the number of missed cues.

The detected cue-evoked spikes in cholinergic activity were superimposed over more slowly changing tonic cholinergic activity. We extracted data on tonic changes by expressing session-related changes relative to a presession baseline and boxcar-averaging data points in order to match the 8-min data point generated by microdialysis experiments conducted in parallel. This analysis roughly reproduced the release data measured by microdialysis and indicated increases in tonic levels beginning with the first trial and lasting throughout the session. Importantly, and in contrast to cue-evoked phasic cholinergic activity, session-related, tonic changes were also observed in motor cortex. This suggests tonic changes in ACh levels may be a cortex-wide phenomenon, reflecting a general increase in cortical input processing readiness and arousal. No such tonic changes in cholinergic activity were observed in trained animals placed into the test chamber but not allowed to perform, indicating that task performance is needed to elicit changes in tonic ACh release.

The origin and regulation of the two modes of cholinergic activity (phasic, tonic) in task-performing animals remain unknown. Nevertheless, one may speculate that the session-related tonic changes in cholinergic activity are influenced primarily by ascending noradrenergic projections (e.g., Berntson et al., 2003), while the cue-evoked phasic increases may be regulated by local prefrontal as well as direct and multisynaptic prefrontal projections to the BF (**Figure 4**).

3.16.7 Necessity of Noradrenergic and Cholinergic Neurotransmission for Attention: Implications for the Definition of a Neuromodulator

As already stressed, there are significant overlaps as well as differences in the characteristics of cognitive performance-associated alterations in noradrenergic and cholinergic activity. Adding to the available evidence, the results of experiments assessing the effects of cholinergic or noradrenergic lesions on performance indicate further important differences in terms of the necessity of these neuromodulator systems for attentional performance.

Neuromodulators are typically described as 'modulating' the cognitive operations conducted within the circuitry of the forebrain. Based on this definition one would not necessarily expect the removal of a modulator system to fundamentally disrupt cognitive operations. Rather, following lesions of a modulator system such operations would be expected to consume more time and be defective and insensitive to variations in task contingencies.

However, removal of the cortical cholinergic input system has been extensively demonstrated to result in persistent and elemental disruption of a wide range of attentional processes and capacities (Voytko et al., 1994; Chiba et al., 1995, 1999; McGaughy et al., 1996, 2000; Turchi and Sarter, 1997, 2000; McGaughy and Sarter, 1998; Burk and Sarter, 2001; Burk et al., 2002; Berntson et al., 2003; Dalley et al., 2004; Martinez and Sarter, 2004). For example, selective immunotoxic cholinergic lesions via 192 immunoglobulin G (IgG)-saporin showed that lesions disrupt the ability to modulate attention within an associative learning framework, leading to a disruption of increments in conditioned stimulus processing (Chiba et al., 1995). Saporin lesions also resulted in impairments in sustained attention performance (McGaughy et al., 1996) and an increase in response latencies as part of a speed–accuracy tradeoff in a divided-attention task (Turchi and Sarter, 1997).

Collectively, the results from these experiments strongly suggest that the modulatory effects of ACh mediate essential aspects of attentional performance, such as cue detection (see earlier discussion). Furthermore, these results suggest that the modulatory effects of ACh are necessary for certain cognitive operations to be initiated. Such a conclusion begins to blur the traditional dissociation between the effects of a neuromodulator system and a neuronal system processing discrete pieces of information and inserting this information into target circuits.

Additionally, the disruption of attentional performance resulting from cholinergic lesions was demonstrated to last for months. In our studies, as well as in the literature, there is very little evidence for a recovery of attentional performance following such lesions, even if animals' daily training is continued for up to about a year. Such a complete absence of functional compensation following cholinergic lesions contrasts with the general view that there is a degree of functional redundancy across the multiple neuromodulator systems. From this viewpoint, the overlapping effects of ACh and NA on cortical neuronal activity and responsivity support the idea that removal of one system would result in only mild, transient impairments, as the complementary functions of intact neuromodulator systems would limit the degree and duration of the functional consequences of such lesions. However, as the attentional impairments resulting from removal of the cholinergic input system to the cortex are profound and do not recover, one can conclude that, in the absence of the cholinergic system, noradrenergic and other modulatory projection systems are not capable of exerting compensatory effects.

The evidence on the necessity of noradrenergic projections for cognitive and specifically attentional performance is more scarce and ambiguous (Sara, 1985; Koger and Mair, 1992). Standard attentional performance generally is unaffected by extensive noradrenergic lesions (Carli et al., 1983; McGaughy et al., 1997). However, lesioned rats fail to respond normally to the alerting effects of stressors (Carli et al., 1983). Assuming such stressor effects normally activate the LC and therefore interfere with standard task performance, these effects correspond with a model that focuses on the ability of the LC to monitor sympathetic reactivity changes, via afferents from the paragigantocellular nucleus, and that suggests such sympathetic reactivity changes serve to 'import' information about stressors, novelty, and other salient events that are capable of modulating sympathetic activity into the noradrenergic ascending projection system (Aston-Jones et al., 1996). This scenario is of particular relevance for hypotheses linking psychopathological increases in emotional reactivity to attentional biasing and the subsequent development of affective disorders (Berntson et al., 1998).

Given the significance of noradrenergic–cholinergic interactions based on noradrenergic inputs to the

BF, the limited collateralization of the cholinergic system, and the open questions about the degree to which ACh acts extrasynaptically, the greater necessity of cholinergic compared to noradrenergic projections to the cortex for attentional performance may be conceptualized. Furthermore, considering the cholinergic system is the most evolutionarily recent and most dorsal addition to the modulator systems (Brockhaus, 1942; Gorry, 1963), the predominantly telencephalic origin of BF afferents, and the generally more discrete and topographic organization of cholinergic efferents (Zaborszky, 2002), it is possible to attribute more selective functions to this system and to describe the cholinergic system in part as a dorsal branch of the noradrenergic system. As such, the critical attentional functions mediated via the cholinergic system are subject to the gain-setting functions of noradrenergic projections (Aston-Jones and Cohen, 2005a,b). This scenario would explain the results reported by Carli et al. (1983) and corresponds with the collective evidence on the differential effects of lesions of the cholinergic and noradrenergic systems.

3.16.8 Future Research: Corecruitment and Comodulation

Noradrenergic projections modulate the cholinergic BF and, perhaps independently, the release of ACh in the cortex based on local regulation of synaptic mechanisms (Beani et al., 1986; Zaborszky et al., 1993; Fort et al., 1995; Berntson et al., 2003; Tzavara et al., 2006). Little is known about the converse, but it is highly likely local cortical NA release is influenced by cholinergic mechanisms (El-Etri et al., 1999). Therefore, the determination of the attentional functions of the cholinergic and noradrenergic ascending systems necessitates further research addressing and probing interactions between these systems in performing subjects. This chapter attempted to draw conclusions concerning the common properties of the effects of the two modulators as well as important dissociations between the regulation, activity, and function of cholinergic and noradrenergic projections to the forebrain. It cannot be excluded that, to a considerable degree, these conclusions represent an artifact that results from the isolated investigation of the individual neuromodulator systems. Measures and manipulations of corelease of ACh and NA as well as interactions between the two systems in the BF and cortex may well reveal the full range of the modulatory potency of these two systems. The current evidence suggests that the combined functions of ACh and NA are likely more complex than the relatively straightforward hypotheses available (e.g., as described in Figure 3 in Aston-Jones and Cohen, 2005b). Cholinergic and noradrenergic interactions may be characterized by antagonistic as well as synergistic relationships, depending on the levels of activity in these systems (Yu and Dayan, 2005). Obviously, this perspective readily extends to interactions with other ascending neuromodulator systems, particularly the mesolimbic dopamine system and serotonergic projections arising from the raphe nucleus (Doya, 2002).

Finally, neuronal systems modulating attentional functions are also, by conceptual necessity, involved in learning (see also Ridley et al., 1999; Power et al., 2002; McGaughy et al., 2005). Given the rather intricate and relatively limited evidence on the role of these systems in learning and memory, it will be important that future studies define and vary the attentional demands associated with the learning about stimuli. Such research would be expected to reveal that the learning of new contingencies necessitates noradrenergic–cholinergic comodulation as a function of the demand for attentional processing of relevant stimuli.

3.17 Procedural Learning in Humans

B. J. Knowlton and T. D. Moody, University of California at Los Angeles, Los Angeles, CA, USA

When one thinks of learning and memory in daily life, it is likely that one considers learning facts about the world and remembering events in the past as being important. However, our ability to function depends on knowing how to do things. From activities as mundane as walking and picking up a pencil, to more complex skills such as typing, playing the piano, or making basketball jump shots, perceptuomotor skills are procedures that we have learned over the course of experience. In addition to knowing how to perform motor skills, people also learn procedures for performing cognitive skills, such as the ability to discriminate your baby's cry from that of another, recognize the style of an artist, or become a chess master. In this chapter we focus on procedural learning and how it differs from learning about facts and events in terms of its behavioral characteristics and neural substrates. Because procedures are ubiquitous in daily life, disruptions in the ability to learn or retrieve procedures can have serious functional consequences.

3.17.1 Defining Procedural Knowledge

Procedural knowledge is generally defined as 'knowing how': It is one's knowledge of procedures that have been learned through experience (Newell and Simon, 1972; Anderson, 1976). Procedural memory is usually contrasted with declarative memory. Declarative memory is 'knowing that,' and is used to

describe memory for facts and events (Cohen and Squire, 1980; Squire, 1986). Declarative memory is distinguished by the ability to verbalize this knowledge. We are able to put our declarative memories into words, hence, we can declare them. We can recount to others happenings in the past or bits of information we have learned. In contrast, procedural memory is not easy to verbalize. It is difficult for someone to explain how to perform a motor skill, like riding a bicycle. Although we have learned the grammatical rules of our native language well enough to easily produce proper sentences, it is an effortful task to describe these grammatical rules. The difficulty in verbalizing procedural knowledge is one of its key features.

According to Anderson (1993, 1995), the difference in the verbalizability of declarative and procedural knowledge arises from differences in the accessibility of these types of knowledge to introspection and conscious awareness. These two types of knowledge are represented in fundamentally different ways. Declarative knowledge is represented as a network of interconnected bits of information, whereas procedural knowledge is represented as a set of condition–action links. This difference in mental representation between the two types of knowledge is derived from earlier concepts in artificial intelligence in which declarative computer languages specify relationships, whereas procedural languages specify steps to be carried out to achieve a goal (e.g., Minsky, 1975). The fact that the distinction between declarative and procedural learning can be made at the computational level is the basis for formal models of cognition such as ACT-R, which explicitly acknowledges the representational differences between the two types of learning (Anderson and Lebiere, 1998; Anderson et al., 2004).

3.17.2 What Are Procedures?

If we use the definition of procedural as 'knowing how,' it would seem to encompass an extremely wide range of knowledge. The knowledge underlying motor and perceptual skills would seem to be clearly procedural, especially after extensive practice (Newell and Rosenbloom, 1981; Anderson, 1983). Knowing how to use a manual transmission or produce your signature are skills that were learned through practice, and it is relatively difficult to verbally describe the knowledge that allows performance of the skill. However, when the right conditions are present (such as sitting in a car in the case of using a manual transmission), the skill can be executed.

Another kind of learning "'how'" is learning rules (Simon, 1975; Anderson, 1993). For example, to learn how to play checkers, one must learn a set of rules. In this example, the basic rules of checkers are simple and verbalizable. However, there are certainly more complex rules, or algorithms, that have been learned by expert checker players that may not be easy to verbalize, but that nevertheless have been learned through experience, are elicited during play, and lead to superior performance. Algorithms can also be learned to solve puzzles, like a Rubik's cube. Here, the algorithm is complex and difficult to state, even by people who are adept at solving the puzzle. Thus, learning rules, especially complex ones, can be an example of procedural learning. However, simple rules can certainly be learned declaratively (e.g., I know that white makes the first move in chess), underscoring the fact that many real-world activities combine procedural and declarative knowledge.

In addition to learning skills and rules, a third category of procedural learning is habit learning (Packard and Knowlton, 2002). Habit learning refers to the gradual acquisition of stimulus–response associations. This view of learning was promoted by Hull (1943), who suggested that all learning could be reduced to stimulus–response associations. Although subsequent work has shown that this is not the case, habit learning is nevertheless pervasive. An everyday example may be driving a well-traveled route to work. Each intersection along the route (or stimulus) comes to elicit a specific turn (or response). Habits are characterized by an independence from the goal state (Yin and Knowlton, 2006). This can be seen in the case where you find that you have made your usual left turn taking you to work when it is a Saturday and you were intending to go somewhere else. When confronted with the intersection stimulus, the response habit controlled behavior. In habit learning, the reinforcer, or goal, is not represented in the association with memory but, rather, plays a role in strengthening the association between the stimulus and response during learning.

Habit learning is less clearly a case of learning how than is skill or rule learning. However, habits are procedures in the sense of being actions elicited by conditions. Thus, the stimulus–response habit representation in memory is similar to the condition–action pair that is theorized to underlay procedural knowledge. Also, like other forms of procedural

knowledge, habits are not necessarily available to awareness (Bayley et al., 2005). You might get into the habit of flipping on a light switch when you first step into your apartment, and it may be the case that you are not aware of this habit until it is pointed out to you while you are performing it.

3.17.3 Motor versus Cognitive Procedures

Procedural learning includes both motor and nonmotor learning. By considering procedural learning to cover both motor and nonmotor domains, it suggests that there are fundamental similarities between them (see Rosenbaum et al., 2001). However, there are also important differences. For example, motor movements are first planned based on the geometry of the environment and then executed, with these processes depending on distinct brain regions (Willingham, 1998). Motor skills are also tied to specific effectors; for example, it is generally not possible to switch left and right hands when playing a well-learned piano piece. Control of motor movements also depends on feedback from the visual and proprioceptive systems. In nonmotor procedures, the planning and execution phases are not so clearly separable, and the mode of expression is more general – a master of go could presumably play equally well with either hand. Also, smooth performance of a cognitive procedure would not necessarily require the integration of feedback in real time. For motor procedures, learning may take place in the planning, execution, or integration of feedback in motor behavior. The brain structures responsible for procedural learning of motor behaviors may differ from those responsible for learning nonmotor procedures. Yet there may nonetheless be common ground in the nervous system. Motor behaviors begin as rather abstract action plans before they are translated into muscle movements. These initial action plans may have much in common with purely cognitive procedures like the learned algorithms invoked in solving puzzles or playing games, in that they may both be reduced to a series of condition–action links. Furthermore, both types of skills have the characteristics of procedural knowledge in that they are not readily transferred to new situations (Healy and Bourne, 1995). For example, learning to program a computer does not appear to facilitate logical reasoning in everyday life (Pea and Kurland, 1984).

3.17.4 What Are the Characteristics of Procedural Learning?

An important focus of behavioral research on procedural learning is to develop a list of the properties that distinguish it from other types of learning. In this chapter, we are using the 'knowing how' definition of procedural knowledge, which leads us to the question of how 'learning how' differs from 'learning that'. One characteristic described earlier is the lack of verbalizability of procedural knowledge. Learning must be measured through improved performance on the procedure; people can't really tell us what they have learned. Another characteristic discussed earlier is that procedural memories appear to be stored as condition–action pairs, or stimulus–response associations. This is clearly the case for habits, and even for complex skills it may be possible to break them down into a series of condition–action pairs.

An intriguing property of procedural learning is that learning is not necessarily accessible to awareness. This is linked to the lack of verbalizability of procedural knowledge, in that it is impossible to verbalize knowledge that you are unaware that you possess. The idea of inaccessibility to awareness is more general, though, in that it suggests that the difficulty is not simply in finding the right words to describe procedural knowledge but, rather, in the availability of this knowledge to other cognitive processes. According to this property, we are able to show improvement in performance on procedural tasks without being aware of getting better. As we discuss later, this dissociation between procedural learning and awareness is most striking in the case of amnesic patients, who can show normal procedural learning in the face of a lack of declarative memory for the training sessions that led to procedural learning. In the study of human learning, this distinction between aware and unaware, or explicit and implicit learning, has been useful in making predictions about new tasks in terms of the performance of amnesic patients and the brain systems that support learning. One conceptual drawback of this property, as well as the property of verbalizability, is that it is difficult to apply these criteria to tasks used in nonhuman animals. This has led to something of a separation between memory models derived from human studies and those derived from animal studies.

One property that may be applied to studies of procedural learning in both humans and animals is the lack of flexibility of the knowledge acquired. Unlike declarative knowledge, which can be used in

many ways, procedural knowledge often can only be used in the context of initial learning. For example, having learned a fact such as "The capital of France is Paris" will allow you to readily answer a question posed different ways, such as "What country is Paris the capital of?" or "Name some European capitals," or "Where would you be most likely to find the French president?" We can use declarative knowledge in different contexts – you may meet your friend's mother at her wedding and then have no trouble recognizing her in a store the following week. We can recombine bits of declarative knowledge to make inferences – you may infer that one of your coworkers is a vegetarian if you remember that each time you see him in the cafeteria he is eating a salad. In contrast, procedural knowledge is not flexible and is not readily applied to contexts outside the one in which learning took place. Even an expert driver often stalls initially when using a manual transmission in a different car. Often, it seems our procedural knowledge is encapsulated in the learning context. It is also often difficult to execute just part of a procedure; for example, it is often hard to start a golf swing or a tennis stroke in the middle. Thus, access to procedures can be limited to the manner in which they were learned.

The property of access flexibility is useful because it can be applied to studies using both human and nonhuman animal subjects. It may be the case that lack of flexible access is an overarching property of procedural knowledge. In humans, declarative knowledge can be accessed by cognitive processes that allow it to enter conscious awareness and allow it to be verbalized. In animals who do not possess the ability to verbalize or may not have conscious awareness, their declarative knowledge would still be accessible to the cognitive processes that are present, allowing the animal to use that knowledge in new situations.

Although the properties listed earlier describe the characteristics of procedural knowledge, the process of acquiring procedural knowledge, that is, procedural learning, appears to differ fundamentally from declarative learning. Although declarative learning can occur in an instant, procedural learning is gradual. When we think of a someone who possesses a high level of skill, whether it is in playing a musical instrument or solving chess puzzles, we marvel in the hours of practice that must have gone into achieving that level of skill. Habits are also learned gradually over time. When we talk about getting into a habit, it is understood that this occurred over a period of time. In contrast, we can have declarative memories for events that last a lifetime; by their very nature, these events occurred only once. Although memory for facts may benefit from repetition, it is certainly possible to remember a particularly interesting fact after hearing it once.

Although procedural learning may be slower than declarative learning, it does appear to require fewer attentional resources. Encoding declarative memories is clearly impaired by distraction. For example, you may not do well on an exam if you studied while chatting on the phone. However, learning skills and habits does not seem to depend on paying attention. So, it may be perfectly fine to practice your knitting while watching television. It appears that procedural learning can proceed without tying up working memory, unlike declarative learning, which does benefit from working memory. As working memory is of limited capacity, other tasks that require working memory will interfere with declarative, but not procedural, learning. Because declarative learning benefits from attention, it is sensitive to whether there is an intention to learn. When we intend to learn, we are able to divert attentional resources to the task. Procedural learning may not benefit as much from this intention to learn. This is most clearly seen in habit learning. We may not intend to develop a habit, but with repeated strengthening of a stimulus–response bond, the habit is acquired automatically.

The behavioral criteria for procedural learning are admittedly somewhat vague, and as we discuss later in the chapter, some of the criteria fit better with some tasks that supposedly measure procedural learning than with others. However, the behavioral differences between declarative and procedural learning suggest that the locus and nature of the neural change supporting learning differ as well.

3.17.5 Interactions between Procedural and Declarative Memory

The differences between procedural and declarative memory may lead one to think of them as independent, meaning that impaired or facilitated performance in one system would not influence the other. However, it is unlikely that different forms of memory are completely independent, given the level of interconnectedness of structures within the brain. According to one view, learning of procedures necessarily begins with learning some declarative knowledge. For example, when learning to drive a manual transmission, you must first learn which

pedal is the gas and where the clutch is located. This initial knowledge is then followed by the gradual acquisition of how to perform the skill. In this view, one would predict that a deficit in declarative memory would retard procedural learning, which generally does not seem to be the case. However, in many skills in the real world, declarative and procedural knowledge both make contributions, and in these cases, it may be that some declarative knowledge is needed to provide a foundation for procedural learning.

Although in some cases declarative knowledge can facilitate procedural learning, it is possible to imagine situations when they may compete with each other. For example, the persistence of an old habit may interfere with new declarative knowledge. One may end up following an old route by force of habit, even when you intend to go somewhere else. On the other hand, declarative knowledge may interfere with procedural knowledge. Athletes are familiar with the phenomenon of choking; performance of a skill fails when you think about what you are doing too much (Baumeister, 1984).

The fact that declarative and procedural knowledge may interfere with each other raises the question of where this interference occurs. According to one view, this competition occurs during learning, such that impairing the functioning of one system facilitates learning in the other system. In studies with human subjects, there is little direct support for this view. It seems more likely that competition is occurring at the level of response output. Thus, people may be able to simultaneously learn declarative and procedural knowledge that can be used to support task performance, with declarative knowledge supporting behavior under some circumstances and procedural knowledge supporting behavior under others. For example, driving may sometimes be based on procedural memory, as in when you are driving a familiar route. However, one could also be using declarative memory, as in when you are in an unfamiliar spot and you are recalling a set of directions to get to your destination. What factors influence which system is used to support behavior? It seems likely that the strength of knowledge is an important determinant. If you have not had the opportunity to develop relevant procedural knowledge, your performance is likely to be based on declarative knowledge, while after extensive practice, procedural knowledge may be stronger. Another factor may be the presence of distraction. As procedural memory appears to be less sensitive to distraction (Foerde et al., 2006), it may be more likely to support performance when someone is engaged in multiple tasks. Other factors, such as the presence of stress or emotional state, may also influence whether declarative or procedural knowledge is dominant. Understanding these factors is currently a key question in studies of optimizing human performance.

3.17.6 Procedural Learning and Brain Systems

The idea that there are different types of learning is the basis of the view that memory is composed of distinct systems that map onto different systems in the brain. In this view, procedural and declarative memory are accomplished using different brain regions. An important aspect of the memory systems view is that there are multiple memory systems, not just a dichotomy between procedural and declarative memory. This fits with the finding that many brain regions exhibit plasticity. Some forms of memory do not satisfy the criteria of declarative memory, in that people are not necessarily aware of what has been learned, but they also do not appear to satisfy the criteria of procedural learning, in that learning may occur rapidly.

A good example is the phenomenon of perceptual priming (Schacter et al., 1993). When people are preexposed to a stimulus, such as a word or picture, they are able to process it a little faster and more accurately than if it were novel. This form of learning occurs after a single exposure. Thus, priming may be a form of nondeclarative memory that is also not procedural. As such, it may depend on a different brain system than those that support declarative and procedural memory. A great deal of evidence has shown that declarative memory depends on structures in the medial temporal lobe. As detailed in other chapters, this includes the hippocampus and associated cortical regions in the parahippocampal gyrus. When these structures are damaged, declarative learning is impaired, but procedural learning is not. Thus, procedural learning appears to depend on other brain structures. As we discuss in the following sections of the chapter, converging evidence points to the basal ganglia as being an important system in at least some forms of procedural learning.

3.17.7 Neuropsychological Studies of Procedural Learning

A rich history of habit learning in animal research has suggested the importance of the basal ganglia in

procedural learning. Neuropsychological studies in patients with basal ganglia damage have provided evidence that procedural learning is impaired in these patients and have helped to establish which brain regions within the basal ganglia are crucial for procedural learning. Studies employing the brain imaging techniques of positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and repetitive transcranial magnetic stimulation (rTMS) are identifying the neural substrates of procedural learning. Using a working definition that procedural learning is learning how to do something, one could identify scores of motor skills that could lend themselves to procedural learning studies; we will focus on only a few of the widely used paradigms.

3.17.7.1 The Pursuit Rotor Task

The pursuit rotor task has been extensively studied in motor learning. In the task, subjects attempt to maintain contact between a handheld stylus and a small (2 cm) metal disk that is mounted near the edge of a rotating turntable. The rotation speed can be adjusted to increase the difficulty of the task, and motor learning is assessed as an increase in time on target across training trials. Normally, subjects make jerky corrections early in training and then gradually increase their time on target and maintain smooth tracking of the metal disk with the tip of the target.

Neuropsychological studies employing the pursuit rotor task in patients groups provided evidence that basal ganglia, in addition to the motor cortex and supplementary motor areas, are important in performance. Patients with Huntington's disease and Parkinson's disease are impaired on the pursuit rotor task (Heindel et al., 1988; Heindel et al., 1989; Harrington et al., 1990).

The pursuit rotor task has been used to quantify motor impairments, but the fact that motor areas and basal ganglia were involved in the learning and performance of motor tasks was not surprising. Other investigators developed tasks to get at the nonmotor aspects of procedural learning – those behaviors that depend on learning new associations.

3.17.7.2 Sequence Learning in the Serial Reaction Time Task

Probably the most widely used experimental paradigm to study motor sequence learning is the serial reaction time (SRT) task (Knopman and Nissen, 1987; Nissen and Bullemer, 1987) (see **Figure 1**). In the SRT, subjects are presented with visual stimuli in one of four screen locations. Subjects are asked to respond as quickly as possible by pressing one of four buttons corresponding to the location of the stimulus. There are two types of testing blocks, sequenced and pseudorandom. During the sequenced blocks, the location of the stimulus follows a specific sequence (usually 8 to 12 items long); however, the subjects are

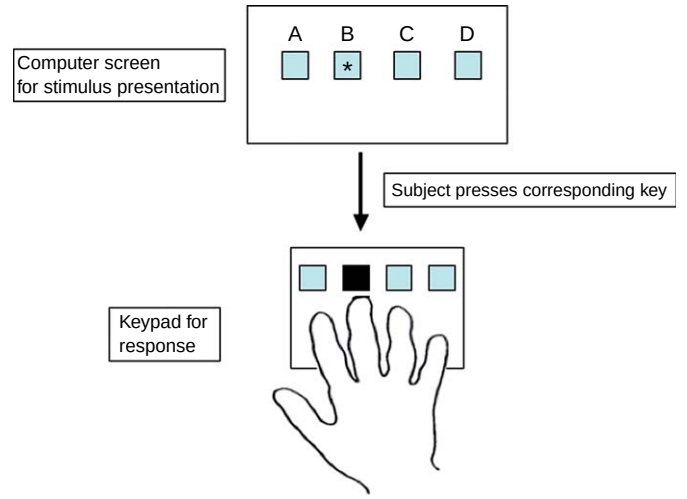

Figure 1 A schematic of the typical procedure of the Serial Reaction Time task, along with a sample sequence.

not informed that the stimulus locations follow a pattern. During the pseudorandom blocks, the stimuli appear in random locations with the stipulation that the stimulus is never shown in the same location on consecutive trials. Learning in the SRT is typically expressed as a reduction in reaction time during the sequenced blocks of trials as compared to the pseudorandom blocks of trials. Probe tests to measure the extent of declarative knowledge of the sequence are often performed, such as asking subjects to explicitly recall the sequence to contrast declarative and procedural learning in the task.

The question of what is learned in the SRT task is important for understanding the capabilities of procedural learning. It is possible that subjects could simply be learning that certain locations come up more frequently, and thus they elicit a quicker response. If so, this would be an example of nonassociative learning. However, most recent studies use sequences in which the occurrence of locations and transitions between locations is equivalent for the random and pseudorandom blocks.

The SRT task fits the criterion of procedural learning, in that at least a substantial subgroup of participants remain unaware of the underlying sequence, yet still show learning of it through their performance on the task (Willingham et al., 1989). A key issue has been what are the most appropriate measures of awareness of the sequence in this task (Shanks et al., 1994). It is possible that using difficult measures like the ability of subjects to generate the sequence or recognize it out of context may underestimate the amount of declarative knowledge that a subject has about the sequence. Data from amnesic patients helps answer the question of whether learning in the SRT could be accomplished without declarative knowledge. As discussed elsewhere in this volume, amnesic patients exhibit severe deficits in declarative memory because of damage to the medial temporal lobe and associated structures. Thus, the fact that amnesic patients show normal performance on the SRT task provides evidence that the task can be done independently of the declarative memory system. (Nissen and Bullemer, 1987; Nissen et al., 1989; Reber and Squire, 1994; Vandenberghe et al., 2006). The concept that sequence learning can be performed independently of the declarative memory system is also supported by other studies in patients with Alzheimer's disease. These patients have severe declarative memory deficits, but are nevertheless able to demonstrate learning in the SRT (Knopman, 1991).

Other behavioral studies using the SRT in patients with Parkinson's disease and Huntington's disease have implicated the basal ganglia as a substrate for sequence learning (Knopman and Nissen, 1991; Ferraro et al., 1993; Pascual-Leone et al. 1993; Willingham and Koroshetz, 1993; Jackson et al., 1995; Doyon et al., 1997, 1998). Even when task demands were modified to minimize the impact of patient motor deficits, by using a verbal version of the task, these patient groups show deficits (Westwater et al., 1998; Smith and McDowall, 2006a). Patients with lesions of the cerebellum show even more striking impairments on the SRT (Doyon et al., 1997, 1998; Molinari et al., 1997; Shin and Ivry, 2003). Thus, sequence learning appears to depend on contributions from two subcortical systems, the basal ganglia and the cerebellum.

3.17.7.3 Probabilistic Classification Learning in the Weather Prediction Task

Probabilistic classification tasks have been used extensively to study nonmotor procedural learning (Knowlton et al., 1994, 1996). A commonly used version of probabilistic classification is presented as a weather prediction game (see **Figure 2**). Subjects are asked to predict the weather, either sunshine or rain, by viewing sets of cue cards with geometric shapes on them. On each trial, after choosing one of the two outcomes, subjects receive feedback about whether their choice was correct or incorrect. The key to the task is that the cue-outcome relationships are probabilistic rather than deterministic. Due to the probabilistic structure of the cue-outcome relationships, memory for individual trials is not particularly useful, and subjects must acquire associations across many trials. Subjects are told to use a gut feeling to make their choices, and most participants report that they do not feel that they are learning early in training.

Studies using the weather task in patient groups have found interesting dissociations. Amnesic patients were found to perform as well as controls (Knowlton et al., 1994), suggesting that the task can be performed without an intact hippocampus. Evidence that the basal ganglia is involved in this type of learning came with other studies in patients with Parkinson's disease and Huntington's disease (Knowlton et al., 1996; Shohamy et al., 2004b; see Ashby and Maddox, 2005, for a review). Deficits in probabilistic classification have been found in patients with Tourette syndrome (Marsh et al., 2004), supporting the idea

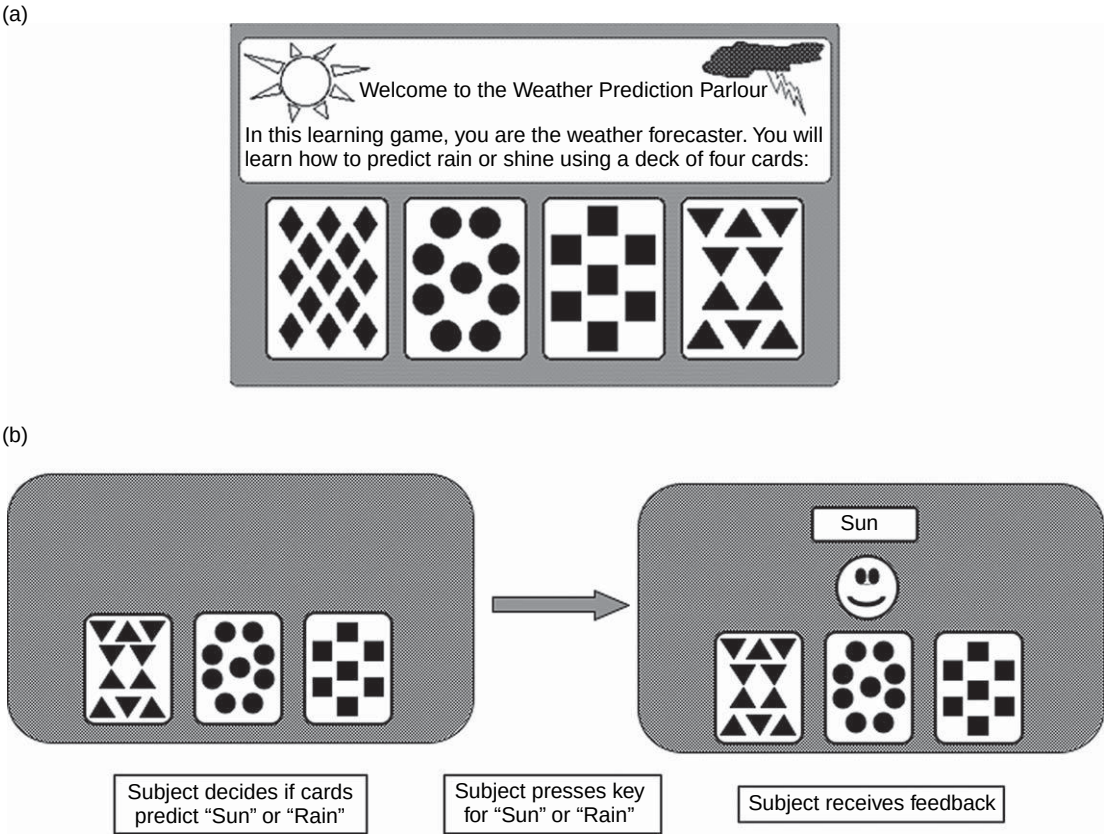

Figure 2 In (a), the instruction screen of the weather prediction task is shown. In (b), the events of a trial are shown.

that this disorder involves disruptions of basal ganglia function.

One important point to be made in interpreting the weather task data is that declarative knowledge of the cue-outcome associations is available and ultimately may be used by participants. Younger adult subjects, who presumably have better declarative memory abilities than older subjects, appear to rely on declarative memory in this task unless they learn while distracted by a secondary task (Foerde et al., 2006). Making the task slightly more deterministic also appears to result in more declarative learning in the task (Hopkins et al., 2004). With more training, even older subjects gain substantial declarative knowledge that can boost their performance above that of amnesic patients. The range of findings in this task underscore the idea that tasks are often not purely declarative or procedural, but, rather, one must examine the content of learning using criteria such as awareness and flexibility of knowledge (Reber et al., 1996).

To characterize the deficit in the weather prediction task in patients with Parkinson's disease, Shohamy et al. (2004b) discovered that a possible source of the lower performance for the patients is the use of a suboptimal strategy. Whereas control subjects based their responding on a single card early on, they shifted to a more optimal strategy as the task progressed in which they based their responding on multiple cards. In contrast, most patients continued using a single-cue strategy throughout the experiment. Since a multicue strategy involves integrating the responses from single-cue stimuli, one way to interpret this finding is that patients with Parkinson's disease might be impaired at response integration. Another way to interpret these findings is that single cards are likely to be learned declaratively because these tend to be easier to remember and are often highly associated with an outcome. Trials with multiple cards are generally less associated with an outcome and may be more difficult to memorize. Thus, learning to classify these trials may be more dependent on procedural memory. In line with the findings of Shohamy et al. (2004b), Sage et al. (2003) found that patients with Parkinson's disease who received a pallidotomy as treatment for motor

impairments exhibited deficits on the weather prediction task restricted to the multicue trials compared with their presurgical performance. By destroying part of the globus pallidus, the pallidotomy effectively eliminates a major source of output from the basal ganglia. Although the pallidotomy resulted in clinical improvement in these patients, removing this input appears to exacerbate the deficit in classifying multiple-cue stimuli.

In Parkinson's disease, the pattern of cell death in the substantia nigra over the course of the disease leads to greater loss of dopamine in the putamen than the caudate nucleus early in the disease (Morrish et al., 1998). As such, it suggests that the putamen plays a greater role in procedural learning in the weather prediction task than the caudate nucleus. However, performance in these patients is negatively correlated with severity of the disease. Patients with milder symptoms can perform within the normal range (Moody et al., 2004; Perretta et al., 2005). It may be that deficits in this task occur only when functioning of the caudate is compromised. Unfortunately, variability in the time course of the disease makes it difficult to use data from these patients to pinpoint which regions are important. Later in the chapter we discuss procedural learning and the anatomy of the basal ganglia in more detail.

3.17.7.4 Concurrent Discrimination

For each trial in a concurrent discrimination task, the participant is asked to choose between two objects of a pair. Subjects are trained across many trials, with one object of each pair being consistently rewarded. Concurrent discrimination tasks have been used extensively to study habit learning in animals. In monkeys, normal performance is seen after medial temporal lobe lesions using several different experimental procedures, suggesting that animals do not necessarily rely on declarative memory in concurrent discrimination, particularly under circumstances when it is difficult for the animal to memorize specific trials (Malamut et al., 1984; Phillips et al., 1988; Teng et al., 2000). Neuropsychological studies have yielded mixed results when the same tasks have been employed in humans to study the effects of medial temporal lobe damage. For example, amnesic patients were impaired in concurrent discrimination tasks in which monkeys with medial temporal lobe lesions are intact (Squire et al., 1988; Hood et al., 1999). In contrast, patients with hippocampal atrophy were shown to learn an 8-item concurrent discrimination as rapidly as controls (Myers et al., 2002). It seems quite possible that the concurrent discrimination task can be learned declaratively or as a set of procedural habits. This view is supported by a study showing that patients with severe amnesia were able to demonstrate learning in a concurrent discrimination task, although at a much slower rate than control subjects (Bayley et al., 2005). Importantly, the amnesic patients performed at chance on a subsequent task in which they were shown all objects on a table and had to sort them according to whether they were rewarded or not. In contrast, control subjects found this task to be easy, suggesting that they had gained declarative, flexible knowledge of which objects were rewarded. These results provide evidence that habit learning can occur for discrimination learning without conscious awareness and without the aid of an intact declarative memory system. However, it could be the case that this does not typically occur in subjects with intact declarative memory, in which discrimination learning may be more efficiently managed by medial temporal lobe structures.

Evidence for a role for the basal ganglia in concurrent discrimination learning comes from work in monkeys showing disruption by lesions of the striatum when 24-hour intervals are used between the presentation of stimuli to thwart declarative memory strategies (Teng et al., 2000; Fernandez-Ruiz et al., 2001). In humans, patients with Parkinson's disease show a deficit in acquiring stimulus-response associations necessary for discrimination learning. For example, Myers et al. (2003) found a deficit in acquisition of stimulus-reward associations in patients with Parkinson's disease.

3.17.7.5 Artificial Grammar Learning

In the typical artificial grammar learning task, subjects are presented with a series of letter strings and are asked to reproduce them. Only after studying the set of letter strings are subjects told that the letter strings were formed according to a set of complex rules, and their task will be to decide for a new set of items whether or not they are formed according to these rules. Although subjects feel that they are simply guessing, they are able to classify new letter strings at a level significantly above chance. Artificial grammar learning has many of the characteristics of procedural learning. It appears to proceed gradually without the awareness of what has been learned, and it does not depend on brain structures that support declarative memory (Reber, 1989; Knowlton et al.,

1992). However, unlike many procedural learning tasks, patients with basal ganglia dysfunction show normal learning (Reber and Squire, 1999; Witt et al., 2002), suggesting that performance of this task depends on other brain regions. One difference between this task and some of the others that do depend on basal ganglia structures is that artificial grammar learning does not require feedback. Thus, the need to integrate feedback during learning may be a key feature of striatal-dependent learning (Aron et al., 2004). In support of this idea, it has been found that patients with Parkinson's disease show deficits in artificial grammar learning when feedback was used (Smith and McDowall, 2006b).

3.17.7.6 Parkinson's Disease as a Model of Striatal Dysfunction

Parkinson's disease affects different brain circuits as the disease progresses and, as such, may reveal a succession of cognitive deficits. At the first sign of motor deficits, the disease has already insidiously destroyed between 70% and 80% of the dopaminergic cells projecting to the dorsal striatum (Agid et al., 1987, 1993; Pakkenberg et al., 1991). However, there is a gradient in dopamine depletion, with greater depletion in the putamen than in the caudate nucleus (Hirsch et al., 1999). Thus, both early- and late-stage Parkinson's disease patients suffer from severe dopamine depletion in the putamen. Later in the disease, the dopaminergic depletion progresses to the caudate nucleus (Agid et al., 1993, Damier et al., 1999). Patients with Parkinson's disease may not provide conclusive information about the role of specific regions in that the disease is somewhat variable in its progression.

The pattern of depletion and regional striatal dysfunction may be an explanation for the sometimes confusing pattern of learning deficits seen in Parkinson's disease populations. Although all Parkinson's disease patients should show impairment on tasks that depend on putamen function, other tasks may reveal dissociations between mildly and severely affected Parkinson's disease patients. Mildly affected Parkinson's disease patients may not show deficits on learning tasks that depend on an intact caudate, whereas deficits may be revealed in more severely affected Parkinson's disease patients who suffer from caudate damage. Few studies have reported data with results assessed separately for early- and late-stage Parkinson's disease patients. Another issue with these patients is the fact that most patients are receiving dopaminergic medications to treat their symptoms. These medications are likely to have wide effects throughout the brain if patients are being tested while on medication, and there are likely to be brain changes in those patients tested off their medication if they are accustomed to taking the medication. Although patients with Parkinson's disease are the most widely used group for assessing the contribution of the basal ganglia to cognition, there are numerous issues to consider in interpreting the data from this population.

3.17.8 Neuroimaging Studies

Neuroimaging techniques have complemented the study of procedural learning in neuropsychological patients. A major advantage of neuroimaging approaches is that they can provide insights into brain regions involved at different stages of learning, thus providing a dynamic picture of procedural learning. Initial studies using PET have shown that different brain regions participate in sequential phases of skill acquisition (sometimes referred to as early, automatic, and skilled). Here, automatic refers to performance that is not affected by the concurrent performance of an additional task – one can perform the automatic task while concentrating on something else. In studies involving simple sequential finger tapping, the cerebellum is activated in all stages of learning, whereas the basal ganglia are activated only in the later skilled stage – implicating a role for the basal ganglia in the performance of automatic skills, with the cerebellum being key for the execution of the movements. Similarly, Grafton et al. (1992) used PET to examine cerebral blood flow while participants were performing the rotor pursuit task. They found an increase in activity in motor areas and the cerebellum, providing evidence for the idea that the cortical–cerebellar loop that supports execution of motor tasks is also involved in learning the task. PET studies of performance on the SRT task with a complex embedded sequence showed sequence learning associated with increases in activity in a network of cortical and subcortical brain structures, with most studies showing increases in the striatum as well as in primary motor cortex, supplementary motor cortex, premotor cortex, thalamus, and cerebellum. In terms of the striatum, both PET and fMRI studies have provided evidence that the caudate head and the anterior putamen show activation during the task (Hazeltine et al., 1997; Peigneux et al., 2000).

As discussed earlier, the SRT is not always a purely implicit learning task, and explicit knowledge can often contribute to performance. A key experimental question is to what extent regions in the basal ganglia and cerebellum can support learning without awareness. Neuroimaging investigators have employed various manipulations to try to force learning without awareness and to compare patterns of performance and brain activity between subjects who did and did not acquire explicit knowledge of the sequence. Grafton et al. (1998) employed a version of the SRT task that added a secondary tone-counting task to make it more difficult for subjects to learn the underlying sequence explicitly. Under dual-task conditions, subjects were considered implicit learners, with only 1 of 20 subjects noticing the repeating sequence. This study revealed that activation in motor cortical areas was associated with sequence learning. However, when subjects transferred their sequence knowledge to a situation where they used different motor effectors, sequence-related activity was seen in the parietal lobe, suggesting that this is the site of abstract sequence knowledge. Using a number of similar tasks, many investigators have found a pattern of activation within corticostriatal networks that parallels procedural learning (Seitz et al., 1990; Doyon et al., 1996; Rauch et al., 1997).

More recent studies have focused on subregions of the basal ganglia to gain insight into how learning progresses. Lehéricy et al. (2005) found evidence for a shift in motor representations during learning in an SRT task. With practice, subjects exhibited a decrease in activity in the rostrodorsal putamen and an increase in the caudoventral putamen. Because the rostrodorsal regions have been implicated in associative learning and the caudoventral regions similarly implicated in sensorimotor tasks, these results suggest a shift of the representations of motor learning from associative to sensorimotor regions. It might be that the associative circuit plays the dominant role during acquisition of the motor skill, but that the sensorimotor circuit takes over to maintain a high level of automated performance. Other studies have provided evidence that these changes in the coritical-striatal circuits are accompanied by similar region-specific changes in the cerebellum (Doyon et al., 2003).

Other recent fMRI studies provide evidence that, in addition to the basal ganglia, the cerebellum and supplementary motor cortex play important roles in this type of procedural learning and that the location of activity may depend on the stage of learning. Some studies have shown that the pattern of sequence-specific activation during the SRT depended on the extent of explicit knowledge of the sequence (Hazeltine et al., 1997; Honda et al., 1998).

As with other recent neuroimaging studies of SRT learning, Poldrack et al. (2005) revealed a pattern of activation that differed early and late in training. There was a decrease in activity with extensive training that was regionally specific. They found that sequence-specific activity in the putamen was high early in training but decreased as training progressed, presumably as automaticity was developing. However, the caudate body showed only a trend for greater sequence-specific activity early in training (there was significant caudate activity under dual-task conditions). If the putamen is primarily involved in motor skill acquisition, this pattern of activation for the putamen is in agreement: The putamen comes online for acquisition of a motor skill, then gradually becomes less active with extensive training and the development of automaticity.

If the caudate were more important for the acquisition of motor sequence knowledge, one would expect early activity in the caudate nucleus during motor sequence learning. Jueptner et al. (1997) found a shifting pattern of striatal activation during sequence learning in a PET study, with early learning activating the caudate nucleus and anterior putamen, followed by a shift in activation to the posterior putamen and sensorimotor cortex when automated performance was achieved.

3.17.8.1 Neuroimaging of Probabilistic Classification

Recent fMRI studies using the weather prediction task shed some light on the issue of the neural substrates of procedural learning. Poldrack et al. (1999) found that normal subjects showed activity in the caudate nucleus (as well as in prefrontal and parietal regions) when performing the weather prediction task. They also found a deactivation in the medial temporal lobe compared with baseline during weather prediction task performance, suggesting that the striatum and medial temporal lobe have a mutually competitive relationship in the control of behavior. Interestingly, patients with Parkinson's disease show activation in the medial temporal lobe during performance of the weather prediction task, suggesting that striatal dysfunction in these patients allows for a greater role for the medial temporal lobe in learning in this task (Moody et al., 2004).

In the weather prediction task, feedback seems to be an important feature, which leads to striatal involvement in this task. Poldrack et al. (2001) showed that striatal activation was greater during performance of the weather prediction task when feedback was used compared with an observational learning condition in which subjects saw the cues presented alongside the outcomes on each trial, without making a choice. This condition was in fact associated with medial temporal lobe activation, suggesting that subjects learned the task declaratively under these circumstances. Consistent with this idea is the fact that patients with Parkinson's disease are able to learn the association between stimuli and responses in the observational condition (Shohamy et al., 2004a), while these patients show impairments in the weather prediction task when feedback is used (Knowlton et al., 1996; Shohamy et al., 2004a). Together, these studies point to the critical role of feedback in the recruitment of the striatum during learning.

Functional neuroimaging approaches have also been used to determine the role of attention in declarative and procedural learning. Using the weather prediction task, Foerde et al. (2006) examined the neural substrates of knowledge learned while subjects were focused on the task and when they were distracted by the need to perform a concurrent task. When subjects were able to focus on learning the weather prediction task, performance correlated with activation in the medial temporal lobe. It appears that these young, neurologically intact subjects were able to acquire declarative knowledge of these cue-outcome associations and were able to later use these associations flexibly in transfer tests. In contrast, for associations learned under distraction, performance appeared to rely on the striatum. For these associations, knowledge was more procedural in that it could not be used readily in transfer tasks in which subjects were asked questions about the associations in a form that was different from the training procedure. A key property of procedural habit learning may be the fact that learning can proceed normally when working memory resources are occupied by a concurrent task. This result has important implications for our multitasking society: We may be able to perform some of our daily activities in dual-task or multitask mode, but when declarative knowledge of new information is required, we need to focus on one task at a time, or the ability to flexibly use this knowledge will suffer.

Another example of the complex interaction of explicit and implicit learning can be found in a recent study examining the impact of basal ganglia damage on motor learning in a continuous tracking task with an embedded repeated sequence (Boyd and Winstein, 2006). The authors found that explicit information actually interfered with learning the motor task for the patients with basal ganglia damage. As expected, the control subjects performed better on the motor task when they were given explicit information of the repeated sequence. One interpretation of this result is that if the basal ganglia are important for switching between modes of processing, damage here may make it particularly difficult for procedural and declarative knowledge to interact.

3.17.8.2 Posttraining Disruptions of Procedural Learning Using TMS

The TMS technique allows researchers to effectively create a temporary lesion in a neurologically intact subject. This technique involves applying a repetitive magnetic field to regions on the surface of the brain using a coil held to the scalp. Although much of the focus on neural structures for procedural learning has been on the basal ganglia, TMS is particularly well suited to examine the involvement of cortical regions important for procedural learning that are part of critical corticostriatal loops. Although neuroimaging studies have shown activation of the dorsolateral prefrontal cortex (DLFPC) during procedural sequence learning, it was not clear whether this region is necessary for learning. Using TMS, Robertson et al. (2001) were able to disrupt the normal function of the DLFPC during a modified version of the SRT. Although this disruption did not cause a general impairment in sequence learning, it did appear to block learning of spatial sequence learning. Their results suggest that the DLPFC helps maintain spatial information in working memory until other cortical and striatal structures can learn the sequence. It appears that, unlike habit learning, spatial sequence learning does require working memory resources (Hsiao and Reber, 2001).

Other researchers have used TMS at different stimulation frequencies to enhance rather than disrupt neural function. Kincses et al. (2004) discovered that electrical stimulation of the prefrontal cortex could improve performance in a probabilistic classification task during direct transcranial stimulation of the left prefrontal cortex. The authors suggested that the weak

stimulation of the left prefrontal cortex increased neuronal excitability, and this facilitated the function of relevant corticostriatal loops. However, as seen recently by Foerde et al. (2006), probabilistic classification tasks can often be learned declaratively by normal subjects.

3.17.8.3 Shifts in Activation with Practice – an Emerging Theme in Basal Ganglia Neuroimaging

Another technique to examine the substrates of procedural learning employs intensive analysis of fMRI data to establish effective connectivity of distinct brain regions during task performance. Toni et al. (2002) have examined connectivity during procedural visuomotor learning and found specific learning-related increases of effective connectivity in temporostriatal and frontostriatal circuits. Connectivity among portions of the frontal cortex decreased with learning, whereas temporofrontal and parietofrontal connectivity did not change across learning trials. This result suggests that visuomotor associations can be established by strengthening specific corticostriatal circuits.

3.17.8.4 Who Is the Teacher?

Recent fMRI studies have allowed researchers to follow the patterns of activity in specific brain regions and to investigate a fascinating time-dependent interaction of different brain regions and possibly different memory systems. One can think of these interactions in terms of a symphony, with different brain regions playing their parts interactively throughout learning, with some regions playing a dominant role early in learning, and others later in learning – like a handoff of the melody between strings and wind instruments. However, an important question regarding the interplay of cortex and striatum in procedural learning is, "Who is teaching whom?" Some researchers have suggested that habit learning is acquired gradually, with the cortex teaching the caudate, and with a gradual buildup of habit representations in the striatum (Graybiel, 1998). In this model, cortical activation precedes striatal activation. However, recent studies provide evidence that this picture may not be so simple. Frank et al. (2001) described evidence that striatal activity can precede frontal activity in some cases. These researchers suggest that the striatum is providing contextual information to the cortex, so that the cortex can then choose an appropriate learning strategy.

3.17.8.5 Time Course of Basal Ganglia Activations

Some procedural learning studies have recently shown that within the basal ganglia there is also a temporally varying pattern of activity, with the head of the caudate playing the dominant role early in learning and the tail of the caudate taking the lead later in learning. Several recent studies have noted these variations that perhaps reflect learning-dependent changes in the coritical-striatal loops involved in the learning. Delgado et al. (2005), using the probabilistic classification task, found that the caudate was more highly activated in early learning than in later learning trials. Seger and Cincotta (2005) found dissociations in the pattern of activity in the head of the caudate versus the body and tail of the caudate. Using a version of the weather prediction task, the investigators also found a high level of activity in the head of the caudate that decreased as learning progressed. Activity in the body and tail of the caudate was found to correlate with successful learning and increased across the learning task. Thus, this pattern in the striatum may relate to the transformation of memories from declarative to procedural. In contrast to these findings, Poldrack et al. (2001) found increases in activation in the caudate nucleus as learning progressed in the probabilistic classification task. As discussed earlier, the probabilistic classification task may be learned declaratively under single task conditions. Thus, it is important to examine the nature of the learned representations in order to understand whether learning was procedural or declarative (Foerde et al., 2006).

3.17.8.6 Consolidation of Procedural Learning: Effects of Sleep

Many studies have pointed to an enhancement of procedural learning following sleep. For example, speed and accuracy in a finger-tapping sequencing task were improved following a night of sleep, but not after an equivalent period of wakefulness (Walker et al., 2002). There is also evidence that declarative learning shares the same benefit (Gais et al., 2006). Robertson (2004) found that whether sleep was of benefit in the performance of a motor sequencing skill depended on the level of declarative knowledge of the task. Those subjects with better declarative

memory for the task showed only overnight improvements in performance, whereas subjects with poorer declarative memory showed improvements in performance with or without sleep. Similarly, skill enhancement occurred following a nighttime retention interval only if there was declarative knowledge of the sequence (Walker, 2004). These results suggest that the benefits of sleep to skill learning are mediated by the contribution of declarative knowledge. However, there is also evidence that procedural and declarative learning can be enhanced by different stages of sleep (Rauchs et al., 2005). As the proportion of these phases may vary with many factors, including the duration and time of sleep, and age of the subjects, different effects on learning may be obtained.

3.17.8.7 Anatomical Basis of Procedural Learning

As discussed earlier, the basal ganglia have been closely associated with procedural learning based on both neuropsychological and neuroimaging studies. However, the basal ganglia are a major division of the brain with broad and heterogeneous functions. It is thus important to attempt to specify in more detail the circuits within the basal ganglia that subserve procedural learning. In addition, as there appear to be different types of procedural learning, these may depend on different circuits within the basal ganglia.

The basal ganglia receive input from all regions of the cortex. The major input structures are the neostriatum, including the caudate and putamen, which receive input from neocortex, and the ventral striatum, including the nucleus accumbens, which receives input from limbic cortices. The output of the basal ganglia is much more limited and is concentrated in projections to regions of the thalamus that project to the frontal cortex. The organization of the basal ganglia has been traditionally thought of in terms of corticostriatal loops (Alexander et al., 1986). These loops are considered to be somewhat segregated, with different regions of the cortex projecting to specific striatal regions, which in turn project to specific regions of the pallidum and substantia nigra. The output of the loops continues to be segregated from the nigra and pallidum to specific thalamic nuclei, which project to distinct cortical regions primarily in the frontal lobe. The segregation of these loops may be consistent with the relative inaccessibility of procedural knowledge from other cognitive processes.

There have been several different views of how these corticostriatal loops are organized. An influential model put forth by Alexander et al. (1986) divided the basal ganglia into five functional loops: skeletomotor, oculomotor, dorsolateral prefrontal, lateral orbitofrontal, and anterior cingulate circuits. These loops are thought to encompass the motor functions of the basal ganglia as well as cognitive, motivational, and emotional functions through the loops terminating in the dorsolateral prefrontal, lateral orbitofrontal, or anterior cingulate circuits. The parallel nature of these loops suggests that different types of procedural learning, such as motor skills, cognitive skills, and habits, may be instantiated in these different loops.

These loops have been grouped based on their targets in the frontal lobes, thus dividing them into motor, association, and limbic loops (Parent, 1990; see **Figure 3**). The motor loops include regions of frontal lobe involved in motor function, the association loop

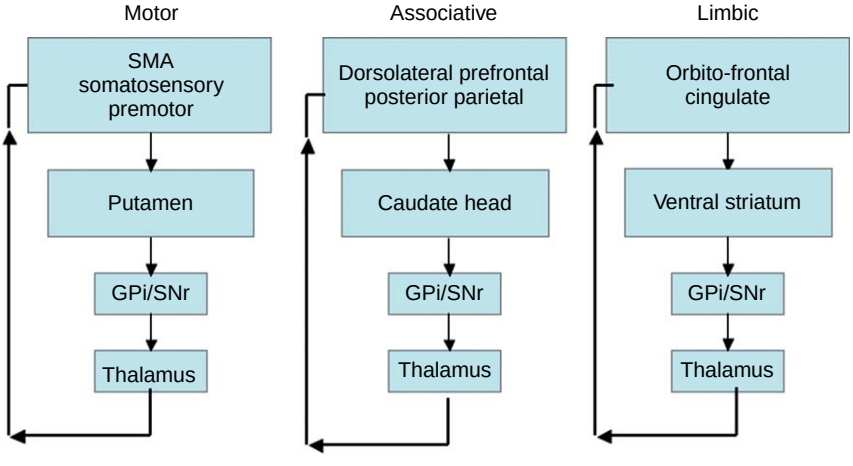

Figure 3 A schematic of the three major corticostriatal loops based on targets in the frontal lobes.

includes prefrontal regions that receive highly processed cortical input, and the limbic loops include frontal regions that have been associated with regulation of behavior and motivation. For the most part, these loops are closed, meaning that these cortical areas project to the striatal regions that eventually provide discrete basal ganglia input to the same cortical area. Such closed loops have recently been reported that include nonfrontal lobe regions including inferotemporal and posterior parietal cortices (Middleton and Strick, 2000; Reep et al., 2003). The closed-loop architecture of the corticostriatal system has been hypothesized to be an efficient means by which to select among and coordinate different actions or responses (Hikosaka, 1998; McHaffie, et al., 2005). By returning input to the original cortical region, responses originating in that cortical region can be inhibited or potentiated based on a central selection mechanism. In this view, the basal ganglia's role is not limited to procedural learning and memory but, rather, is key in selecting between responses based on procedural or declarative knowledge to smoothly produce ongoing behavior.

For the basal ganglia to be involved in response selection, there must also be integration across loops to coordinate their output. In addition to the prominent closed loops, there are additional open-loop projections by which functional subdivisions of the striatum can influence the output of other loops (Joel and Weiner, 1994). For example, the associative striatum can influence motor cortical regions via projections to pallidal regions that project to thalamic nuclei afferent to the premotor cortex.

In addition to the cortical input to the striatum, there is a prominent dopaminergic projection from the pars compacta region of the substantia nigra to the dorsal striatum and from the ventral tegmental area to the ventral striatum. Dopamine plays a key role in the function of the basal ganglia, and in turn, dopamine's greatest effect on cerebral processing is arguably in the basal ganglia. The limbic striatum in particular is able to influence other striatal loops via its projections to dopaminergic neurons in the substantia nigra (Haber et al., 2000; Joel and Weiner, 2000). This specialized role of the limbic striatum suggests that reward and motivation may be particularly important in response selection.

3.17.8.8 Caudate and Putamen

As discussed earlier, a comprehensive view of the basal ganglia holds that it has a general role in selecting between possible responses rather than a specific role in procedural learning and memory. It is thus important to identify those circuits within the basal ganglia that may be important for procedural learning. In the primate striatum, an initial distinction may be made between the caudate and putamen, which are the main input structures of the associative and motor loops. Differentiating the function of the caudate and putamen is somewhat difficult in human subjects, as diseases that affect the basal ganglia are not completely selective for one subset of the striatum, and neuroimaging techniques in the past have lacked the resolution necessary to differentiate striatal subregions. However, as spatial resolution improves, it is becoming possible to see activation within specific circuits using fMRI.

As a component of the motor circuit, the putamen would appear to be important for motor skill learning. However, it may be more accurate to think of the motor striatum as being involved in responses more abstractly, and not simply in effector-specific movements. Frontal cortical regions in the motor loop include premotor cortex, which has a role in motor planning. Thus, the putamen may be particularly involved in habits, in which particular responses become linked to environmental triggers (Yin and Knowlton, 2006). These responses may not be confined to specific movements, but they may also be more abstract actions (such as turning on a light switch or opening a cabinet) that have come to be automatically elicited by specific cues. Electrophysiological evidence from nonhuman primates indicates that neurons in the putamen respond during movements that are overlearned and habitual (Kimura et al., 1993). Also, fMRI studies of human habit learning tasks also demonstrate activation centered around the putamen (Foerde et al., 2006).

In contrast, the primate caudate nucleus appears to play an important role in executive functions. This is consistent with its connections with prefrontal cortex. Neurons in the caudate nucleus respond during goal-directed actions and working memory tasks (Levy et al., 1997). In patients with early Huntington's disease, in which degeneration is focused in the head of the caudate, poor performance is detected in learning cognitive skills (Watkins et al., 2000). It may be that acquiring rules and algorithms depends on this region, because of the importance of working memory in extracting structure from the environment.

3.17.8.9 Motor Cortex and Procedural Learning

In addition to the striatum, the cortical components of the corticostriatal loops are important for procedural learning. The motor cortex in particular shows plastic changes associated with learning motor skills (Monfils et al., 2005). For example, extensive practice of a motor sequence results in long-term increases in the extent of activation in primary motor cortex when the skill is performed. These data suggest that skill learning is accompanied by reorganization of primary motor cortex. These findings bring up the question of whether the motor cortex is the initial site of plasticity for motor skill learning, or if this representation is formed through signals originating from the striatum. According to this view, the basal ganglia show initial changes related to skill development, but with extended practice over the course of weeks or months, the learned skill is represented in the cortex (Ungerleider et al., 2002). These data suggest that the putamen may have a role in setting up the changes in motor cortex that support the performance of skills as well as setting up associations between stimuli and responses in habit learning. As motor skills may require extremely precise patterns of movement, changes in motor cortex may be necessary to support skilled behavior. The relationship between the striatum and cortex in skill learning underscores the idea that there may not be a single site of plasticity in procedural learning, but, rather, different structures become involved at different points during training.

3.17.8.10 The Role of Reinforcement

Dopamine has long been associated with reinforcement. Patients with Parkinson's disease who suffer from low levels of striatal dopamine exhibit deficits in learning trial-and-error tasks in which performance in shaped by feedback (Knowlton et al., 1996; Ashby et al., 1998; Frank et al., 2004; Shohamy et al., 2004a). In some forms of procedural learning, feedback plays a fundamental role. In habit learning, reinforcement is needed for the formation of the stimulus–response bond. Dopamine acts through D1 receptors in the direct pathway, which has the net effect of disinhibiting thalamic nuclei and facilitating behavior in the cortex, and through inhibitory effects on D2 receptors, which are part of an indirect pathway, which has the net effect of inhibiting thalamic nuclei and reducing behavior (Hikosaka, 1998). According to recent models of reinforcement learning, reward leads to dopamine bursts that increase synaptic plasticity in the D1 pathway and decrease plasticity in the D2 pathway, supporting learning to engage in a response (Frank et al., 2004; Frank, 2005). These models would predict that plastic changes within the striatum subserve habit learning. Other forms of procedural learning, such as motor and cognitive skill learning, may also be facilitated by reinforcement, but it would seem that additional mechanisms must come into play that are specific to the task. These would include programming the precise timing of movements and integrating sensory feedback in the case of motor skill learning, or gaining the ability to chunk different aspect of a problem so as not to exceed working memory limitations in cognitive skill learning.

3.17.8.11 Evolutionary Perspective on Procedural Memory

Considerable evidence indicates that multiple systems of learning depend on different brain systems. Procedural learning refers to one class of abilities that share features such as independence from awareness and lack of flexibility. The existence of these different systems raises the question of why we have evolved different forms of learning and what advantages this could have over a situation in which there was a single learning mechanism. Considering the brain from an evolutionary perspective, it would seem unlikely that there would be a general purpose learning and memory system. Rather, cognitive structures and their underlying neural circuitry would emerge through selection pressure (Sherry and Schacter, 1987). Procedural learning has been argued to have emerged earlier, based on the idea that knowing how to perform basic skills is more critical for survival than knowing that certain facts are true (Reber, 1992). Also, the striatum, which is likely to be important for many forms of procedural learning, is a phylogenetically older structure than the medial temporal lobe structures that are important for declarative memory. One of the most intriguing questions in cognitive neuroscience is what drove the evolution of declarative memory. What advantages does declarative memory convey over other forms of memory? One argument is that declarative memory evolved as a means to link spatial and nonspatial information – such as memory for items in locations, which would be useful in foraging behavior

(Manns and Eichenbaum, 2006). This required a learning system that received a confluence of information from different sources. This anatomical convergence may support the key feature of declarative memory – its accessibility to numerous cognitive processes. On the other hand, the evolution of declarative memory did not usurp the importance of procedural learning. Procedural learning is clearly well suited to acquiring skills and habits necessary for survival, and the fact that it does not rely on attentional resources makes it efficient.

Although procedural learning may be phylogenetically old, it is certainly the case that procedural learning has continued to evolve in humans. It is also the case that cognitive structures that evolved in the past may become exapted for different uses through time (Gould and Vrba, 1982). A learning system that evolved based on one set of environmental conditions may become adaptive in new situations as well. For example, it may be that complex skills like reading or playing a musical instrument exploit neural mechanisms that evolved for learning simple motor skills. As procedural learning mechanisms are likely to have emerged phylogenetically earlier than declarative learning mechanisms, and have been subject to a longer history of selection processes, they are likely to be more resilient to disruption. Thus, factors such as age, stress, and fatigue would be less likely to affect procedural learning than declarative learning, as has generally been found to be the case (Poolton et al., 2007).

3.17.8.12 Procedural Learning and Disorders of Cognition

Although procedural learning is robust to many of the changes that affect declarative learning, it is the case that disruptions of basal ganglia function result in procedural learning disorders. Are there functional consequences of disordered procedural learning? Patients with Huntington's disease or Parkinson's disease may have difficulty with learning complex skills, although motor limitations in these patients may make such difficulties less relevant for daily life activities than the primary difficulties in performing tasks. One possible consequence is that tasks that would normally become automatic may continue to draw on working memory resources in these patients. Thus, routines that could be accomplished with little mental effort after extensive practice (e.g., getting ready for work in the morning) would need each step to be accomplished deliberately in these patients and would make it more difficult to accomplish additional tasks concurrently. Thus, a procedural learning deficit may result in a lack of mental efficiency in everyday life.

In addition to neurological disorders, corticostriatal loops are involved in a number of psychiatric disorders as well. For example, schizophrenia appears to involve deficits in the cognitive loop and also to be accompanied by deficits in automating cognitive skills. It is likely that this impairment contributes to the difficulties these patients have in work and social settings (Granholm et al., 1991; Strauss, 1993). Although in general we implicitly learn how to behave around others, in patients with schizophrenia, these rules of social conduct must be consciously learned and applied. Other psychiatric disorders could be viewed as an overactive procedural system. Obsessive compulsive disorder is accompanied by overactivity in corticostriatal circuitry and involves the repetition of stimulus-bound behaviors such as washing, counting, and checking (Saxena et al., 1998). Addiction in those who would like to quit may also be seen as the triumph of habit over goal-directed action (Everitt and Robbins, 2005). Progress can be made in treating these disorders if we learn how the striatum affects the selection between habit and goal-directed responses.

From the time a baby is born, it is continuing to learn numerous procedures – both motor and cognitive skills. Reading is a skill that is learned during development and is crucial for success in our society. However, unlike evolutionarily older skills, including language production and understanding, reading difficulties are relatively common in otherwise normally developing children. It may be that in children with reading difficulties, the skill of reading may not become fully automatic. Understanding the process by which skills become automatized may yield insights into how this process may go awry and could lead to early identification of risk factors.

In all these cases, understanding the mechanisms of procedural learning is likely to lead to benefits to human health. Because of the central role procedures play in daily life, it is arguably as important, if not more so, to study the mechanisms of procedural learning as it is to study declarative learning. As our knowledge of basal ganglia function expands, we are gaining a grasp on knowing how we function in the world.

3.18 Neurobiology of Procedural Learning in Animals

M. G. Packard, Texas A&M University, College Station, TX, USA

3.18.1 Introduction

Research investigating learning and memory from a neurobiological perspective provides support for the hypothesis that multiple memory systems exist in the mammalian brain (for reviews, see Eichenbaum and Cohen, 2001; White and McDonald, 2002). Several theories outlining the psychological operating principles that define different types of memory have been proposed (e.g., Hirsh, 1974; O'Keefe and Nadel, 1978; Olton and Papas, 1979; Cohen and Squire, 1980; Mishkin and Petri, 1984; Graf and Schacter, 1985). In lower animals in particular, theoretical development of the sets of psychological mechanisms that distinguish different types of memory has been significantly influenced by the classic debate between cognitive (e.g., Tolman, 1932) and stimulus-response (e.g., Thorndike, 1933; Hull, 1943) learning theorists. One prominent dual-memory theory draws a distinction between declarative and procedural memory (Cohen and Squire, 1980; Squire and Zola-Morgan, 1991; Eichenbaum and Cohen, 2001). In lower animals, declarative memory involves the acquisition, consolidation, and retrieval of relational representations that allow for flexibility during behavioral expression (Eichenbaum and Cohen, 2001) in a manner analogous to the cognitive (Tolman, 1932) view of learning and memory. Declarative memory relies largely on a neuroanatomical system composed of the hippocampus and related structures in the medial temporal lobe (Squire et al., 1993; Eichenbaum and Cohen, 2001). In contrast, procedural memory involves the acquisition, consolidation, and retrieval of individual representations that are behaviorally expressed in an inflexible manner (Eichenbaum and Cohen, 2001), analogous, at least in part, to the stimulus-response or habit (Hull, 1943) view of learning and memory.

In rats, numerous findings from studies employing lesion, pharmacological, molecular, and electrophysiological approaches provide converging evidence supporting the hypothesis that the dorsal striatum (i.e., caudate-putamen) mediates the formation of stimulus–response habits. The goals of the present chapter are to provide a brief historical perspective to the development of this hypothesis and to summarize evidence of the role of the dorsal striatum in this form of procedural learning. Studies employing brain lesion techniques and pharmacological approaches in rats are emphasized, particularly in those instances in which dorsal striatal involvement in procedural and declarative memory tasks has been directly compared. However, it should be noted that neurobehavioral findings from electrophysiological (e.g., Graybiel et al., 1994; Rolls, 1994; Graybiel, 1998; Jog et al., 1999) and molecular (e.g., Colombo et al., 2003; Teather et al., 2005; Pittenger et al., 2006) experiments in rats and nonhuman primates also implicate the dorsal striatum in procedural learning.

In addition to dorsal striatal-dependent stimulus-response memory, learning that is selectively mediated

by other brain structures might also be considered procedural in nature, at least to the extent that they involve acquisition, consolidation, and retrieval of information that is behaviorally expressed in a relatively inflexible, stimulus-bound manner (Eichenbaum and Cohen, 2001). For example, under this definition, cerebellar-dependent classical conditioning of skeletal musculature (for review, see Thompson, 2005) and basolateral amygdala-dependent stimulus-affect learning (for review, see McDonald and White, 2002; *See* Chapter 3.24) might also be broadly construed as forms of procedural learning (Squire and Zola-Morgan, 1991). Findings of several studies have dissociated the roles of the dorsal striatum and basolateral amygdala in learning and memory. Therefore, following a consideration of dorsal striatal involvement in stimulus-response learning, data suggesting that learning based on stimulus-affect associations is mediated by the basolateral amygdala is briefly discussed.

3.18.2 The Neural Bases of Procedural Learning: Emergence of the Dorsal Striatal Hypothesis

In lower animals, the hypothesis that multiple memory systems exist was derived from an analysis of the effects of damage to the hippocampal system on behavior across a wide range of learning tasks (for reviews, see Hirsh, 1974; O'Keefe and Nadel, 1978; Olton, 1979). Similar to the selective behavioral pattern that is observed in rats, lesions of the hippocampal system in monkeys impair behavior in tasks requiring declarative/cognitive memory and spare acquisition of tasks that can be acquired by a putative procedural or habit learning mechanism (for review, see Mishkin and Appenzeller, 1987). In an attempt to identify the neural bases of this spared learning, the hypothesis that the primate dorsal striatum and associated putamen mediate procedural learning that involves the formation of stimulus–response habits was introduced (Mishkin et al., 1984; Mishkin and Petri, 1984; Mahut et al., 1984). At the time that it was originally proposed, this hypothesis was based largely on anatomical considerations. Specifically, the dorsal striatum receives sensory stimulus input from all regions of the cortex via topographically arranged corticostriatal projections and can readily influence motor output via downstream projections to brainstem structures and/or via corticothalamic-basal ganglia loops (e.g., Webster, 1961; Van Hoesen et al., 1981; Alexander et al., 1986). Thus, it was suggested that the dorsal striatum is anatomically well situated to mediate S-R habit learning across various sensory modalities (Mishkin and Petri, 1984; Mahut et al., 1984), although the behavioral evidence implicating the striatum in procedural learning in nonhuman primates was fairly meager (Divac et al., 1967; Buerger et al., 1974).

As noted by Iversen (1979), researchers interested in the neurobiology of learning and memory were not likely encouraged to examine a potential role for the dorsal striatum in view of Karl Lashley's premature conclusion that "the evidence seems conclusive that in mammals the basal ganglia are not an essential link in the patterning of learned activities" (Lashley, 1950, p. 454). Nonetheless, prior to the advent of multiple memory system theories, several experiments examining the effects of lesions of the dorsal striatum on learning were conducted in rats. When considered in retrospect, the findings of many of these studies are consistent with the hypothesized role of this structure in procedural learning and memory. For example, dorsal striatal lesions impair acquisition of various conditioned avoidance behaviors that can be readily acquired using a procedural learning mechanism (e.g., Kirkby and Kimble, 1968; Winocur and Mills, 1969; Neill and Grossman, 1971; Mitcham and Thomas, 1972; Allen and Davidson, 1973; Kirkby and Polgar, 1974). In addition, by the mid-1970s several studies in rats had demonstrated a modulatory effect of posttraining electrical stimulation of the dorsal striatum on memory consolidation using various tasks that could conceivably be acquired using a procedural learning mechanism (for review, see Kesner and Wilburn, 1974).

3.18.3 Dorsal Striatum and Procedural Learning: Dissociation Lesion Experiments

The impairments observed following dorsal striatal lesions in simultaneous discrimination learning in monkeys (Divac et al., 1967; Buerger et al., 1974) and in conditioned avoidance behaviors in rats (for review, see Oberg and Divac, 1979) are consistent with a putative role for this brain structure in procedural learning and memory. However, rather than impairing learning or memory processes per se, a lesion-induced deficit in acquisition of a single type of task may reflect an influence on nonmnemonic

factors that are involved in task performance (e.g., sensory, motor, or motivational processes).

Dissociation methodology provides an experimental design that more directly addresses the question of whether a particular brain structure plays a selective role in learned behavior. In a single dissociation design, the role of a single brain structure (X) in behavior is contrasted using a pair of behavioral tasks (A, B). For example, lesions of the dorsal striatum impair retention of an egocentric left-right discrimination in a radial maze but do not impair retention of an allocentric place learning task (Cook and Kesner, 1988). In addition, dorsal striatal lesions impair acquisition of a tactile discrimination procedural learning task in a T maze but do not impair declarative memory guiding goal-arm alternation (Colombo et al., 1989). These examples of single dissociations provide evidence consistent with a selective role of the dorsal striatum in procedural learning and are clearly more compelling than studies using only one behavioral task. Nonetheless, the presence of single dissociations may not reflect a strict functional independence of procedural and declarative memory systems in the brain (Eichenbaum and Cohen, 2001; Packard, 2002).

A more stringent test of the hypothesis that the dorsal striatum selectively mediates procedural learning employs double dissociation methodology. In this experimental design, the function of two brain structures in behavior is contrasted in two behavioral tasks. Ideally, this approach involves the use of a pair of tasks that possess similar nonmnemonic (e.g., sensory, motor, motivational) characteristics but that differ in terms of the type of learning and memory processes required. The first study to implement this design to investigate the role of the dorsal striatum in learning employed two radial maze tasks to compare the effects of dorsal striatum and hippocampal system lesions on procedural and declarative memory in rats (Packard et al., 1989). In a declarative or cognitive memory version of the task, rats obtained food rewards by visiting each arm of the radial maze once within a daily training session, and reentries into maze arms that were previously visited are scored as errors. This task requires rats to remember which maze arms have been previously visited within a trial and is essentially a test of declarative knowledge that may involve spatial working memory (Olton, 1979) and/or the use of a cognitive mapping strategy (O'Keefe and Nadel, 1978). In a procedural memory version of the task, rats obtained food rewards by visiting four randomly selected and illuminated maze arms twice within a daily training session, and visits to unlit maze arms are scored as errors. Every visit to an illuminated maze arm was reinforced, and thus there was no requirement to use declarative memory to remember specific arm entries. Rather, this task can be acquired by a procedural or habit learning mechanism by which a light cue (i.e., a stimulus) evokes approach behavior (i.e., a response). Pretraining electrolytic lesions of the dorsal striatum produce a dissociation in behavior in these two radial maze tasks, impairing acquisition of the procedural task and leaving acquisition of the declarative task unaffected (**Figure 1**). In contrast, lesions of the fimbria-fornix (a major input/output pathway of the hippocampus) selectively impaired acquisition of the declarative radial maze task, resulting in a double dissociation of the effects of dorsal striatal and hippocampal system lesions on learning (Packard et al., 1989). These findings were later replicated in a study examining the effects of neurotoxic lesions of the dorsal striatum and hippocampus (McDonald and White, 1993).

Although lesions of the dorsal striatum selectively impair acquisition of visual discrimination behavior in a procedural learning version of the radial maze task (Packard et al., 1989; McDonald and White, 1993), it is possible that this deficit reflects disruption of a stimulus–stimulus (light–food) association, rather than a stimulus–response (light–approach) association. The nature of the association guiding the expression of learned behavior can be assessed in a reinforcer devaluation paradigm (Adams and Dickinson, 1981). Rats exposed to reinforcer devaluation following acquisition of the dorsal striatal-dependent radial maze task continue to approach illuminated maze arms, indicating that performance of the task involves expression of a stimulus-response/habit form of procedural memory (Sage and Knowlton, 2000).

A second study used two water maze tasks to demonstrate that the selective role of the dorsal striatum in procedural learning generalizes to aversively motivated behavior (Packard and McGaugh, 1992). In these tasks, two rubber balls differing in visual appearance (vertical vs. horizontal black and white stripes) served as visual cues. One ball (correct) was located on top of a platform that could be used to escape the water, and the other ball (incorrect) was located on top of a thin rod that did not provide escape. In a declarative version of the task, the correct platform was located in the same spatial location on every trial. However, the visual pattern on the ball associated

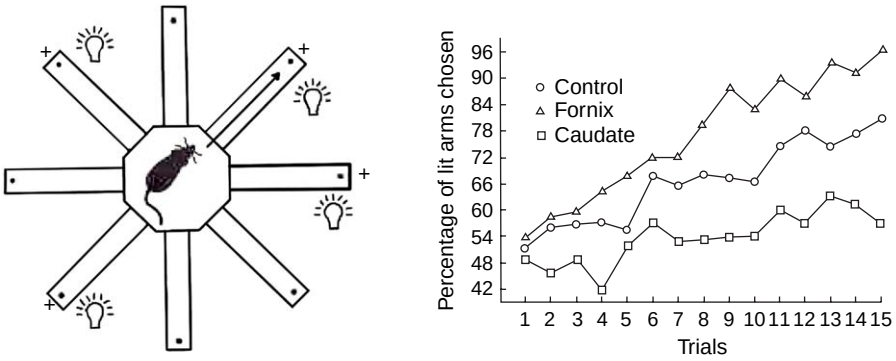

Figure 1 (a) In a radial maze task that can be acquired using a procedural learning mechanism, rats obtain eight food pellets by visiting each of four randomly selected and illuminated maze arms twice within a daily training session (Packard et al., 1989). This task can be acquired using a stimulus (light)–response (approach) form of procedural learning. Consistent with this suggestion, rats trained in this task and exposed to reinforcer devaluation continue to approach illuminated maze arms (Sage and Knowlton, 2000). Radial maze illustration used with permission from Eichenbaum H and Cohen NJ (2001) *From Conditioning to Conscious Recollection: Memory Systems of the Brain*. Oxford Psychology Series, no. 35. New York: Oxford University Press. (b) Lesions of the caudate (i.e., dorsal striatum) severely impair acquisition, consistent with the hypothesis that the dorsal striatum mediates procedural learning and memory. Note that lesions of the hippocampal system (i.e., fornix) actually enhance acquisition. This finding suggests that in some learning situations, hippocampus-dependent declarative memory interferes with dorsal striatal–dependent procedural memory (for a review of competitive interactions among multiple memory systems, see Poldrack and Packard, 2003). Data/graph used with permission from Packard MG, Hirsh R, and White NM (1989) Differential effects of fornix and caudate nucleus lesions on two radial maze tasks: Evidence for multiple memory systems. *J. Neurosci.* 9: 1465–1472.

with the correct platform varied across trials, and thus acquisition of this task required animals to use a spatial form of declarative memory. In a procedural version of the task, the visual pattern on the ball associated with the correct platform was consistent, but the platform was located in different spatial locations across trials. Therefore, this task can be acquired by a procedural learning mechanism that involved performing an approach response to a specific visual cue. Pretraining lesions of the dorsal striatum impair acquisition of the procedural task without affecting acquisition of the declarative task (**Figure 2**). An analogous dissociation is observed using a single-platform water maze task in which rats are trained to swim to a visible escape platform that is always located in the same spatial location. In this situation,

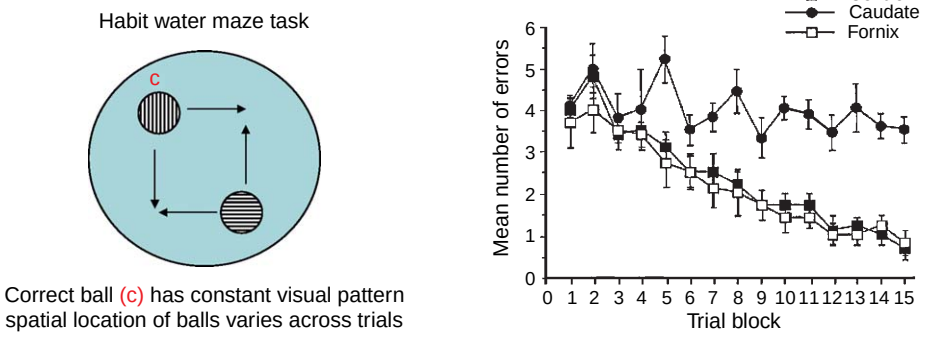

Figure 2 (a) A two-platform water maze task that can be acquired using a stimulus (visual pattern)–response (approach) form of procedural learning (Packard and McGaugh, 1992). Rats learn to swim to a correct (C) escape platform with a distinct visual pattern (ball with vertical stripes). Contact with an incorrect and inescapable platform (ball with horizontal stripes) is scored as an error. The spatial location of both balls varies across trials, and therefore a spatial form of declarative memory is not adequate for task acquisition. (b) Lesions of the caudate (i.e., dorsal striatum) severely impair acquisition, consistent with the hypothesis that the dorsal striatum mediates procedural learning and memory. Note that lesions of the hippocampal system (i.e., fornix) have no effect on acquisition. Data/graph used with permission from Packard MG and McGaugh JL (1992) Double dissociation of fornix and caudate nucleus lesions on acquisition of two water maze tasks: Further evidence for multiple memory systems. *Behav. Neurosci.* 106: 439–446.

when the visible platform is moved to a new spatial location following training, rats with pretraining lesions of the dorsal striatum exhibit a declarative/cognitive strategy and swim to the spatial location that the platform was previously located in, whereas control rats exhibit a procedural/habit strategy and swim to the visible platform in its new location (McDonald and White, 1994).

A third example of a lesion study providing evidence of a selective role for the dorsal striatum in procedural learning employed a plus-maze task that was originally introduced as a means of distinguishing between cognitive and stimulus-response habit theories of learning (Tolman et al., 1946, 1947). The plus-maze apparatus is arranged so that a goal box (e.g., east or west) can be approached from one of two start boxes (e.g., north or south). In a dual-solution version of the task, rats are trained to obtain food from a consistently baited goal box (e.g., east) from the same start box (e.g., north). According to a declarative or cognitive view of learning, rats trained in this task learn the spatial location of the reinforcer, and this relational information can be used to guide an approach response to the baited goal box. In contrast, according to a procedural or stimulus-response view of learning, rats can learn to approach the baited goal box by acquiring a response tendency (i.e., a specific body turn) at the choice point of the maze. Note that either a declarative or a procedural learning mechanism can be used to successfully acquire this dual-solution task. Following acquisition, a probe trial in which rats are given a trial starting from the opposite start box (e.g., north) can be used to assess the type of learning acquired. Thus, rats with declarative knowledge of the spatial location of the reinforcer should continue to approach the baited goal box on the probe trial (i.e., termed place learning), whereas rats that have learned a specific body turn should choose the opposite goal box on the probe trial (i.e., termed response learning). The hypothesis that the dorsal striatum may play a selective role in the expression of procedural/response learning in the plus-maze was examined using a reversible brain lesion technique (Packard and McGaugh, 1996). In this study, rats were trained in a daily session to obtain food from a consistently baited goal box and were allowed to approach this maze arm from the same start box on each trial. Following 7 days of training (i.e., on day 8), rats were given a probe trial to determine whether they had acquired the task using place information or had learned a specific body turn response. Prior to the probe trial, a localized and reversible brain lesion was produced via intradorsolateral striatal injections of the sodium channel blocker lidocaine. On the day 8 probe trial, rats receiving lidocaine or saline vehicle injections into the dorsal striatum were predominantly place learners. Thus, consistent with the findings from the radial and water maze studies described above, infusions of lidocaine into the dorsal striatum did not impair the expression of declarative/place learning. With extended training in the dual-solution plus-maze, intact rats eventually switch from the use of place learning to a response-learning tendency (Ritchie et al., 1950; Hicks, 1964). Therefore, the rats were trained for an additional 7 days, given a second probe trial on day 16, and again received intracerebral injections of lidocaine prior to the probe trial. On this second probe trial, rats receiving vehicle injections into the dorsal striatum were now predominantly response learners. However, rats receiving intradorsal striatal injections of lidocaine prior to the second probe trial exhibited place learning, indicating a blockade of the expression of response learning (**Figure 3**). The selective impairment in expression of response learning in the plus-maze following neural inactivation of the dorsolateral striatum is consistent with other evidence implicating this brain region in egocentric learning (e.g., Potegal. 1969; Cook and Kesner, 1988; Kesner et al., 1993). The results also suggest that the shift or transition from the use of place learning to response learning in a dual-solution plus-maze task involves the gradual recruitment of a dorsal striatal-based procedural learning system to guide behavior. The functional integrity of the dorsolateral striatum is also necessary for the acquisition of a single-solution plus-maze task that requires rats to use procedural response learning by varying the start point on each trial and reinforcing the same body turn at the choice point (Chang and Gold, 2004).

It is important to note that in the radial maze (Packard et al., 1989; McDonald and White, 1993), water maze (Packard and McGaugh, 1992; McDonald and White, 1994), and plus-maze, (Packard and McGaugh, 1996) tasks described above, lesions of the hippocampal system produce the opposite effect of dorsal striatal lesions. Specifically, hippocampal damage impairs acquisition of the declarative/cognitive versions of the tasks and spares (or in some cases enhances) acquisition of procedural learning. Moreover, the individual pairs of maze tasks used in these studies possess the same motivational, sensory, and motoric characteristics, suggesting that the double dissociations observed reflect differential roles of

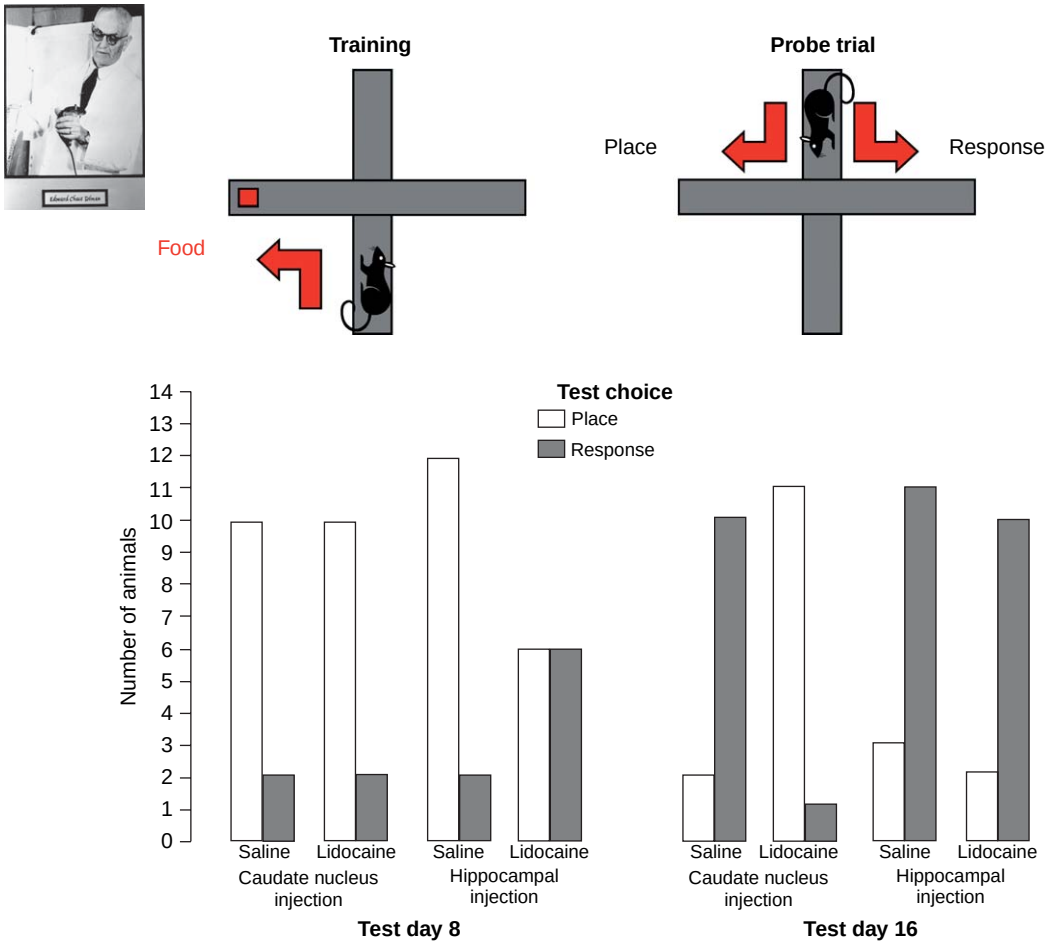

Figure 3 (a) In a dual-solution plus-maze task (Tolman et al., 1946), rats are trained to obtain food from a consistently baited goal box (e.g., west) from the same start box (e.g., south). Either a declarative (i.e., place) or a procedural (i.e., response) memory mechanism can be used to acquire this task. Following acquisition, a probe trial starting from the opposite start box (e.g., north) is used to assess the type of learning strategy employed. Rats approaching the maze arm that was baited during training are designated place learners, whereas rats that perform the specific body turn that was reinforced during training are designated response learners. Photograph of E.C. Tolman provided courtesy of James L. McGaugh. (b) On an initial probe trial (day 8), rats receiving intrastriatal saline or lidocaine are predominantly place learners, indicating that inactivation of the striatum does not impair expression of declarative memory. On a second probe trial given after additional training (day 16), rats receiving saline have switched to the use of response learning. In contrast, rats receiving intrastriatal lidocaine display place learning, indicating a blockade of the expression of procedural learning. Note that hippocampal injections of lidocaine produce the opposite effect, blocking expression of place (day 8), but not response learning (day 16). Thus, the transition to response learning involves an anatomical shift from the use of the hippocampus to the dorsal striatum. In rats receiving intrastriatal lidocaine, the use of place at the time point at which saline-treated rats have transitioned to response learning indicates a continued functional independence of declarative and procedural memory. Data/graph used with permission from Packard MG and McGaugh JL (1996) Inactivation of the hippocampus or caudate nucleus with lidocaine differentially affects expression of place and response learning. *Neurobiol. Learn. Mem.* 65: 65–72.

the hippocampus and dorsal striatum in declarative and procedural memory, rather than lesion-induced deficits in non-mnemonic factors. The observed double dissociations also allow for a more compelling argument that deficits in task acquisition following dorsal striatal lesions in studies employing a single task reflect a selective impairment of procedural learning. Examples include one-way and two-way active avoidance (e.g., Kirkby and Kimble, 1968; Neill and Grossman, 1971; Kirkby and Polgar, 1974; Mitcham and Thomas, 1972; Winocur, 1974), auditory discrimination learning (Adams et al., 2001), and straight-alley runway behavior (Kirkby et al., 1981; Salinas and White, 1998).

3.18.4 The Dorsal Striatum and Procedural Memory Revisited: Functional Heterogeneity

Although extensive evidence supports a role for the dorsal striatum in a stimulus–response form of procedural learning (for reviews, see White, 1997; Packard and Knowlton, 2002; Yin and Knowlton, 2006), increasing evidence from brain lesion studies in rats suggests that this function does not involve the entirety of this brain structure. Rather, lateral, but not medial, regions of the dorsal striatum may be particularly critical in procedural learning that results in the formation of stimulus–response habits. The hypothesis that functional heterogeneity exists in the learning and memory processes mediated by the dorsal striatum is based in part on recognition that this brain structure receives input from all areas of the neocortex (e.g., Webster, 1961; Carman et al., 1963; Webster, 1965; Kemp and Powell, 1970; Veening et al., 1980; McGeorge and Faull, 1989). This idea was explored behaviorally in several early lesion experiments investigating the functional relationship between the frontal cortex and the anteromedial regions of the dorsal striatum in delayed alternation behavior and reversal learning (Rosvold, 1968; Divac, 1968, 1972; Kolb, 1977; for reviews, see Iversen, 1979; Oberg and Divac, 1979).

In rats, damage to the medial dorsal striatum can in some cases produce cognitive learning deficits fairly similar to those observed following hippocampal system damage (e.g., Divac, 1968; Kolb, 1977; Whishaw et al., 1987; Devan et. al., 1999; Devan and White, 1999; but see also Packard and McGaugh, 1992; DeCoteau and Kesner, 2000; Adams et al., 2001; Sakamoto and Okaichi, 2001). Consistent with the idea that medial and lateral regions of the dorsal striatum are differentially involved in learning and memory, lesions of the posterior dorsomedial, but not the dorsolateral striatum, block the ability of reinforcer devaluation to reduce instrumental responding (Yin et. al., 2004, 2005, 2006). These findings suggest that the dorsomedial striatum selectively mediates expression of behavior based on action-outcome associations in instrumental conditioning, whereas the dorsolateral striatum selectively mediates stimulus–response habit formation. In addition, pretraining lesions of a posterior region of the dorsomedial striatum, but not the dorsolateral striatum, result in the predominant use of response learning in the dual-solution plus-maze (Yin and Knowlton, 2004). Further examples of dissociations between the role of medial and lateral regions of the dorsal striatum in learning include evidence that neurotoxic lesions of the dorsolateral, but not dorsomedial striatum, impair acquisition of an operant visual discrimination task (Reading et al., 1991) and of a conditional discrimination task that presumably involves stimulus-response procedural learning (Featherstone and McDonald, 2004a,b).

In addition to evidence suggesting that lateral, but not medial, regions of the rat dorsal striatum mediate procedural learning involving stimulus–response habit formation, other findings indicate that mnemonic function of the lateral dorsal striatum is organized based on the nature of the sensory information provided by cortical input. For example, lesions of the ventrolateral dorsal striatum, an area that receives olfactory cortical input, impairs procedural learning involving olfactory, but not visual sensory, information (Viaud and White, 1989). In contrast, lesions of the posteroventrolateral dorsal striatum, an area that receives visual cortical input, impairs procedural learning involving visual but not olfactory sensory information (Viaud and White, 1989). Similarly, the impairing effect of lesions of the dorsolateral striatum on response learning in the plus-maze may reflect a role for the vestibular/kinesthetic information that this striatal region receives from the somatosensory cortex.

In summary, modification of the hypothesis that stimulus-response procedural learning is mediated by the dorsal striatum is likely necessary to account for evidence indicating functional heterogeneity in the mnemonic functions of this brain structure. At least two levels of functional heterogeneity in the mnemonic functions of the dorsal striatum may exist. Specifically, a medial-to-lateral anatomical gradient may exist in the dorsal striatum that corresponds to a differential functional involvement in declarative and procedural memory, respectively. Second, within the lateral regions of the dorsal striatum, stimulus-response procedural learning appears to be organized based on the nature of the specific sensory input that is received from different cortical regions.

3.18.5 Dorsal Striatum and Procedural Learning: Pharmacological Experiments

The dorsal striatum contains several different neurotransmitters and neuropeptides (for review, see Graybiel, 1990). With regard to the function of this

brain structure in procedural learning and memory, several studies have focused on the role of dopaminergic, glutamatergic, and cholinergic neurotransmission. Dopaminergic projections to the dorsal striatum originate in the substantia nigra (Moore and Bloom, 1978; Gerfen and Wilson, 1996) and may provide a reinforcing signal that is critical in the initial formation of stimulus–response associations (White 1989a; White et al., 1994). Corticostriatal projections are primarily glutamatergic in nature (Fonnum et al., 1981) and are hypothesized to provide sensory or stimulus information embedded in stimulus–response associations (White 1989; White et al., 1994). Acetylcholine is present in the dorsal striatum within a substantial population of interneurons (Lynch et al., 1972) and can interact with dopaminergic transmission to modulate habit memory (White et al., 1994). In addition, the proportional amounts of acetylcholine release in the hippocampus and dorsal striatum may influence the use of habit memory relative to other available learning strategies (for review, see Gold, 2004).

Evidence implicating each of these three neurotransmitters in dorsal striatal-dependent procedural learning and memory is briefly described here. Particular emphasis is placed on studies investigating the effects of posttraining manipulations of neurotransmission in the dorsal striatum on the consolidation of procedural memory. This experimental approach is based on evidence that memory is in a labile state following early exposure(s) to new information (Muller and Pilzecker 1900) and can therefore be either strengthened or weakened by experimental manipulations (e.g., Duncan, 1949; Breen and McGaugh, 1961; McGaugh, 1966). Importantly, this approach avoids several potential nonmnemonic confounds that arise in interpretation of drug effects on memory when pretraining pharmacological treatments are administered (for review, see McGaugh, 1989).

3.18.5.1 Dopamine

Impairments in the acquisition of various conditioned avoidance behaviors following depletion of dopamine in the nigrostriatal pathway memory provided the initial evidence of a possible role for striatal dopamine in procedural learning and memory (Neill et al., 1974; Zis et al., 1974). Subsequent research demonstrated that posttraining electrical stimulation of the nigrostriatal bundle enhances memory (Major and White, 1978), and this effect is blocked by administration of the dopamine receptor antagonist pimozide (White and Major, 1978). An enhancement of procedural memory is also observed following posttraining injections of the indirect catecholamine agonist amphetamine directly into the dorsal striatum (Carr and White, 1984). Moreover, in a manner analogous to the double dissociation produced by irreversible lesions, posttraining intracerebral infusions of amphetamine (Viaud and White, 1989) or the dopamine D2 receptor agonist quinpirole (White and Viaud, 1991) into the ventrolateral dorsal striatum selectively enhance procedural memory involving olfactory sensory information, whereas infusion of these drugs into the posteroventrolateral dorsal striatum selectively enhances procedural memory involving visual sensory information. The latter findings suggest that dopamine release in the dorsal striatum enhances memory consolidation underlying procedural memory in a site-specific manner that is dependent on the nature of the sensory input provided by corticostriatal projections.

The first study to directly compare the role of dopaminergic function in the dorsal striatum in declarative and procedural learning and memory utilized versions of the two radial maze tasks described earlier (Packard and White, 1991). In a declarative memory version of the task, rats were first allowed to obtain food from four of eight randomly selected maze arms. They were then removed from the maze and received an intradorsal striatal injection of saline vehicle, amphetamine, the dopamine D1 receptor agonist SKF 38393, or the dopamine D2 receptor agonist quinpirole. Eighteen hours later, the rats were returned to the maze for a retention test with all eight maze arms open, and only the four arms that had not been visited prior to the delay contained food. In a procedural memory version of the task, rats obtained food rewards by visiting four randomly selected and illuminated maze arms. Rats were removed from the maze following training on day 5 and received an intradorsal striatal injection of either vehicle, amphetamine, SKF 38393, or quinpirole and were returned for a retention test 24 h later. Posttraining injection of all three dopamine agonists enhanced memory in the procedural memory radial maze task but had no effect on memory in the declarative memory radial maze task (Packard and White, 1991). Similarly, in a cued water maze task in which a visible escape platform is moved to a new spatial location on each trial, procedural memory consolidation is enhanced by posttraining peripheral injections of amphetamine and quinpirole

(Packard and McGaugh, 1994) and by intradorsal striatum infusions of amphetamine (Packard et al., 1994; Packard and Teather, 1998). In contrast, posttraining intradorsal striatal infusions of amphetamine have no effect on memory in a declarative/cognitive version of the water maze task in which rats are trained to swim to a hidden escape platform that is located in the same spatial location across trials.

In each of the above studies, posttraining intradorsal striatal infusions of amphetamine or direct dopamine agonists that were delayed until 2 h after training did not enhance memory. The time-dependent nature of the effects of the posttraining infusions suggest that the drug treatments enhanced the consolidation of procedural memory and argue against the possibility that the drugs affected behavior by influencing nonmnemonic factors (McGaugh, 1989). Posttraining intradorsal striatal injection of the dopamine receptor antagonist cis-flupenthixol impairs procedural memory in the radial maze (Legault et al., 2006), suggesting that intact dopamine function is a necessary component of habit formation.

Whereas extensive evidence implicates dorsal striatal dopamine in the initial consolidation of procedural memory, other findings suggest that dopaminergic function in this brain region may not be necessary for the expression of stimulus–response habits after they have been acquired (but see also Aosaki et al., 1994). For example, 6-hydroxydopamine lesions of the nigrostriatal pathway impair acquisition of active avoidance conditioning but do not affect task performance when the lesions are produced after acquisition has occurred (Zis et al., 1974). In addition, relative to early stages of training, significant decreases in neuronal responses of midbrain dopamine neurons are observed in monkeys following extended habit training (Ljungberg et al., 1992), and peripheral administration of dopamine receptor antagonists impair performance of a simple appetitive response only during early stages of training (Choi et al., 2005).

Taken together, evidence indicating a role for dorsal striatal dopamine in memory consolidation but not the expression of procedural memory is consistent with the hypothesis that dopamine release may act as a reinforcing signal in the initial formation of stimulus–response habits (White, 1989a). According to this view, dopamine release in the dorsolateral striatum may function as the proverbial stamp or glue (e.g., Thorndike, 1933) that binds stimulus–response associations rather than providing a representation of a specific stimulus or response. Note that the hypothesized reinforcing effect of dopamine on habit formation in the dorsal striatum is active in both appetitively and aversively motivated habit learning tasks (Packard and White, 1991; Packard and McGaugh, 1994; Packard and Teather, 1998). Therefore, this dopaminergic function is conceptually different (White, 1989b) than the putative reward signal often associated with dopamine release in the nucleus accumbens. In contrast to the stimulus–response learning mediated by the dorsal striatum, the nucleus accumbens has been implicated in stimulus-reward learning (for review, see Cador et al., 1989) and hippocampus-dependent declarative memory (for review, see Setlow, 1997).

3.18.5.2 Glutamate

Glutamatergic input to the dorsal striatum is supplied primarily via corticostriatal projections (Fonnum et al., 1981). Glutamate release in the dorsal striatum resulting from activation of corticostriatal pathways is hypothesized to provide sensory input critical to the formation of stimulus–response habits (White, 1989; White et al., 1994), and behavioral evidence is consistent with a role for this transmitter in procedural learning. For example, in a cued water maze task in which rats are trained to swim to a visible escape platform, procedural memory consolidation is impaired by posttraining intradorsal striatal injection of the glutamatergic *N*-methyl-D-aspartate (NMDA) receptor antagonist AP5 (Packard and Teather, 1997) and enhanced by injection of glutamate (Packard and Teather, 1999). In contrast, posttraining intradorsal striatal infusions of AP5 or glutamate have no effect on memory in a declarative version of the water maze task in which rats are trained to swim to a hidden escape platform that is located in the same spatial location across trials. The role of dorsal striatal glutamate in procedural memory is not limited to the fast excitatory neurotransmission mediated by NMDA receptor activation, as posttraining intrastriatal infusions of metabotropic glutamate receptor antagonists (i.e., MCPG, ACPD) also impair memory consolidation in procedural, but not declarative, memory water maze tasks (Packard et al., 2001).

Further evidence of a selective role for dorsal striatal glutamate in procedural learning and memory was obtained using the dual-solution plus-maze task (Packard, 1999). As described previously, rats that are given extended training in this task eventually transition from the use of hippocampus-dependent place learning to dorsal striatal-dependent response learning

(Packard and McGaugh, 1996). Interestingly, the transition to procedural learning can be facilitated by posttraining intradorsal striatal injections of glutamate. Specifically, intradorsal striatal injections of glutamate following initial training trials in the plus-maze result in the predominant use of response learning during an early probe trial on which control rats predominantly display place learning. Thus, in a task for which a declarative and a procedural learning strategy each provide an adequate solution, an increase in glutamatergic tone in the dorsolateral striatum during early learning appears to favor a more rapid adoption of procedural/response learning. In contrast, posttraining intrahippocampal infusions of glutamate following early training in the plus-maze prevents the transition to procedural learning that is normally produced by extended training. This finding suggests that a relative increase in glutamatergic tone in the hippocampus during early training is detrimental to the development of dorsal striatal-dependent procedural memory.

Consistent with an enhancing function of glutamate on memory consolidation underlying procedural learning (Packard, 1999), infusions of the NMDA receptor antagonist AP5 into the dorsolateral striatum impair acquisition of response learning in a plus-maze (Palencia and Raggozino, 2005). The region of the dorsal striatum targeted in these two latter studies receives glutamatergic input from somatosensory cortex (Fonnum et al., 1981; McGeorge and Faull, 1989). Therefore, similar to dopamine (Viaud and White, 1989, 1991), glutamatergic input to lateral regions of the dorsal striatum may enhance procedural memory in a site-specific manner that is organized based on the nature of the sensory information provided by the cortex. Moreover, infusions of AP5 into the dorsomedial striatum do not impair acquisition of response learning in the plus-maze (Palencia and Ragozzino, 2004), consistent with evidence from the lesion studies reviewed earlier indicating that this region of the dorsal striatum does not mediate procedural learning.

3.18.5.3 Acetylcholine

Prominent cholinergic systems (e.g., the basal forebrain cholinergic system) provide diffuse projections to widespread regions of the mammalian brain. In contrast, acetylcholine within the dorsal striatum is contained within a population of interneurons (Lynch et al., 1972). Numerous studies examining the effects of posttraining intracerebral injections of acetylcholine agonist and antagonist drugs on avoidance behavior implicate dorsal striatal cholinergic activity in consolidation of procedural memory (Haycock et al., 1973; Prado-Alcala and Cobos-Zapian, 1977, 1979; Prado-Alcala et al., 1981; Packard et al., 1996). Taken together, these several findings indicate that posttraining intrastriatal infusions of cholinergic agonists (e.g., oxotremorine, choline) enhance procedural memory consolidation in a time-dependent manner, whereas cholinergic antagonists (e.g., atropine, scopolamine) impair memory. In addition, immunotoxin-induced ablation of striatal cholinergic neurons impairs acquisition of a tone-cued T maze task but does not impair declarative memory in a hidden platform water maze task (Kitabatake et. al., 2003), suggesting that the facilitatory role of striatal acetylcholine may be selective for procedural memory.

A series of experiments using intracerebral microdialysis to monitor neurotransmitter release in the hippocampus and dorsolateral striatum during performance of the dual-solution plus-maze task suggests that the relative amount of acetylcholine release in these two brain regions influences the use of striatal-dependent procedural learning (for review, see Gold, 2004). For example, following training in the plus-maze, rats that exhibit response learning on a subsequent probe trial also display a higher ratio of acetylcholine release in the dorsolateral striatum relative to the hippocampus, whereas the opposite pattern of acetylcholine release is observed in rats displaying place learning (McIntyre et al., 2003). In addition, the transition from hippocampus-dependent place learning to dorsal-striatal response learning that occurs with extended training in the plus-maze (e.g., Packard and McGaugh, 1996; Packard, 1999) coincides temporally with an asymptotic value of acetylcholine release in the dorsolateral striatum (Chang and Gold, 2003). A similar relationship between increases in acetylcholine release and transition from a spatial strategy to a response learning strategy was observed in rats trained in a food-rewarded Y maze task (Pych et al., 2005).

Finally, the cholinergic interneurons in the striatum appear to correspond to the tonically active neurons (TANs) that have been identified in this brain structure using *in vivo* electrophysiological recordings (for review, see Zhou et al., 2002). During procedural sensorimotor learning, striatal TANs develop responsiveness to conditioned stimuli (reflected in part as a brief pause in tonic firing) and are hypothesized to integrate dopaminergic and

cholinergic transmission in the striatum and ultimately influence the activity of afferent projection neurons (Aosaki et al., 1994). The idea that dopamine and acetylcholine interact to influence striatal-dependent procedural learning is supported by several pharmacological studies in rats (for reviews, see Beninger, 1983; White et al., 1994).

In summary, several lines of evidence implicate dorsal striatal dopamine, glutamate, and acetylcholine in stimulus–response procedural learning. Similar to the effects of irreversible and reversible brain lesions, posttraining pharmacological manipulations also result in a double dissociation of dorsal striatal and hippocampal involvement in procedural and declarative memory, respectively. For example, in the radial maze, water maze, and plus-maze, intrahippocampal infusions of dopaminergic and glutamatergic drugs selectively affect consolidation underlying declarative memory. Thus, as multiple memory systems evolved in the vertebrate brain (Sherry and Schacter, 1987), a role for specific neurotransmitters in different types of memory appears to have been conserved. A challenge for future research is to understand how activity of essentially the same neurotransmitters can differentially influence the type of information acquired in multiple memory systems. The relative activation of transmitter systems produced by engaging in a particular learning task appears to shape the participation of different brain structures in guiding learned behavior (Packard, 1999; Gold, 2004; Korol, 2004). However, future research investigating potential differences in the physiological characteristics of the various forms of synaptic plasticity that have been observed in brain structures mediating declarative and procedural memory (e.g., long-term potentiation and long-term depression; Garcia-Munoz et al., 1992; Lovinger et al., 1993; Charpier and Deniau, 1997; Fino et al., 2005) may ultimately help define the neural mechanisms that allow independent brain systems to acquire different types of information in a given learning situation.

3.18.6 Procedural Learning Beyond the Dorsal Striatum: Amygdala and Stimulus-Affect Associations

In addition to findings implicating the dorsal striatum in procedural learning involving stimulus–response habits, other research suggests that the amygdala may mediate a form of procedural learning in which stimulus–affect associations are acquired. This hypothesis is consistent with extensive evidence indicating involvement of the amygdala in specific fear conditioning paradigms (for reviews, see Davis, 1992; LeDoux, 1995; *See* Chapter 3.24). However, the role of the amygdala in stimulus–affect procedural learning is clearly not limited to aversively motivated tasks (e.g., Cador et al., 1989). For example, the functional integrity of the basolateral amygdala is necessary for acquisition of conditioned place preference behavior for both natural rewards (e.g., food, McDonald and White, 1993; Schroeder and Packard, 2002) and addictive drugs (e.g., amphetamine; Hiroi and White, 1991; Hsu et al., 2002). In a conditioned place preference task, rats are confined on alternating days to one distinct environmental context paired with natural or drug rewards and a second context that is not paired with the rewarding treatment. On a reward-free test session given following training, the amount of time spent in the two environments is measured, and rats demonstrate a reliable preference for the environment previously paired with the rewarding stimulus. The conditioned place preference task has been used to demonstrate a double dissociation between the roles of the basolateral amygdala and dorsal striatum in stimulus–affect and stimulus–response procedural learning (McDonald and White, 1993). Specifically, lesions of the basolateral amygdala but not dorsal striatum impair acquisition of stimulus–affect learning underlying conditioned place preference behavior. In contrast, lesions of the dorsal striatum but not basolateral amygdala impair acquisition of stimulus–response learning underlying simultaneous visual discrimination behavior.

Finally, activation of efferent basolateral amygdala projections can act to modulate memory consolidation occurring in other brain structures, including declarative memory processes mediated by the hippocampus and procedural learning mediated by the dorsal striatum (e.g., Packard et al., 1994; for review, see Cahill and McGaugh, 1998; McGaugh, 2002). The modulatory role of the basolateral amygdala on memory consolidation is associated in part with hormonal influences on emotional arousal (for review, see McGaugh, 2004; *See* Chapter 3.26). Moreover, an organism's emotional state may interact with amygdala function to influence the relative use of multiple memory systems. For example, peripheral and intrabasolateral amygdala injections of anxiogenic drugs result in a predominant use of dorsal striatal-dependent procedural learning in the dual-solution plus-maze task (Packard and

Wingard, 2004). Finally, the memory storage and modulation views have at times been contrasted as mutually exclusive and competing theories of amygdala function (e.g., Cahill et al., 1999; Fanselow and LeDoux, 1999). However, a time-limited modulatory role for the basolateral amygdala in some types of learning and memory (e.g., hippocampus-dependent declarative or dorsal striatal-dependent habit memory) does not necessarily rule out a possible long-term role for this structure in stimulus–affect procedural learning and memory (or vice versa).

3.18.7 Conclusions

Significant progress has been made in identifying the neuroanatomical and neurochemical bases of stimulus–response habit learning in lower animals. Extensive evidence supports the hypothesis that this form of procedural learning is mediated by a neural system that contains the dorsal striatum as a primary component. Studies employing irreversible and reversible brain lesion techniques have dissociated the role of the dorsal striatum in procedural and declarative memory. In addition, pharmacological experiments indicate a selective role for dorsal striatal dopamine, acetylcholine, and glutamate in memory consolidation underlying stimulus–response procedural learning.

Finally, although the present chapter focused on studies involving rats, it is important to note that similar evidence for the role of the dorsal striatum in procedural learning also exists in nonhuman primates (e.g., Teng et al., 2000; Fernandez-Ruiz. et al., 2001) and humans (e.g., Knowlton et al., 1996; for reviews, see Packard and Knowlton, 2002; *See* Chapter 3.17). Understanding the influence of the dorsal striatal habit learning system on human behavior ranging from adaptive social interaction and self-regulation (e.g., Lieberman, 2000; Wood et al., 2002) to maladaptive psychopathology (e.g., White, 1996; McDonald et al., 2004; Marsh et al., 2004; Everitt and Robbins, 2005) is an exciting and challenging prospect for future research.

3.19 Procedural Learning: Classical Conditioning

A. M. Poulos, University of California at Los Angeles, Los Angeles, CA, USA

K. M. Christian, National Institutes of Health, Bethesda, MD, USA

R. F. Thompson, University of Southern California, Los Angeles, CA, USA

3.19.1 Introduction

The two best understood and most extensively studied aspects of procedural learning are classical conditioning of discrete skeletal muscle responses and conditioning of fear. Indeed, more is known about the neural substrates of these two forms of learning than about any other aspects of learning and memory (*See* Chapter 4.11). A schema illustrating the different forms or aspects of memory is shown in **Figure 1**. The major distinction is between declarative and procedural memory (see Squire and Knowlton, 1994). Classical or Pavlovian conditioning is the *sine qua non* of procedural memory; it is defined by the procedure used. The "neutral" conditioned stimulus (CS) and the reflex-eliciting unconditioned stimulus (US) are presented paired together, with CS onset preceding US onset, and the outcome compared to various control procedures where the stimuli are not paired together. The stimuli are presented to the organism regardless of what the organism does, in contrast to instrumental or operant learning, where the organism's response can control the occurrence of the stimuli, e.g., responding so as to avoid presentation of the US.

Another way of distinguishing between declarative and procedural memory is in terms of awareness – declarative memory provides the capacity for conscious recollection of facts and events, whereas procedural memory is typically not accessible to conscious recollection – it can't be brought to mind and declared. Rather, procedural memory is expressed through performance (see Clark and Thompson, in press, for a more detailed discussion and history of these concepts).

Classical conditioning provides a temporal structure where the organism learns about the causal fabric of the environment. The CS provides the organism with information concerning the subsequent occurrence of another stimulus. However, mere temporal pairings of the CS and US, simple contiguity, are not sufficient for learning. Instead, it is the contingency, the probability that the CS will be followed by the US, that determines learning. As Rescorla showed in classic studies, if there are many presentations of the US alone, as well as paired presentations of CS and US, little or nothing may be learned (see Rescorla, 1988). Indeed the learning that occurs in classical conditioning is a good predictor of the probability one stimulus will be followed by

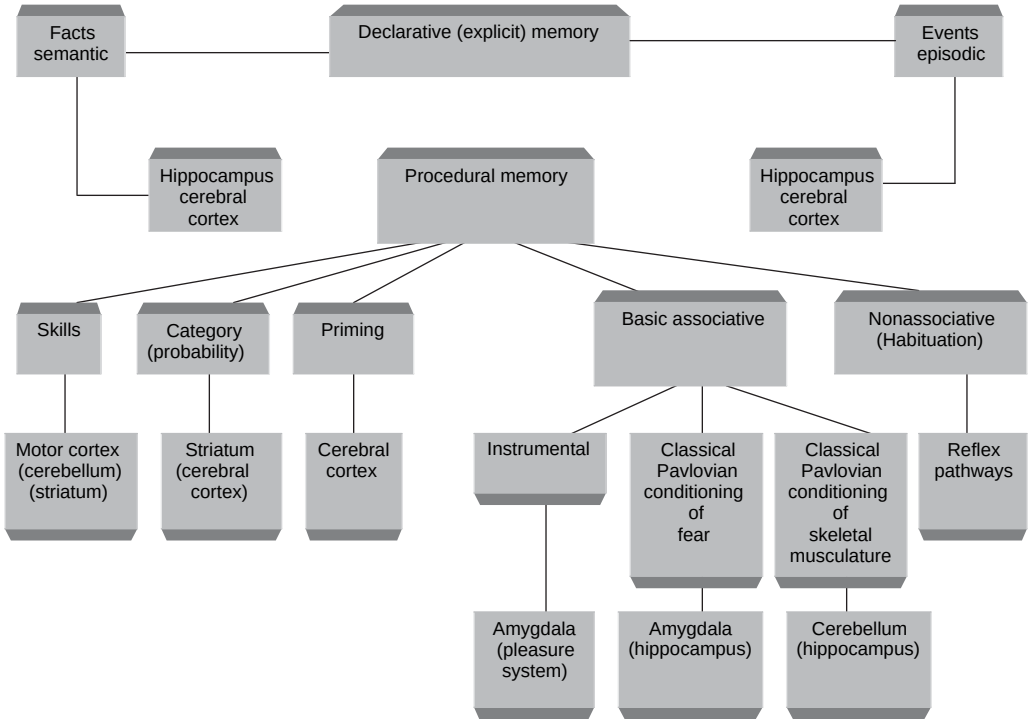

Figure 1 Taxonomy of long-term memory and the putative associated neural structures. Adapted from Squire LR (1998) Memory systems. *C. R. Acad. Sci. III* 321: 153–156, with permission.

another. This causal aspect of classical conditioning has led many to believe it is the most basic aspect of learning and memory.

Here, we focus on providing a comparative analysis of the behavioral and neurobiological mechanisms of two of the most well-understood forms of classical conditioning: eyeblink and fear conditioning.

3.19.2 Classical Conditioning of the Eyeblink Response

Eyeblink conditioning is perhaps the most widely studied form of procedural learning in mammals, including humans. In standard delay conditioning, a tone or a light precedes and coterminates with a reflex-eliciting stimulus such as a puff of air to the cornea. Following several presentations of these paired stimuli, an eyeblink conditioned response (CR) will develop that reflects the learned contingency between the CS and US. Extensive investigation into the neural substrates of this associative memory has resulted in perhaps the most complete description of mammalian memory formation to date (see Thompson and Krupa, 1994; Thompson and Kim, 1996; Kim and Thompson, 1997; Yeo and Hesslow, 1998; Nores et al., 2000; Steinmetz, 2000a,b; Woodruff-Pak and Steinmetz, 2000; Christian and Thompson, 2003, for reviews).

3.19.2.1 The Nature of the Eyeblink Conditioned Response

Gormezano et al. (1962) showed some years ago in separate studies in the rabbit that conditioned eyeball retraction, nictitating membrane (NM) extension, and external eyelid closure all had essentially identical acquisition functions. Simultaneous recording of NM extension and external eyelid closure (electromyographic (EMG) recordings from *orbicularis oculi*) during acquisition and extinction showed that they were, in essence, perfectly correlated, both within trials and over training (McCormick et al., 1982c; Lavond et al., 1990). Furthermore, some degree of conditioned contraction of facial and neck musculature also developed and was also strongly correlated with NM extension. These observations led to characterization of the CR as a "synchronous facial 'flinch' centered about closure of the eyelids and extension of the NM" (McCormick et al., 1982c: 773; see Thompson and Krupa, 1994, for overview). Substantial learning-induced increases in neuronal unit activity that correlate very closely with the conditioned NM extension response have been reported in several motor nuclei: oculomotor, trochlear, motor trigeminal, abducens, accessory abducens, and facial. These are all components of the same global CR involving, to the extent studied, essentially perfectly coordinated activity in a number of muscles and associated motor nuclei. The NM extension response is but one component of the CR. The suggestion that different motor nuclei might somehow exhibit different CR in the eyeblink conditioning paradigm (Delgado-Garcia et al., 1990) is not supported by evidence.

The CR and the unconditioned response (UR) are similar in eyeblink conditioning in the sense that, to a large extent, the same muscles and motor nuclei are engaged. However, the CR and the UR differ fundamentally in a number of respects. The minimum onset latency of the CR to a tone CS in well-trained rabbits, measured as NM extension, is about 90–100 ms; the minimum onset latency of the NM extension UR to a 3-psi corneal airpuff US in the rabbit is about 25–40 ms. Perhaps most important, the variables that determine the topographies of the UR and CR are quite different. The topography of the UR is under the control of the properties of the US: for example, stimulus intensity, rise-time, and duration. In marked contrast, the topography of the CR is substantially independent of the properties of the US and is determined primarily by the interstimulus interval (the CS-US onset interval) – the CR peaking at about the onset of the US over a wide range of effective CS-US onset intervals (Coleman and Gormezano, 1971; Steinmetz, 1990a). This key property of the CR cannot be derived from the properties of the US or the UR. The CR and the UR also differ in that certain components of the UR can be elicited separately by appropriate peripheral stimuli, but the CR always occurs as a global coordinated response (McCormick et al., 1982c). Another important difference is that the CR exhibits much greater plasticity in recovery from lesions of the motor nuclei that impair performance of the UR than does the UR itself (Disterhoft et al., 1985; Steinmetz et al., 1992a).

In sum, the conditioned eyeblink response involves highly coordinated activity in a number of motor nuclei and muscles; it is one global defensive response that is conditioned to a neutral stimulus as a result of associative training. Electrical stimulation of the small critical region of the cerebellar interpositus nucleus (see following) elicits this full complement of coordinated behaviors; it is a 'higher motor program.' The very small lesion of interpositus nucleus, which is effective in completely and permanently abolishing

the conditioned NM extension response, also completely and permanently abolishes all other components of the CR that have been studied—eyeball retraction, external eyelid closure, orbicularis oculi EMG—without producing any impairment in performance of the reflex response (Steinmetz et al., 1992a).

3.19.2.2 Brain Systems Engaged in Eyeblink Conditioning

Electrophysiological recordings of neural activity in eyeblink conditioning indicate that a number of brain areas and systems become engaged, most prominently motor nuclei, the hippocampus, and the cerebellum (see Thompson and Kim, 1996; Steinmetz et al., 2001; Christian and Thompson, 2003, for overviews). In all these systems neuronal activity in the CS period increases over the course of learning and precedes the onset of the behavioral CR within trials. Indeed, this increased pattern of action potential discharges in the hippocampus and cerebellum predicts the occurrence and the actual temporal form of the CR (but not the reflex response). In standard delay conditioning when the CS and the US overlap, the cerebellar system is critical, but the hippocampal system is not (see below and Berger et al., 1986; Thompson and Krupa, 1994, for overviews.) Within the cerebellar system, the following regions developed the predictive response: relevant motor nuclei, a region of the fifth nucleus, various reticular brainstem regions, the cerebellar cortex (ansiform and anterior lobes), the cerebellar interpositus nucleus, the pontine nuclei, and the red nucleus (McCormick et al., 1983).

3.19.2.3 The Cerebellar System

3.19.2.3.1 Lesions

The initial discovery of the key role of the cerebellum in eyeblink conditioning involved both large aspiration lesions including cerebellar cortex and nuclei and electrolytic lesions of the dentate-interpositus nuclear region (McCormick et al., 1981). Neuronal recordings in both cortex and nuclei showed learning-induced increases of neuronal unit activity that preceded and predicted the occurrence of the behavioral CR, as noted earlier. Stimulation of the critical nuclear region elicited the eyeblink before training; the circuit is hard-wired from nuclei to behavior, as noted. In a subsequent series of studies it was found that the key nuclear region is the anterior lateral interpositus nucleus ipsilateral to the trained eye. Very large lesions of the cerebellar cortex that did not damage the interpositus nucleus did not abolish the behavioral CR, although CR latency was altered such that the eye closed and opened before the onset of the US – the timing of the behavioral response was no longer adaptive (McCormick and Thompson, 1984a,b; Logan, 1991).

In these initial studies it was shown that the interpositus lesion effect was ipsilateral – it abolished the eyeblink CR on the side of the lesion but did not impair eyeblink conditioning of the contralateral eye, providing a control for possible nonspecific or state variables (McCormick et al., 1982a). Strikingly, no recovery of the CR is observed even with extensive postlesion training (Steinmetz et al., 1992b). Furthermore, if the lesion is made before training, learning is completely prevented. These lesions had no effects at all on performance of the UR. There have now been more than 30 studies on several species of mammals showing that appropriate lesions of the anterior interpositus nucleus before training completely prevent learning of the eyeblink and other discrete responses and completely and permanently abolish already learned responses (Christian and Thompson, 2003).

Kainic acid lesions of the interpositus as small as about $1\,mm^3$ in the anterior lateral region of the nucleus abolished the CR, indicating extreme localization of the critical region and ruling out the possibility that fibers of passage were involved (Lavond et al., 1984b). Finally, lesions of the output of the cerebellar nuclei, the superior cerebellar peduncle (scp), abolished the behavioral CR with no effect on the UR (McCormick et al., 1982b; Rosenfeld et al., 1985; Voneida, 2000 (limb flexion CR in cat)). It is important to emphasize that the cerebellar interpositus nucleus is essential for the learning of all discrete movements trained with an aversive US: eyeblink, limb flexion, head turn, etc. To the extent tested, the memory traces for all those learned movements are stored at separate loci in the interpositus nucleus. Eyeblink conditioning has simply been the most widely studied, although there is also considerable evidence for head turn and for limb flexion conditioning (see Voneida, 2000; Mintz and Wang-Ninio, 2001; Christian and Thompson, 2003).

Results of clinical studies of eyeblink conditioning in humans with brain damage are strikingly parallel to the infrahuman animal literature. Appropriate

cerebellar lesions markedly impair or completely prevent learning of the standard delay eyeblink conditioning task; if the cerebellar damage is unilateral, only the ipsilateral eye is affected (Daum et al., 1993; Woodruff-Pak, 1997). In general, effective lesions are large, including damage to cerebellar cortical regions and nuclei, although exact extent of damage is difficult to determine from the brain scans. Schugens et al. (2000) conclude that damage to cerebellar nuclei appears likely in most of these studies.

3.19.2.3.2 Recordings

As noted briefly, recordings of neuronal unit activity from the interpositus nucleus during eyeblink conditioning revealed populations of cells in the critical region of the nucleus that, as a result of training, discharged prior to the execution of the learned eyeblink response and fired in a pattern of increased frequency of response that predicted the temporal form of the behavioral CR (the 'neuronal model' of the CR in at least 20 studies to date in several species of mammals (Christian and Thompson, 2003). Single-unit activity sampled from the interpositus and immediately adjacent regions can be categorized into several distinct response patterns (Tracy, 1995). Some cells show stimulus-evoked activity to the CS and/or the US over the course of training, a pattern that demonstrates appropriate convergence of sensory information in the interpositus but does not directly support a role for the interpositus in CR generation. Likewise, some cells show behavior-related changes in firing patterns coincident with but not prior to the onset of the CR. However, many cells, particularly in the critical region of the anterior dorsolateral interpositus, significantly increase firing in a precise temporal pattern that is delayed from the onset of the CS, occurs before the onset of the behavior, and is temporally correlated with the onset of the behavior. It is clear from recordings such as these that neurons in the interpositus are capable of contributing to the generation of the CR. While there are certainly several distinct response profiles for single cells that are likely to reflect functional subdivisions within the population of neurons in the deep nuclei, it is compelling that multiple- and single-unit activity recorded from the critical interpositus region reflects an increase in activity appropriately timed to effect the downstream motor pathway and culminate in the well-timed CR.

3.19.2.4 The Pathways

A large literature is in general agreement in identifying the essential circuitry for classical conditioning of eyeblink and other discrete responses. This circuitry follows closely the well-established anatomy of the cerebellar system (Brodal, 1981) and is in general accord with classical theories of cerebellar learning (Marr, 1969; Albus, 1971; Ito, 1972; Gilbert, 1975; Eccles, 1977). We summarize this work only briefly here. See Christian and Thompson (2003) for detailed citation of evidence.

3.19.2.4.1 The UR pathways

The eyeblink reflex in the rabbit is a coordinated response involving simultaneous and perfectly correlated external eyelid closure, eyeball retraction, and resulting passive extension of the NM, as noted.

In terms of the reflex pathways, there are direct projections from neurons in regions of the trigeminal nucleus to the accessory abducens (and abducens) nuclei and to the facial nucleus, as well as indirect projections relaying via the brainstem reticular formation, at least to the facial nucleus. Although the CR and UR share many common features, there are critical qualitative differences between the two that include both variations in the intrinsic properties and the neural substrates responsible for each response (see earlier discussion). Standard eyeblink training procedures typically result in a progressive increase in the amplitude of the UR due to both associative and nonassociative factors (Steinmetz et al., 1992a). Interpositus lesions can impair the associative component of the UR increase (Wikgren et al., 2002).

Lesions of the interpositus that are successful in abolishing the CR have only a transient depressive effect on UR amplitude in initial postlesion assays at the same US intensity level used in prelesion training (Steinmetz et al., 1992a). Subsequent training fully restored UR amplitudes to prelesion levels, demonstrating a lack of interpositus involvement in the sustained eyeblink reflex modification following conditioning. Steinmetz et al. (1992a) investigated numerous parameters of the UR including amplitude, rise time, frequency, and latency in the same animals at several US intensities and found no significant lasting effects of interpositus lesions in any of these properties. Ivkovich et al. (1993) lowered US intensity levels to threshold to equate amplitudes of prelesion CRs and URs, and it was again

shown that interpositus lesions that completely abolished the CR had no significant effect on postlesion UR amplitude.

3.19.2.4.2 The CR pathway

Neurons in a localized region of the interpositus nucleus ipsilateral to the trained eye develop a neuronal model of the learned behavioral CR; lesions of this region selectively abolish the CR with no effect in the UR; electrical stimulation of this region evokes the eyeblink response before training (as noted). This region of the interpositus projects via the superior cerebellar peduncle to a region of the contralateral magnocellular red nucleus. Lesions of the peduncle abolish the CR, as do lesions of the key region of red nucleus, where neurons also show a model of the learned response. Stimulation of this rubral region also elicits the eyeblink response. The descending rubral pathways project contralaterally to premotor and motor nuclei, seventh for external eyelid closure, and accessory sixth and sixth for NM extension. Overwhelming evidence identifies this circuit as the efferent CR pathway for the conditioned eyeblink response (see detailed review in Thompson and Krupa, 1994). A similar pathway projecting to the spinal cord subserves classical conditioning of the limb flexion response in the cat (Voneida, 1999, 2000).

3.19.2.4.3 The CS pathway

The pontine nuclei send axons as mossy fibers directly to the cerebellar cortex and interpositus nucleus, mostly contralaterally. The pontine nuclei in turn receive projections from auditory, visual, somatosensory, and association systems, both cortical and subcortical. Appropriate lesions of the pontine nuclei can abolish the CR established to a tone CS but not a light CS, i.e., can be selective for CS modality (interpositus lesions abolish the CR to all modalities of CS) (Steinmetz et al., 1987). Lesions of the region of the pons receiving projections from the auditory cortex abolish the CR established with electrical stimulation of auditory cortex as a CS (Knowlton and Thompson, 1992; Knowlton et al., 1993). Extensive lesions of the middle cerebellar peduncle (mcp), which conveys mossy fibers from the pontine nuclei and other sources to the cerebellum, abolish the CR to all modalities of CS (Lewis et al., 1987).

Electrical stimulation of the pontine nuclei serves as a 'supernormal' CS, yielding more rapid learning than does a tone or light CS (Steinmetz et al., 1986; Tracy et al., 1998; Freeman and Rabinak, 2004). Stimulation of the mcp itself is an effective CS (Steinmetz, 1990a; Svensson and Ivarsson, 1999), and lesion of the interpositus nucleus abolishes the CR established with a pontine or middle peduncle stimulation CS (Steinmetz et al., 1986). When animals are trained using electrical stimulation of the pontine nuclei as a CS (corneal airpuff US), some animals show immediate and complete transfer of the behavioral CR and of the learning-induced neural responses in the interpositus nucleus to a tone CS (Steinmetz, 1990b) and complete transfer from peripheral CSs to mossy fiber stimulation in the mcp (Hesslow et al., 1999). These results indicate that the pontine–mcp stimulus and tone must activate a large number of memory circuit elements (neurons) in common. In sum, the mossy fiber system, coming mostly from the pontine nuclei, is the CS-activated pathway to the cerebellum (Thompson et al., 1997).

3.19.2.4.4 The US pathway

Neurons in the inferior olive (IO) send climbing fiber projections contralaterally directly to cerebellar cortex and interpositus nucleus. The critical region of the IO for eyeblink conditioning is the dorsal accessory olive (DAO), which receives predominantly somatosensory input relayed from the spinal cord and appropriate cranial nuclei, including nociceptive input (Brodal, 1981). Lesions of the critical region of the IO, the face representation in the DAO, completely prevent learning if made before training and result in extinction of the CR if made after training (McCormick et al., 1985; Mintz et al., 1994). Neurons in this critical DAO region do not respond to auditory stimuli (CS), respond only to US onset, and show no learning-related activity, and the US-evoked response decreases as animals learn (Sears and Steinmetz, 1991). Electrical microstimulation of this region serves as a very effective US (Mauk et al., 1986). All these data argue that the DAO-climbing fibers system is the essential US-reinforcing pathway for the learning of discrete responses (Thompson et al., 1998).

In a classic but largely forgotten study, Brogden and Gantt (1942) reported that stimulation of cerebellar white matter elicited discrete behavioral movements, e.g., limb flexion, head turn, eyeblink, and these movements so elicited could easily be conditioned to any neutral stimulus, e.g., light or sound. These observations have been replicated and extended in recent years (Thompson et al., 2000).

Swain et al. (1992) used a tone CS and showed that stimulation of cerebellar white matter in lobule HVI (rabbit) did indeed elicit movements: eyeblink, NM extension, and movements of the head and upper lip. These movements all conditioned, extinguished, and reconditioned to a tone CS in a manner identical to CRs established with aversive peripheral USs. Further, kainic acid lesions of the interpositus that spared fibers abolished both the CR and the white matter stimulation–elicited UR, thus ruling out antidromic activation via pontine nuclei or IO of the UR (Swain et al., 1999).

Shinkman et al. (1996) stimulated cerebellar cortical parallel fibers as a CS (white matter US) with similar results. In this study the parallel fiber stimulus (CS) intensity was well below movement threshold. With sufficiently intense stimulation, movements could be evoked by this parallel fiber stimulus. Interestingly, these were often quite different from the behavioral response (UR) evoked by the white matter US. However, as a result of training, the earlier subthreshold parallel fiber CS now evoked a CR that was identical to the white matter UR and often quite different from the suprathreshold response evoked by the parallel fiber stimulus prior to training. There is extraordinary plasticity in the organization of the parallel fiber actions on the cerebellar circuitry (see also Poulos and Thompson, 2004).

Evidence is consistent with stimulation of climbing fibers in cerebellar white matter as the US effective for learning. To our knowledge the IO-climbing fiber system is the only system in the brain, other than reflex afferents, where the exact response elicited by electrical stimulation can be conditioned to any neutral stimulus. Thus, such movements elicited by stimulation of the motor neocortex cannot be so conditioned (Loucks, 1935; Wagner et al., 1967; Thompson et al., 2000). We therefore argue that this system is the essential reinforcing pathway for the learning of discrete responses.

The interpositus nucleus sends direct GABAergic (GABA: gamma-aminobutyric acid) projections to the DAO (Nelson and Mugnaini, 1989). Hence, as learning-induced increases in interpositus neuron activity develop, inhibition of the DAO neurons will increase (Hesslow and Ivarsson, 1996). This accounts for the fact that US-evoked activity in the DAO decreases as learning develops (Sears and Steinmetz, 1991), consistent with the Rescorla and Wagner (1972) formulation. This also appears to serve as a part of the neural circuit essential for the behavioral learning phenomenon of 'blocking,' where prior training to one CS, e.g., tone, prevents subsequent learning to a light CS when it is then presented together with the tone in paired compound stimulus training (Kamin, 1969). Infusion of picrotoxin in the DAO to block the GABA inhibition from the interpositus during compound stimulus training completely blocks the development of behavioral blocking (Kim et al., 1998).

3.19.2.4.5 Conjoint activation of CS and US pathways

If the aforementioned hypotheses concerning the identities of the CS and US pathways are correct, it should be possible to train behavioral conditioned responses by conjoint stimulation of these pathways. Steinmetz et al. (1989) stimulated the pontine nuclei – mossy fibers as a CS (below movement threshold) and DAO-climbing fibers as a US. Stimulus (US)-elicited movements included eyeblink, head turn, and limb flexion. The stimulus-elicited movements were learned to the mossy fiber stimulation CS just as was the case for peripheral CSs. In an even more reduced preparation, the CS was stimulation of parallel fibers by an electrode (concentric pair of ovoids) resting on the surface of the cortex of lobule HVI, and the US was a stimulation delivered through an electrode pair in the white matter directly beneath the surface electrode, as noted (Shinkman et al., 1996). Again, the movements elicited by white matter stimulation were learned in a normal fashion to the parallel fiber stimulation CS. It is tempting but premature to conclude that this procedure established a memory trace in the localized region of cortical tissue activated.

3.19.2.4.6 Reversible inactivation

Although the evidence cited is consistent with the interpositus nucleus being the site of the conditioned eyeblink memory trace, it does not prove this hypothesis. Predictive neuronal models of the CR develop in the interpositus nucleus, the red nucleus, and the motor nuclei, as noted. Further, lesions of the interpositus, of the scp (that conveys all the efferent projections from the interpositus), and of the red nucleus all abolish the CR with no effect on the UR. Lesions of the motor nuclei of course abolish both the CR and the UR. The technique of reversible inactivation was used to determine where within the circuit the memory trace was formed and stored (see Clark and Lavond, 1993; Thompson

et al., 1993; Thompson and Krupa, 1994; Christian and Thompson, 2003, for details).

Several parts of the cerebellar circuit, illustrated in **Figure 2**, have been reversibly inactivated for the duration of training (eyeblink conditioning) in naive animals. Motor nuclei essential for generating UR and CR (primarily seventh and accessory sixth and adjacent reticular regions) were inactivated during standard tone–airpuff training. The animals showed no CRs and no URs during this inactivation training; indeed, performance was completely abolished. However, the animals exhibited asymptotic CR performance and normal UR performance from the very beginning of postinactivation training. Thus, performance of the CR and UR is completely unnecessary and makes no contribution at all to formation of the memory trace – the CR and the UR are completely efferent from the trace. Inactivation of the magnocellular red nucleus during training had no effect on the UR, but completely prevented expression of the CR. Animals showed asymptotic learned performance of the CR from the beginning of postinactivation training. Consequently, the red nucleus must be efferent from the memory trace.

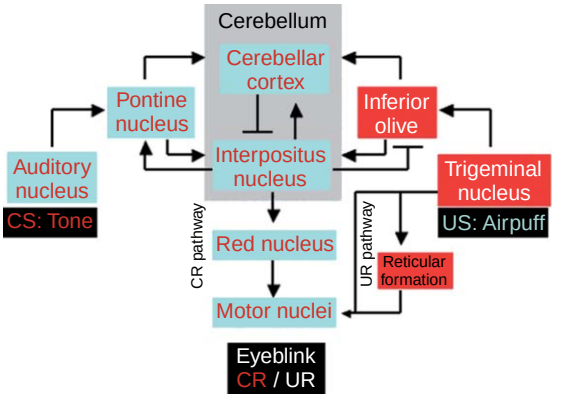

Figure 2 Simplified schemata of the neural circuits underlying Pavlovian eyeblink conditioning. In auditory eyeblink conditioning, information pertaining to a tone conditional stimulus (CS) is relayed to the cerebellar cortex and interpositus nucleus via auditory projections from the pontine nucleus, while nociceptive information about the airpuff unconditional stimulus (US) is conveyed by the trigeminal nucleus to the inferior olive, which in turn projects to both the cerebellar cortex and interpositus nucleus. Conditional eyeblink responses established and maintained within the cerebellar cortex and interpositus nucleus are relayed to the red nucleus. The final common out for both the conditional and unconditional eyeblink response is expressed via facial motor nuclei. Modified from Thompson DF and Krupa DJ (1994) Organization of memory traces in the mammalian brain. *Annu. Rev. Neurosci*. 17: 519–549, with permission.

Inactivation of the dorsal anterior interpositus and overlying cortex resulted in no expression of CRs during inactivation training and in no evidence of any learning during inactivation training. In subsequent postinactivation training, animals learned normally as though completely naive; they showed no savings at all relative to noninactivated control animals. If any part of the memory trace were established prior to the interpositus nucleus in the essential circuit, then the animals would have shown savings, but they did not. None of the methods of inactivation had any effect at all on the performance of the UR on US-alone trials. Infusions of very low doses of muscimol (1.0 nmole in 0.1 µl of vehicle) limited to the anterior lateral interpositus nucleus, (with no significant ^{3}H label in cerebellar cortex) completely prevented learning of the eyeblink CR.

Finally, the output of the cerebellum was inactivated by infusion of tetrodotoxin (TTX) in the scp during training. This inactivates both descending and ascending efferent projections of the cerebellar hemisphere. TTX infusion in the scp completely prevented expression of the CR (with no effect on the UR) during training. In subsequent postinactivation training the animals immediately showed asymptotic learned performance of the CR. Collectively, these data strongly support the hypothesis that the memory trace is formed and stored in the interpositus nucleus.

3.19.2.5 Mechanisms of Memory Storage in the Interpositus Nucleus

Infusion of GABA antagonists, picrotoxin or bicuculline methiodide, into the interpositus in trained animals blocks performance of the behavioral eyeblink CR and the neuronal unit model of the CR in the interpositus in a dose-dependent manner with no effects on the UR (Mamounas et al., 1987). Picrotoxin infusion in the interpositus during training completely prevents learning (Bao et al., 2002). Infusion of the $GABA_B$ antagonist baclofen in the interpositus during training similarly prevents learning and performance of the CR (Ramirez et al., 1997). These results suggest that GABA and its actions on GABA receptors in the interpositus are important for both learning and performance of the CR. However, equivalent doses of strychnine had no effect on the CR or the UR, suggesting that glycine receptors are not involved (Mamounas et al., 1987). Infusion of AP5 into the interpositus markedly impaired acquisition of the eyeblink CR (Chen

and Steinmetz, 2000). However, after learning, AP5 infusion had little effect on CRs. This argues for a role of glutamate *N*-methyl-D-aspartate (NMDA) receptors in the interpositus in acquisition but not performance of the CR.

Bracha et al. (1998) reported that infusion of anisomycin into the region of the interpositus nucleus impaired acquisition of the eyeblink CR but had no effect on expression of the CR. Gomi et al. (1999) reported that infusion of actinomycin D into the interpositus nucleus completely prevented acquisition of the eyeblink CR but had no effect on performance of the learned response. By the same token Chen and Steinmetz (2000) reported that infusion of the protein kinase inhibitor H7 into the interpositus markedly impaired acquisition but had no effect on performance of the learned response. Results of all these studies argue strongly that protein synthesis (both transcription and translation) in the interpositus nucleus is necessary for learning of the eyeblink CR, but not for its expression once learned. Indeed, Gomi et al. (1999) identified a kinase whose expression was increased in interpositus neurons following eyeblink conditioning. The cDNA was isolated, and the deduced amino acid sequence of the kinase contains the KKIAMRE motif, conserved among cell division cycle 2–related kinases. All these results argue for the formation of neuronal/synaptic plasticity, a memory trace, in the interpositus itself. Even with 1 month of overtraining or rest, the memory trace remains in the interpositus (Christian and Thompson, 2005).

Extremely important direct evidence for a strengthening of the mossy fiber–interpositus neuron synapses has been presented by Kleim et al. (2002), using eyeblink conditioning in the rat. They demonstrated a highly significant increase in the number of excitatory synapses in the interpositus nucleus but no change in inhibitory synapses following eyeblink conditioning, compared to unpaired stimulation control animals. We note that some years earlier Racine et al. (1986) reported the development of LTP in interpositus following mossy fiber tetanus in the rat *in vivo,* a result recently replicated *in vitro* by Linden (Aizenman and Linden, 2000).

In sum, the evidence is now very strong from behavioral, physiological, pharmacological, anatomical, and inactivation studies that the basic associative memory trace in eyeblink conditioning is established in the interpositus nucleus. The next step is to elucidate the causal chain from behavioral training to increased synaptic efficacy and synapse formation.

3.19.2.6 Cerebellar Cortex

After more than two decades of research, the role of the cerebellar cortex in eyeblink conditioning is still unclear and embedded in controversy (see Yeo and Hardiman, 1992; Christian and Thompson, 2003, for reviews). However, it is clear that it plays a very important role in normal learning – animals with large cortical lesions learn more slowly than normal and not as well. In the first study to explicitly address cerebellar cortical function in eyeblink conditioning, large aspiration lesions of ansiform or ansiform and paramedian lobules in well-trained rabbits resulted in the expression of short-latency, small-amplitude CRs (McCormick and Thompson, 1984b). Yeo and associates reported that lesions of lobule HVI of cerebellar cortex abolished the conditioned eyeblink response (Yeo et al., 1984, 1985). However, subsequent studies in several laboratories, including Yeo's, have been unable to replicate this result (e.g., Lavond et al., 1987; Clark et al., 1990; Harvey et al., 1993; Perrett and Mauk, 1995; Yeo and Hardiman, 1992).

In an experiment designed to assess the role of the cortex in acquisition, extensive unilateral lesions including complete removal of HVI and HVIIa lobules and significant portions of the anterior lobe were shown to significantly impair the rate of learning (Lavond and Steinmetz, 1989). Lesioned animals took seven times longer to reach criterion, and asymptotic levels of CR frequency were much reduced. Despite these specific learning deficits, animals were able to achieve significant levels of conditioned responding in the absence of HVI. This result was confirmed by another study in which extensive cortical lesions were shown to significantly impair the rate of acquisition but not prevent learning (Logan, 1991). Animals with complete or near-complete removal of HVI and crura I and II of the ansiform lobe took six times longer to reach criterion. Rabbits with less extensive damage to HVI and the ansiform lobe showed moderate decreases in learning rates. Both moderate and extensive lesions decreased asymptotic CR frequency, whereas extensive lesions also impaired CR magnitude and timing.

Using a different methodological approach to investigate cortical function, the HVI lobule has been temporarily inactivated via infusions of the $GABA_A$ receptor agonist muscimol, during both acquisition and retention. Muscimol acts to hyperpolarize neurons, prohibitively raising the firing threshold and thus disrupting the cortical output mediated by Purkinje cells. Muscimol inactivation

restricted to the ventral HVI region has no effect on the rate of acquisition or quality of the CRs (Krupa, 1993). Extensive cortical inactivation encompassing both HVI and portions of the anterior lobe significantly impairs but does not prevent acquisition and has no effect on the CR performance once the animal reaches asymptotic levels of conditioned responding (Krupa, 1993; Thompson et al., 2001). Similarly, reversible inactivation of the HVI region achieved with a cortical cooling probe significantly decreased the learning rate but did not disrupt CR expression in well-trained animals (Clark et al., 1997).

The great difficulty in all these studies is the limitation of the permanent lesion approach. The depths of cortical tissue in lobule HVI are only a mm or so above the critical region of the interpositus nucleus. It is impossible to remove all relevant cerebellar cortex without damaging the interpositus nucleus. To circumvent these anatomical complications, several attempts have been made to investigate the effects of functionally inactivating the entire cerebellar cortex. The most definitive of these studies tested acquisition of eyeblink conditioning in mutant mice (pcd mice) in which Purkinje cells degenerate approximately 2 weeks postnatally (Chen et al., 1996). Elimination of these sole-output neurons in the cortex effectively eliminates the cerebellar cortex itself. pcd mice show significant deficits in both the rate of acquisition and the asymptotic level of conditioning, but nevertheless express significant levels of learning and extinction in the absence of cortical input to the interpositus. Peak latencies of the CRs in the mutants were significantly decreased compared to wild-type mice, although the effect was not great. A later study confirmed that the interpositus was responsible for the residual learning, by demonstrating that bilateral lesions of the interpositus in pcd mice completely block acquisition (Chen et al., 1999). In a recent study, OX7-saporin, an immunotoxin selective for Purkinje cells, was infused intraventricularly prior to conditioning, and deficits in both acquisition and extinction were observed which correlated with cell loss in HVI and the anterior lobe (Nolan and Freeman, 2006).

Functional and reversible lesions of the entire cerebellar cortex can also be achieved through a targeted disruption of the Purkinje cell afferents at the level of the interpositus. In one study, application of the GABA antagonist picrotoxin into the anterior interpositus nucleus resulted in short-latency, reduced-amplitude, prolonged CRs but at a frequency similar to that observed in the absence of infusion (Garcia and Mauk, 1998). These results are contradicted by other studies in which picrotoxin infusions into the interpositus blocked the expression of CRs completely (Mamounas et al., 1987; Bao et al., 2002). A much more precise elimination of cortical input can be achieved through sequential infusions of muscimol and picrotoxin. Muscimol first blocks the synaptic transmission from the cortex, and the baseline level of excitability in the interpositus neurons is restored through application of picrotoxin (Bao et al., 2002). With this procedure, onset and peak latencies were decreased in well-trained animals, CR amplitudes were increased, and no effects (i.e., no CRs) were observed in naive animals. Although studies of cerebellar patients cannot address these questions with anatomical precision, it was recently reported that damage primarily to the cerebellar cortex impaired the acquisition and timing of conditioned eyeblink responses (Gerwig et al., 2005).

In sum, it is clear that the cerebellar cortex plays a critical role in normal learning and adaptive timing of the eyeblink CR. The cortex exerts inhibitory control over the interpositus neurons; this inhibition could control precisely the timing of interpositus neurons' activation by the CS to generate the CR. Further, a decrease in this inhibition could permit the necessary activation of the interpositus neurons to express the CR. The most prominent mechanism for decreasing Purkinje neuron activity is long-term depression (LTD) at parallel fiber synapses on Purkinje dendrites, first discovered by Masao Ito (see Ito, 1984).

The majority of evidence suggesting a role for cortical LTD in learning and memory comes from behavioral assays of mutant mice with deficits in LTD expression. There is a consistent relationship between deficits in eyeblink conditioning and deficits in cerebellar cortical LTD (Kim and Thompson, 1997). It has been shown that activation of metabotropic and ionotropic glutamate receptors (mGluR and AMPAR) on the Purkinje cell dendrites is necessary for the induction of LTD (Linden and Connor, 1993; Jeromin et al., 1996). Although the downstream signaling pathway is not entirely known, several key molecules have been identified. Factors required for LTD include Ca^{2+} influx via voltage-activated channels and transient protein kinase C (PKC) activation (Hansel et al., 2001). Mutant mice in which the mGluR1 subunit is not expressed, rendering the receptor nonfunctional, have shown deficient LTD and impaired eyeblink conditioning (Aiba et al., 1994). Phospholipase Cbetas (PLCbetas) are

downstream signaling molecules of mGluR activation, and the PLCbeta4 isoform is expressed selectively in Purkinje cells in the rostral cerebellum, including portions of HVI. Mutant mice deficient in PLCbeta4 also show impaired LTD and an impairment in acquisition of CRs (Kishimoto et al., 2001a; Miyata et al., 2001). Mutants lacking the $\delta 2$ subunit of the glutamate receptor exclusively in the cerebellar cortex are likewise impaired in LTD and delay eyeblink conditioning (Kishimoto et al., 2001b,c).

3.19.2.7 Eyeblink Conditioning and the Hippocampus

In eyeblink conditioning, neuronal unit cluster recordings in hippocampal fields CA1 and CA3 increase in discharge frequency in paired (tone CS–corneal airpuff US) training trials very rapidly, shift forward in time as learning develops, and form a predictive 'temporal model' of the learned behavioral response, both within trials and over the trials of training (Berger et al., 1976). To summarize a large body of research, the growth of the hippocampal unit response is, under normal conditions, an invariable and strongly predictive concomitant of subsequent behavioral learning (see reviews in Berger et al., 1986). This increase in neuronal activity in the hippocampus becomes significant by the second or third trial of training, long before behavioral signs of learning develop, as would be expected of a declarative memory system. This initial hippocampal unit increase is in the US period; increases in the CS period appear at about the time point in training when behavioral CRs appear. With continued training the hippocampal neuronal model eventually declines (Katz and Steinmetz, 1994).

Many neurons that could be identified as pyramidal neurons in CA1 and CA3 (antidromic stimulation and collision) showed learning-related increases in discharge frequency in the trial period. Typically, a given neuron modeled only some limited time period of the trial. Cumulating many such single pyramidal neuron responses produced the typical unit cluster model of the behavioral learned response. So the pyramidal neuron representation of the behavioral learned response is distributed over both space and time in the hippocampus. The high percentage of learning-influenced pyramidal neurons and their spatially distributed loci have been strikingly verified in studies by Disterhoft and associates (Disterhoft et al., 1986; de Jonge et al., 1990) using *in vitro* studies of hippocampal slices from trained versus control animals. The work described was all done using the basic delay paradigm, where hippocampal lesions do not impair simple acquisition (Schmaltz and Theios, 1972; Solomon and Moore, 1975). Similarly, humans with hippocampal-temporal lobe anterograde amnesia are able to learn simple acquisition of the eyeblink CR, but cannot describe it (Weiskrantz and Warrington, 1979).

3.19.2.7.1 Trace conditioning

Trace conditioning was first described by Pavlov; the CS terminates and there is a period of no stimulation between CS offset and US onset (as Pavlov stressed, the organism must maintain a 'trace' of the CS in the brain in order for the CS and the US to become associated). In eyeblink conditioning in animals, a typical trace interval is 500 ms. The trace CR is more difficult to learn than the standard 'delay' procedure where the CS and US overlap in time.

McEchron and Disterhoft (1997) reported marked increases in hippocampal neuronal activity in trace conditioning, as was reported earlier for delay conditioning. Further, with extensive training, the neuronal model declines. Very large bilateral removal of the dorsal plus some ventral hippocampus in rabbits markedly impaired subsequent acquisition of the 500-ms trace CR, an example of anterograde amnesia (Solomon et al., 1986; Moyer et al., 1990). Consistent with this finding, scopolamine at doses sufficiently low to have little effect on delay learning completely prevents acquisition of the trace CR (Kaneko and Thompson, 1997). If rabbits are first trained in the trace procedure, large bilateral hippocampal lesions made immediately after training completely abolish the trace CR (such immediate lesions have little effect on the delay CR). However, if these same hippocampal lesions are made a month after training, they do not impair performance of the trace CR at all (Kim et al., 1995).

To summarize, large bilateral lesions of the hippocampus made before training markedly impair learning of the trace CR. If the animals are first trained, lesions immediately after training abolish the trace CR, but lesions made 1 month after training have no effect on memory of the trace CR. These results are strikingly consistent with the literature concerned with the declarative memory deficit following damage to the hippocampal-medial temporal lobe system in humans and monkeys. These deficits have two key temporal characteristics: (1) profound and permanent anterograde amnesia, and (2)

profound but clearly time-limited retrograde amnesia. Subjects have great difficulty learning new declarative tasks/information and have substantial memory loss for events for some period just preceding brain damage (1 or more years in humans, 2–3 months for monkeys) but relatively intact memory for earlier events (Zola-Morgan and Squire, 1990). Very similar results were found for classical conditioning of fear to context in rats (Kim and Fanselow, 1992).

These results from studies on animals suggest that trace eyeblink conditioning provides a simple model of hippocampal-dependent declarative memory, a possibility strongly supported by studies of humans with hippocampal-medial temporal lobe amnesia. In brief, such patients are markedly impaired on acquisition of trace eyeblink conditioning if the trace interval is sufficiently long (see reviews by Clark and Squire, 1998; McGlinchey-Berroth, 2000). It is important to emphasize that lesions of the cerebellar interpositus nucleus completely and permanently abolish the trace conditioned eyeblink response (rabbits) (Woodruff-Pak et al., 1985).

Clark and Squire (1998, 1999) made the striking observation that awareness of the training contingencies in normal human subjects correlated highly with the degree of trace conditioning. They showed that awareness played no role in delay conditioning, that awareness does play a role in both single-cue and differential trace conditioning and that expectancy of US occurrence influenced trace but not delay conditioning (Clark and Squire, 2000; Manns et al., 2000a,b; Clark et al., 2001). They conclude that delay and trace conditioning are fundamentally different phenomena, delay inducing nondeclarative or procedural memory and trace inducing declarative memory. It would seem that this very simple procedural classical conditioning task, where the CS and US are separated by a very brief period of time, has converted the memory from a procedural memory to a declarative memory! Interestingly, new neurons persist in the dentate gyrus in trace but not delay eyeblink conditioning, and blocking formation of new neurons impairs trace but not delay conditioning (Gould et al., 1999a,b; Shors et al., 2001).

3.19.3 Classical Fear Conditioning

Within the past few decades Pavlovian fear conditioning has become one of the most intensely studied forms of mammalian procedural learning (*See* Chapter 4.11). In fear conditioning a discrete stimulus such as a tone or static features of the training context (i.e., shape, feel, lighting, and smell) is paired with an aversive stimulus. Upon return to the original training environment or presentation of the previously paired tone, fear is expressed as an array of autonomic, hormonal, and behavioral responses. The development of neurobiological, behavioral, molecular, and genetic methods and their application to rodent models of fear conditioning has yielded tremendous insight into our understanding of the neural substrates of Pavlovian fear conditioning (see Maren and Quirk, 2004; Walker and Davis, 2004; Fanselow and Poulos, 2005; Phelps and LeDoux, 2005, for reviews).

3.19.3.1 Nature of Conditional Fear

As described some years ago by Bolles (1970) the ability to rapidly predict impending danger is crucial for the survival of any organism; therefore mammals have evolved a series of preprogrammed species-specific defensive reactions. For example in response to threat, the chameleon changes color, the opossum plays dead, the skunk releases an odor, the turtle retreats in its shell, and the rat or mouse freezes (Bolles, 1967).

Fear has been described as the perception and recognition of danger, the learning and remembering about dangerous experiences, and the coordination of defensive behaviors to environmental threat (Fanselow and Gale, 2003). In addition to more overt behavioral responses, conditional fear has been measured by collective changes in heart rate (Antoniadis and McDonald, 2000), body temperature (Godsil et al., 2000), defecation (Antoniadis and McDonald, 2000), cortisol release (Goldstein et al., 1996), and opiate-related analgesia (Fanselow, 1986). In rodent models of fear, arguably the most reliable measure of learned fear is freezing, a defensive posture exhibited by some mammals (e.g., rats, mice, rabbits, and deer) that is best described as the absence of movement with exception of those related to respiration. Other prominent indices of conditional fear include enhancement in startle to loud acoustic stimuli (Brown et al., 1951; Rosen and Davis, 1988) as well as suppression of previously reinforced lever press in rats (Estes and Skinner, 1941; Angladа-Figueroa and Quirk, 2005). In addition, work by McGaugh and colleagues has made tremendous strides in our understanding of the role of the

amygdala in memory consolidation using an inhibitory avoidance procedure (McGaugh, 2004). Here, to limit the scope of this chapter, much of the work described will primarily focus on freezing as a measure of fear, as described in rodents, unless otherwise noted.

In contrast to eyeblink classical conditioning, the UR to footshock and the CR as measured by freezing are notably different in that footshocks evoke a reflexive burst of locomotor activity (Fanselow, 1980). Following even a single pairing of the CS and US, postfootshock freezing begins to emerge soon after the offset of the activity burst and has been used as a reliable online measure of fear learning (Fanselow, 1980).

3.19.3.2 Brain Systems Engaged in Fear Conditioning

The primary brain area engaged during fear conditioning is the basolateral amygdala complex (BLAc), a region composed of several heterogeneous subnuclei, including the lateral (LA), basomedial (BM), and basolateral nuclei (BL). Other brain regions that play a prominent role include the hippocampus, medial geniculate nucleus, anterior cingulate cortex, and ventral periaqueductal gray. In auditory fear conditioning, the BLAc is essential; however, under conditions in which fear to the original training context is assessed, not only is the BLAc important, but so is the hippocampus.

3.19.3.3 The Amygdalar System

3.19.3.3.1 Lesions

The primary foundation for the role of the amygdala in fear conditioning was laid by Brown and Shafer (1888) in humans and Kluver and Bucy (1937) in monkeys: damage to the medial temporal lobes that included the amygdala resulted in profound changes in emotional responsiveness and most notably a loss of fear. Later, work by Weiskrantz et al. (1956) showed that lesions specific to the amygdala could produce similar changes in emotional reactivity. Subsequent work by Kellicutt and Schwartzbaum (1963) showed that lesions of the amygdala attenuated fear-motivated bar-press suppression. The crucial finding for the key role of the amygdala in fear conditioning was provided by Blanchard and Blanchard (1972), who demonstrated that electrolytic lesions of the amygdala in rats prevented contextual fear conditioning as measured by freezing. In addition, McGaugh and colleagues revealed posttraining electrical stimulation of the amygdala resulted in deficits in inhibitory avoidance memory retention (Gold et al., 1973). Since then, further work in a number of laboratories has demonstrated that discrete lesions of the BLAc prior to training prevent the development of both contextual and cued fear responses (LeDoux et al., 1990; Campeau and Davis, 1995; Cousens and Otto, 1998). Conversely, similar lesions in previously trained animals completely abolish all measures of fear responding to all CS modalities tested (Phillips and LeDoux, 1992; Sananes and Davis, 1992; Campeau and Davis, 1995; Lee et al., 1996; Cousens and Otto, 1998; Koo et al., 2004). In an interesting experiment by Gale et al. (2004), lesions of the BLA 17 months following fear training, nearly equivalent to the entire life span of the rat, completely abolished the expression of conditional fear responses, suggesting that, once Pavlovian fear memories are established, they are permanently maintained by the BLAc. It should be noted that the lack of fear responding such as freezing is not due to an inability to perform the response, given that extensive overtraining (>75 footshocks) can yield significant freezing (Maren, 1999; Gale et al., 2004).

Neuropsychological studies in humans with Urbach-Weithe disease, a condition resulting in degeneration of the amygdala that leaves intact surrounding temporal lobe structures, reveal deficits in delay fear conditioning (Bechara et al., 1995). Consistent with patients with amygdala damage, magnetic resonance imaging reveals activation of the amygdala during both fear conditioning and expression (Cheng et al., 2003; Knight et al., 2005).

3.19.3.3.2 Measures of neuronal activity

Electrophysiological recordings and quantification of immediate early gene expression in neurons of the BLAc are consistent with lesion studies and reveal that these neurons are actively engaged during and as a result of fear conditioning. Indeed, populations of neurons in the LA nuclei respond to both the CS and US. LeDoux and colleagues have shown that responding of these individual neurons to a tone CS is enhanced as a result of fear conditioning (Quirk et al., 1995, 1997; Li et al., 1996). Similar learning-related changes have been also observed in neurons of BL nucleus (Maren and Quirk, 2004). Consistent with these findings, measurements of immediate early gene *c-fos* are elevated in regions of the amygdala (Beck and Fibiger, 1995) and interestingly show a significant

lateralization within the right BLA and central nucleus of the amygdala (CeA) (Scicli et al., 2004).

3.19.3.3.3 The pathways

There is a general agreement within the literature that the neural circuitry underlying Pavlovian fear conditioning is centered around the BLAc (Fanselow and LeDoux, 1999; but see McGaugh, 2004) and that distinct neural efferents support the expression of different components of the conditional fear response (**Figure 3**). In contrast, examinations of pathways by which CS- and US-related information converges upon the amygdala suggest that multiple pathways are sufficient, none of which seem solely necessary for fear conditioning (Fanselow and Poulos, 2005).

3.19.3.3.3.1 The CS pathway In auditory fear conditioning, both the auditory cortex and medial geniculate nucleus (mGN) convey CS-related information to the lateral nucleus of the amygdala (LeDoux et al., 1990). Lesions of afferents to the LA or the LA itself disrupt the acquisition of tone-cued fear conditioning (LeDoux, et al., 1990; Romanski and LeDoux, 1992). Moreover, tone-evoked responses in the mGN occur within 12 ms, whereas learning-related increases in tone-evoked spike firing in the lateral nucleus occur around 15 ms (Li et al., 1996), suggesting that mGN activity precedes the development of learning-related LA activity.

Under conditions in which the fear response is signaled by the training context, both hippocampus and perirhinal cortex play an important role in conveying environmental cues to the BLA neurons. Either posttraining lesions of the ventral angular bundle, a primary source of hippocampal and perirhinal input to the BL, or single lesions of the hippocampus and perirhinal cortex produce deficits in the expression of contextual fear responses, but fail to disrupt tone-cued fear responses (Maren and Fanselow, 1995; Bucci et al., 2000; Burwell et al., 2004). Finally, blockade of hippocampal NMDA receptors prior to training severely attenuates contextual fear conditioning (Young et al., 1994; Quinn et al., 2005).

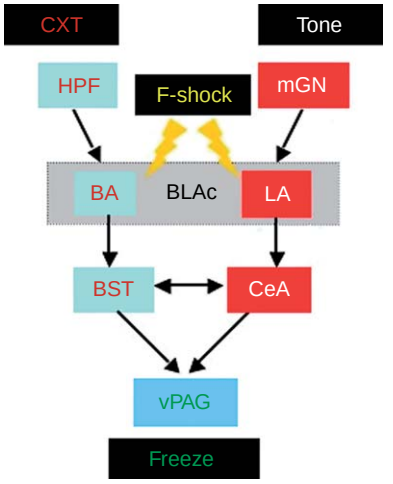

Figure 3 Simplified schemata of the neural circuits underlying Pavlovian fear conditioning. In contextual fear conditioning, information pertaining to the training context (CXT) is relayed to the basal amygdala (BA) via the hippocampal formation (HPF), where it converges with footshock-related (F-shock) information. In auditory fear conditioning, information pertaining to tone is relayed to the lateral amygdala (LA) via the medial geniculate nucleus (mGN) and converges with F-shock. Contextual and auditory fear established and maintained within the basolateral amygdala complex (BLAc) are relayed to the bed nuclei of the stria terminalis (BST) and central nucleus of the amygdala (CeA), respectively. The final common output for the generation of freezing is expressed via the ventral periaqueductal gray (vPAG).

3.19.3.3.3.2 The US pathway In order for the BLAc to support fear conditioning, pathways conveying information pertaining to the US must reach this region. Unlike the CS pathway, relatively less is known about how information related to the footshock is conveyed. Regions of the thalamus that respond to somatosensory information receive input from the spinothalamic tract and send projections to the lateral amygdala. In addition, insular cortex seems to play a role in relaying pain-related information as well (Shi and Davis, 1999). Interestingly, combined but not single lesions of the posterior thalamus and insular cortex attenuate tone-cued fear conditioning, but leave contextual fear conditioning intact (Brunzell and Kim, 2001). The central nucleus receives nociceptive input from the parabrachial nucleus and nucleus of the solitary tract and directly from the dorsal horn of the spinal cord (Bernard and Benson, 1990; Burnstein and Potrebic, 1993; Gauriau and Bernard, 2002). The function of such inputs at the central nucleus needs further investigation, given that this region does not project back to any regions of the basolateral amygdala complex in rats (Fanselow and Poulos, 2005).

3.19.3.3.3.3 The CR pathway Neurons within the lateral amygdala which undergo auditory fear learning–related plasticity project to intercalated

inhibitory neurons, which project to the CeA. Lesions limited to lateral amygdala or central nucleus disrupt tone-cued fear conditioning (Nader et al., 2001). In parallel, environmental cues encoded by the hippocampus in correspondence with activation by US input drive the development of learning-related plasticity among neurons of the BLA and send axonal projections which course through the central amygdala nucleus and terminate at the bed nuclei of the stria terminalis. Electrolytic lesions of the BLA, CeA, or bed nuclei of the stria terminalis disrupt the expression of contextual fear responses (Phillips and LeDoux, 1992; Sullivan et al., 2004). Excitotoxic lesions of the CeA that spare fibers of passage, as confirmed by fiber staining methods, selectively attenuate cued but not contextual fear responses (Koo et al., 2004). Whereas, if these lesions (electrolytic) include damage to fibers of passage, both context and cued-fear responses are disrupted. This suggests that projections from the lateral amygdala → central nucleus and basolateral amygdala → bed nuclei of stria terminalis may represent separate response pathways for freezing to tone and contextual fear conditioning, respectively. Conversely, both the central nucleus and bed nuclei of the stria terminalis heavily innervate the periaqueductal gray, a region critical for the expression of defensive responses such as a freezing. Lesions of the periaqueductal gray, which abolish the expression of freezing, do not disrupt the expression of other conditional fear responses, such as alterations in blood pressure, while damage to the lateral hypothalamus affects blood pressure but not freezing (LeDoux et al., 1988). Therefore, the important point here is that distinct neural pathways initialized within the BLAc mediate the expression of different components of the conditional fear responses and to the some extent the signals that predict danger.

3.19.3.3.4 Reversible inactivation

Although the aforementioned studies strongly implicate the BLAc in fear conditioning, they do not indicate whether effects of lesions result from learning or performance deficits or whether learning-related changes in neuronal responding are due to plasticity efferent to the BLAc. Therefore, as previously described, reversible inactivation has become a valuable tool in localizing memory traces in the brain. Reversible inactivations targeting the BLAc via direct microinfusion of the $GABA_A$ receptor agonist muscimol prior to fear conditioning prevent the development of context and cued-fear memories. Reversible inactivations of the BLAc after training and prior to tests of memory retention completely abolish the expression of cued and contextual fear responses. These results indicate that functions of BLAc neurons are vital for the development and expression of Pavlovian fear memory. In an attempt to distinguish the relative contribution of the LA and BL in cued versus contextual fear conditioning, Jaffard and colleagues demonstrated that reversible inactivation (via the sodium channel blocker lidocaine that inactivates both soma and axons) targeting the LA attenuated the acquisition of cued, but not context fear, while inactivations of the BL attenuated the acquisition of context, but not cued fear (Calandreau et al., 2005). Finally a study by Maren and colleagues showed that both development of learning-related activity in mGN and cued-fear conditioning are disrupted by reversible inactivation of the BLAc (Maren et al., 2001).

3.19.3.3.5 Mechanisms of storage in the basolateral amygdala complex

Since the initial demonstration of long-term potentiation (LTP) by Bliss and Lomo (1973) showing that normally weak synapses in the hippocampus could be strengthened by high-frequency stimulation, LTP has become an extremely attractive cellular model of Pavlovian learning. For example, in fear conditioning, CS-generated input could be strengthened by US activation of the BLA, and thus subsequent presentations of the CS could more readily activate the amygdala and promote expression of conditional fear responses. If it were the case that amygdalar LTP represents a substrate of conditional fear memories, then manipulations that attenuate LTP should correlate with deficits in fear conditioning. A number of *in vitro* experiments have demonstrated the establishment of LTP within amygdala circuits (Racine et al., 1983; Chapman et al., 1990; Clugnet and LeDoux, 1990; Maren and Fanselow, 1995). Stimulation of previously described CS pathways, the mGN (Clugnet and LeDoux, 1990) or the hippocampus (Maren and Fanselow, 1995), are able to support LTP at BLAc synapses. Consistent with the LTP hypothesis, McKernan and Shinnick-Galagher (1997) demonstrated that brain slices taken from fear-conditioned rats with the LA and auditory nucleus intact showed larger excitatory postsynaptic potentials (EPSPs) in the LA following stimulation of the auditory nucleus than untrained control rats.

Further studies have demonstrated that, as in the hippocampus, the induction of amygdala LTP

requires the activation of NMDA receptors (Bliss and Collingridge, 1993; Maren and Baudry, 1995; Fanselow and Maren, 1995; Huang and Kandel, 1998). Indeed, the induction of LTP is blocked when amygdala slices are treated with NMDA receptor antagonist aminophosphonovaleric acid (APV), whereas once LTP is established APV fails to affect its expression.

Consistent with this line of thought, Davis and colleagues demonstrated that infusion of NMDA receptor antagonist APV into the BLAc blocked the acquisition but not the expression of fear-potentiated startle (Miserendino et al., 1990). Further studies measuring freezing have yielded similar effects, with NMDA blockade disrupting the acquisition but not the expression of conditional fear (Fanselow et al., 1994; Rodrigues et al., 2001). Other forms of the glutamate receptor also implicated in LTP and fear conditioning are mGluRs, in particular mGluR5. Antagonism of this receptor not only impairs the induction of amygdala LTP, but also selectively blocks the acquisition, while leaving expression of conditional fear intact (Rodrigues et al., 2002). Both of these receptors are thought to trigger an influx of extracellular and intracellular Ca^{2+}, resulting in the activation of calcium/calmodulin-dependent protein kinase II (CaMKII). In turn, auditory fear conditioning and the induction of amygdalar LTP by stimulation of mGN result in an increased activation of αCaMKII in the lateral amygdala (Rodrigues et al., 2004). Conversely, BLAc infusion of a CaMKII blocker disrupts fear conditioning (Rodrigues et al., 2004). Along with αCaMKII, protein kinases A and C (PKA and PKC) and Akt are known signals that converge upon the microtubule-affinity regulating kinase (MARK) signaling pathway. BLA infusion of St-Ht32, which blocks PKA anchoring to scaffolding proteins, disrupts the establishment of conditional fear memory (Moita et al., 2002). In addition, blockade of tyrosine kinase B (TrkB) receptor activation of PKC signaling pathways via pharmacological blockade of brain-derived neurotrophic factor (BDNF) binding or in heterozygous BDNF knockout mice results in severe fear conditioning deficits (Liu et al., 2004; Rattiner et al., 2004). Moreover, if mitogen-activated protein kinase (MAPK) expression, which is elevated following fear conditioning, is blocked, fear memory at 24 h following training is markedly attenuated (Schafe et al., 2000). Consistent with these data, amygdala slices bathed in MAPK inhibitor U0126 have impaired LTP (Schafe et al., 2000). Both MAPK and PKA are thought to activate transcription factors such as cyclic adenosine monophosphate (cAMP) response element binding protein (CREB), which are critical for establishment of memory (Rodrigues et al., 2004). Indeed, levels of phosphorylated CREB are increased in the BLAc following fear conditioning (Hall et al., 2001; Stanciu et al., 2001), while overexpression of CREB in the amygdala enhances fear conditioning (Hall et al., 2001) and fear potentiated startle (Josselyn et al., 2001). Moreover, direct BLAc infusion of transcription inhibitor actinomycin-D blocks the acquisition of fear conditioning (Bailey et al., 1999). Further studies have demonstrated that lateral amygdala LTP results in the phosphorylation of CREB and that inhibition of protein synthesis blocks the late phase of LTP as well as the long-term fear memories (Huang et al., 2000; Schafe and LeDoux, 2000; Maren et al., 2003). Finally, *de novo* protein synthesis has been thought to promote the maintenance of both LTP and fear memory by the insertion of postsynaptic alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. Indeed, Malinow and colleagues, in a striking set of experiments, have demonstrated that both LTP and fear conditioning drive the insertion of AMPA receptors, and that if insertion of receptors is inhibited, fear memory is reduced (Hayashi et al., 2000; Rumpel et al., 2005).

3.19.3.4 Fear Conditioning and the Hippocampus

3.19.3.4.1 Contextual fear conditioning

As described earlier, the hippocampus composes part of the CS pathway, which converges with US input at the BLAc in contextual fear conditioning. A number of studies suggest that in contextual fear conditioning the hippocampus is not just a passive relay of multisensory information pertaining to the organism's immediate environment, but rather encodes a unified time-limited mnemonic representation of the context CS (Kim and Fanselow, 1992; LeDoux and Phillips, 1992; Fanselow, 2000; Anagnostaras et al., 2001; Rudy et al., 2004). Indeed, this account is in accord with other views that the hippocampus plays an important role in memory (Milner and Ettlinger, 1970; O'Keefe and Nadel, 1978; Zola-Morgan et al., 1986).

The initial study implicating the hippocampus in fear conditioning was by Blanchard and Fial (1968), demonstrating that electrolytic lesions of the hippocampus disrupted fear conditioning. Years later, Phillips and LeDoux (1992) showed that amygdala lesions disrupted both cued and context fear, while lesions of the hippocampus selectively produced

anterograde amnesia of contextual fear conditioning, suggesting that the amygdala had a more general role in fear conditioning, whereas the hippocampus appeared to relay information about the training context in fear conditioning. Kim and Fanselow (1992) further showed that electrolytic lesions of the hippocampus 1 day after training abolished contextual fear, whereas lesions made at 7, 14, and 28 days showed significant contextual fear. Moreover, in the same animals, lesions failed to affect fear responses to tone at any time. Together these results were consistent with the hippocampus playing a time-dependent role in the consolidation of memory and at the same time encoding spatial cues in the animals' immediate environment. However, further studies employing excitotoxic hippocampal lesions, which continued to demonstrate retrograde memory deficits, failed to show anterograde amnesia of contextual fear (Philips and LeDoux, 1994; Maren et al., 1997; Frankland et al., 1998). A number of explanations have been posited based on these discrepancies (Anagnostaras et al., 2001). (1) Excitotoxic infusion could result in damage to neighboring areas such as the amygdala (Mintz and Knowlton, 1993). (2) Ventral hippocampal lesions could result in damage to projections that may affect normal amygdalar function (Maren and Fanselow, 1995). (3) Excitotoxic lesions may result in a sustained seizure-like activation of efferents such as the amygdala, resulting in partial damage (McCelland et al., 1995). Given this, the resulting amygdala dysfunction could result in memory deficits most apparent for recently encoded information (Anagnostaras et al., 2001). A more recent study by Fanselow and colleagues demonstrated that complete excitotoxic lesions of the hippocampus in naive rats failed to disrupt the acquisition of contextual fear, whereas in previously fear-conditioned rats, similar lesions abolish the expression of contextual fear responses (Wiltgen et al., 2006). However, these posttraining deficits could be overcome with retraining.

An alternate possibility is that under normal conditions a slowly established configural mnemonic representation of the training context is encoded by the hippocampus; however, in the absence of the hippocampus, single elements of the context, like cued conditioning, may be sufficient to produce associative plasticity within the BLAc. However, if lesions of the hippocampus are made after BLA plasticity has already been established using a configural representation, then the remaining elemental system may not be sufficient to support the retrieval of contextual fear memories (Fanselow, 2000). Indeed, a number of studies are consistent with this view. (1) Immediate delivery of footshock upon placement into the training context does not yield contextual fear conditioning (Landeira-Fernandez et al., 2006). (2) Posttraining lesions of the hippocampus are more detrimental than pretraining lesions. (3) Preexposure to the training context followed by fear conditioning 35 days later mitigates retrograde amnesia effects of hippocampal lesions (Anagnostaras et al., 1999). Moreover, an elegant study by Rudy and colleagues showed that mRNA of *Arc* and immediate early gene *c-fos* mRNA are induced in the hippocampus following context exposure or context plus shock experience, but not after immediate shock (Huff et al., 2006). However, if the BLA is inactivated, *Arc* and *c-fos* mRNA were attenuated following contextual fear training, but *Arc* mRNA levels remained unaffected by context preexposure alone. Perhaps under normal conditions hippocampal LTP may be critical for assembling elemental components of the training context into a cognitive and/or configural representation of the context (Anagnostaras et al., 2001), which is further consolidated via amygdala-dependent fear conditioning.

3.19.3.4.2 Trace fear conditioning

In fear conditioning, as in eyeblink conditioning, the addition of a stimulus-free period or 'trace' (>10 s) between the auditory CS and footshock requires the hippocampus (Chowdhury et al., 2005; Misane et al., 2005). Pretraining lesions of the hippocampus disrupt the acquisition of trace fear conditioning (McEchron et al., 1998; Burman et al., 2006), while posttraining lesions attenuate the expression of trace fear conditioning (Chowdhury et al., 2005; Burman et al., 2006). Subsequently Fanselow and associates revealed that blockade of dorsal hippocampal NMDA receptors disrupted the acquisition but not the expression trace fear memories (Quinn et al., 2005). Interestingly, the presentation of a visual distracter disrupts trace, but does not delay fear conditioning, suggesting that attention is required for the acquisition of trace fear memory. Finally, trace fear conditioning, which is associated with an increase in *c-fos* activation in the anterior cingulate cortex, is attenuated by lesions of this same region (Han et al., 2003).

3.19.3.4.3 Recent versus remote fear memories

An important question posed by the results of Kim and Fanselow (1992) is that, if the hippocampus is

transiently involved in the consolidation of contextual fear memory, what brain region(s) are involved in retrieving more remotely established contextual fear memories? A series of elegant studies by Silva and colleagues suggests that a number of regions of the cortex including the anterior cingulate cortex may be required (Frankland et al., 2001, 2004, 2006). In genetically engineered mice with reduced levels of αCaMKII, recent contextual fear memory tested 24 h later is normal, whereas remote fear memory tested at 10 to 50 days is completely absent (Frankland et al., 2001). Interestingly these mice, which failed to show remote fear memory, revealed no changes in cortical immediate early gene expression following recent or remote memory tests, whereas wild-type mice showed correlated increases of cortical gene expression and remote context fear memory (Frankland et al., 2004). Conversely, reversible inactivation of the anterior cingulate cortex at remote, but not recent, retention intervals disrupts the retrieval of contextual fear memories. Moreover, αCaMKII mutant mice, which showed normal levels of hippocampal LTP, have impaired cortical LTP. These experiments suggest that αCaMKII expression within a number of regions, notably the anterior cingulate cortex, plays an important role in the retrieval of remote contextual fear memory.

3.19.4 Interactions Between Conditioned Fear and Eyeblink Conditioning: The Two-Stage Hypothesis

A number of authors have distinguished between two classes of CRs: diffuse or nonspecific preparatory CRs and precise, specific, adaptive CRs (e.g., Konorski, 1967; Rescorla and Solomon, 1967; Thompson et al., 1984). According to the 'two-stage theory,' the association between the CS and the aversive US is formed within the first few conditioning trials and results in the acquisition of emotional CRs taking the form of nonspecific, autonomic arousal. Nonspecific responses are usually autonomic but also include generalized body movements, are learned rapidly, and prepare the organism to do something. Such responses are viewed as manifestations of a 'conditioned emotional state,' e.g., conditioned fear. Conditioning of specific responses, for example, eyelid closure or leg flexion, involves learning precise, adaptive CRs that deal specifically with the US and requires more extensive training. The two learning processes proceed not only at different rates but also at different brain sites.

The two-stage hypothesis suggests that the initial conditioned fear may be necessary or at least play a role in subsequent learning of discrete movements and that the learning of discrete movements may impact subsequent retention of conditioned fear. Powell and associates (1974) showed that, when heart rate and eyeblink conditioning were given simultaneously, conditioned heart rate developed very rapidly in a very few trials, but then as eyeblink conditioning developed, the conditioned heart rate diminished. As noted earlier the essential brain substrates for these two aspects of learning are quite different: amygdala for fear and cerebellum for eyeblink. Neufeld and Mintz (2001) showed that prior fear conditioning facilitated subsequent eyeblink conditioning and amygdala lesions abolished this facilitation. Weisz et al. (1992) showed that amygdala lesions could actually impair rate of learning of the eyeblink response. Lavond et al. (1984a) showed that appropriate cerebellar interpositus lesions that abolished the conditioned eyeblink response had no effect on initial acquisition of the conditioned heart rate response, as expected. However, Mintz and Wang-Ninio (2001) showed that interpositus lesions, which prevented discrete response conditioning, also prevented the subsequent decline in fear conditioning with extensive eyeblink training that normally occurs in intact animals. If the animal cannot learn to deal with the aversive US, then fear does not extinguish. Patterns of gene expression over the course of eyeblink conditioning in the interpositus nucleus (mouse) support the two-stage hypothesis (Park et al., 2006). Indeed, further work examining the relative activation of gene expression in both regions of the amygdala and cerebellum over the course of simultaneous eyeblink and heart rate conditioning could directly test the two-stage hypothesis of Pavlovian conditioning.

3.19.5 Conclusions

The findings described here indicate that two forms of procedural learning, eyeblink conditioning, a slowly acquired fine motor behavior, and fear conditioning, a rapidly acquired global defensive response, are established, maintained, and expressed by two different sets of neural circuits centered around the cerebellum and amygdala, respectively. Moreover, the mechanisms of plasticity within each of these brain regions at cellular and genetic levels suggest that different forms of Hebbian plasticity (LTP vs. LTD) and gene expression

may be crucial for each form of procedural learning. However, at the systems level, there are similarities in eyeblink and fear conditioning in that increasing task difficulty or the interval of time between training and testing seems to differentially engage the hippocampus and regions of the neocortex. In addition, accumulating data seem to suggest that eyeblink conditioning may develop normally in a two-stage process, where initial training establishes a conditioned emotional component requiring the amygdala, which with further training facilitates the acquisition of cerebellar-dependent eyeblink responses. Collectively, these studies strongly indicate that each of these forms of procedural learning, which depend on different neural loci and mechanisms of memory, may indeed work in conjunction to promote the establishment of appropriately timed and coordinated adaptive behaviors.

3.20 Procedural Learning: VOR

K. E. Cullen, McGill University, Montreal, QC, Canada

3.20.1 Introduction

Humans can learn skilled motor tasks, such as riding a bike, playing the piano or even hitting an accurate topspin serve in tennis. This long-term 'motor memory' is referred to as procedural memory. Although practice can improve performance, memories of these learned movements remain remarkably intact, even after years of disuse. Procedural or 'motor' learning also serves an important role in calibrating simpler movements such as eye movements and reflexes. One class of eye movements, the vestibulo-ocular reflex (VOR), is a particularly useful model system. The VOR produces compensatory eye movements that are required to stabilize gaze and ensure clear vision during the head movements that are generated during everyday activities such as walking and running. The VOR shows impressive adaptation in response to environmental requirements. Furthermore, the relative simplicity of the neural circuit that mediates this reflex has proven to be well suited to linking systems and cellular levels of analyses of motor learning.

Procedural memory is generally contrasted with declarative memory, which is the memory of facts or experiences. Over the past decade, work on learned

reaching movements has provided evidence to support the idea that procedural memory, like declarative memory, passes through multiple stages before becoming stable, including encoding, consolidation, and retrieval (see a recent review by Robertson, 2004). Similarly, the findings of recent behavioral, single-unit recording and lesion studies have established that VOR motor learning passes through distinct stages. Moreover, neural substrates underlying the progression of learning in this model system have been localized, and significant progress has been made in understanding the cellular mechanisms that control their formation. In addition, the commonly held idea that procedural learning is characterized by the transformation of a memory from a fragile state to a new permanent memory has been challenged. Recent studies of the VOR, in particular, have emphasized the importance of contextual cues in guiding the retrieval of learned responses.

This chapter will review the findings of behavioral, single-unit recording and lesion studies of VOR motor learning. First, the current understanding of the neural mechanisms that underlie motor learning in the VOR will be reviewed. Then recent evidence supporting the idea that VOR motor learning is characterized by a progression of changes in multiple brain areas will be discussed. Finally, these findings will be integrated in relation to recent experiments that have characterized context-dependent learning in the VOR.

3.20.2 Why Do We Need to Adapt the Gain of the VOR?

3.20.2.1 A Brief Introduction to the VOR

The simplicity of the three-neuron arc that produces the VOR is reflected in its fast response time (**Figure 1(a)**); compensatory eye movements lag head movements by only 5–6 ms in the primate (reviewed in Cullen and Roy, 2004). This reflex produces eye movements in response to both the angular and linear components of head movement and functions to move the eyes in the opposite direction of the concurrent head motion. For example, if a subject undergoes passive head rotation in darkness, the gain of the VOR, which is defined as compensatory eye velocity divided by head velocity, is ~1.0. The VOR initiates eye movements at much shorter latencies than those of visually mediated eye movements. As a result, the VOR is fast enough to stabilize gaze during common activities such as locomotion. Bilateral loss of vestibular function is extremely debilitating because without a functional VOR, simple activities such as walking or driving are accompanied by oscillopsia – the illusion that the environment is moving when we move our heads.

3.20.2.2 The Adaptive Capabilities of the VOR

The VOR is capable of impressive adaptation in response to environmental requirements. To date, perhaps the most dramatic illustration of the adaptive capabilities of this reflex was provided by a study in which participants wore prisms, which reverse the world such that left was right and vice versa (Gonshor and Jones 1976; **Figures 1(b)–1(c)**). Within minutes of wearing the prisms, the gain of the VOR substantially declined. Moreover, when reversing prisms were worn for extended periods (3–4 weeks), the response of the VOR actually reversed; head movements induced an eye movement in the same rather than opposite direction. This change was appropriate to account for the new demands that were imposed on the reflex by the spectacles and accordingly produced improved stabilization of the world on the retina during head movements.

In more commonly encountered situations, the demands on the VOR are less challenging. Nevertheless, the adaptive capabilities of the VOR are essential to guarantee gaze stability throughout life. In humans the VOR must be continuously adjusted in the first years of life to compensate for significant changes in head circumference (~30% in the first year). Later in life, adaptive changes in VOR performance are required to compensate for the magnification of corrective lenses that are worn for common visual conditions. For example, the VOR gain in myopic individuals who wear convex lenses will be lower than for individuals with normal vision. The adaptability of the VOR is also critical to compensate for the effects of aging, disease, and trauma on the nervous system. Notably, the VOR shows remarkable recovery following the loss of unilateral labyrinthine input as a result of injury. Similarly, the reflex shows robust adaptation to the incremental loss of the receptor cells that occur naturally during aging.

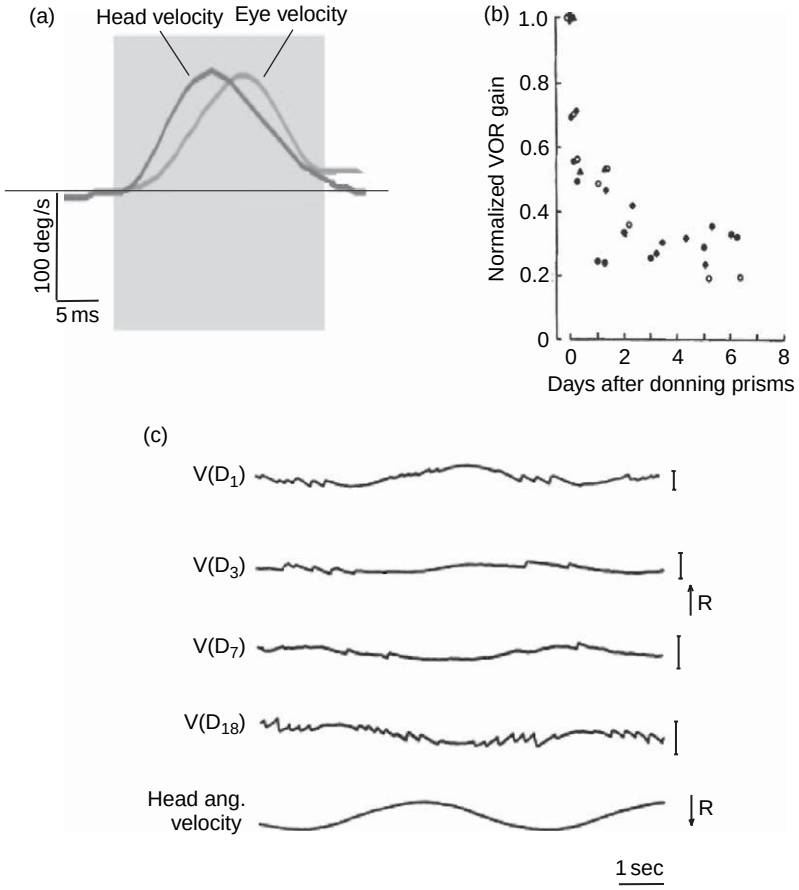

Figure 1 (a) Eye response following a transient head perturbation. Following the onset of head rotation, the eye begins to counterrotate after a latency of 5–6 ms. The gain of the reflex is eye velocity divided by head velocity. Note that eye velocity has been inverted to facilitate comparison. (b) Changes of VOR gain after wearing reversing prisms for 8 days. (c) Example of the VOR in a subject who continuously wore reversing prisms for 49 days. By day 18, the mean response phase was nearly inverted (i.e., −∼140 deg phase shift) relative to the correct nonreversed compensatory response. From (a) Marko Huterer M and Kathleen E. Cullen KE (2002) Vestibuloocular reflex dynamics during high-frequency and high- acceleration rotations of the head on body in rhesus monkey. *J Neurophysiol.* 88: 13–28; 10.1152/jn.01034.2001. 3.20.3 Historical and Current Models of VOR Adaptation

3.20.3.1 The Cerebellum and Motor Learning

The cerebellum is required for VOR motor learning; new gains cannot be learned after the vestibular cerebellum is removed. The basic circuitry of the cerebellum is highly organized and consists of repeating motifs of five primary cell types: Purkinje cells, granule cells, basket cells, stellate cells, and Golgi cells which are organized into the same basic circuit all across the cerebellum (Eccles et al. 1976). The Purkinje cells are the only neurons whose axons leave the cerebellum, and it is noteworthy that these cells send inhibitory projections to their targets within the vestibular and deep cerebellar nuclei. The other cell types are local circuit neurons whose axons make synaptic connections within the cerebellar cortex.

There are two main input pathways to the cerebellum – mossy fibers and climbing fibers. Mossy fiber inputs arise from many regions of the brainstem and spinal cord, including those from the vestibular system via direct projections from the vestibular nerve and vestibular nuclei. Mossy fibers affect the discharges of Purkinje cells through cerebellar interneurons called granule cells. These latter neurons

send projections to Purkinje cells via parallel fibers. Climbing fiber inputs arise from the inferior olive and make powerful excitatory synaptic connections with Purkinje cells. Typically each Purkinje cell receives only one climbing fiber input, but each climbing fiber spike evokes a powerful EPSP, which causes repetitive discharge in Purkinje cells. The Purkinje cell discharge is then followed by a prolonged pause in its firing rate due to additional climbing fiber synapses on inhibitory interneurons (**Figure 2(a)**).

Mossy fiber and climbing fiber inputs to the cerebellum each shape the discharge patterns of Purkinje cells in a very specific way. Inputs from the climbing fibers result in generation of complex spikes (or alternatively climbing fiber responses) in the Purkinje cells. In contrast, mossy fiber inputs are responsible for the simple spike activity of Purkinje cells. Simple spikes (SS) occur much more frequently (discharge rates reaching up to 300 sp/s) as compared to complex spike activity (~1 sp/s). In addition SSs are shorter in duration than complex spikes, which can last as long as 2–5 ms.

The conceptual framework put forth by Marr (1969) and Albus (1971) more than three decades ago has been extremely influential in shaping our current view of the role of the cerebellum in motor learning. In this framework, the role of the climbing fiber input to the cerebellum is to modify the response of Purkinje cells to mossy fiber inputs. The specific hypothesis is that climbing fibers signal errors in motor performance and alter parallel fiber (i.e., mossy fiber-related) Purkinje cell synaptic efficacy. There is considerable evidence to support this idea: Lesions of the cerebellum abolish several types of motor learning, climbing fibers can carry signals that are related to motor performance error, and lesions of the inferior olive abolish some types of motor learning (reviewed in Boyden et al., 2004).

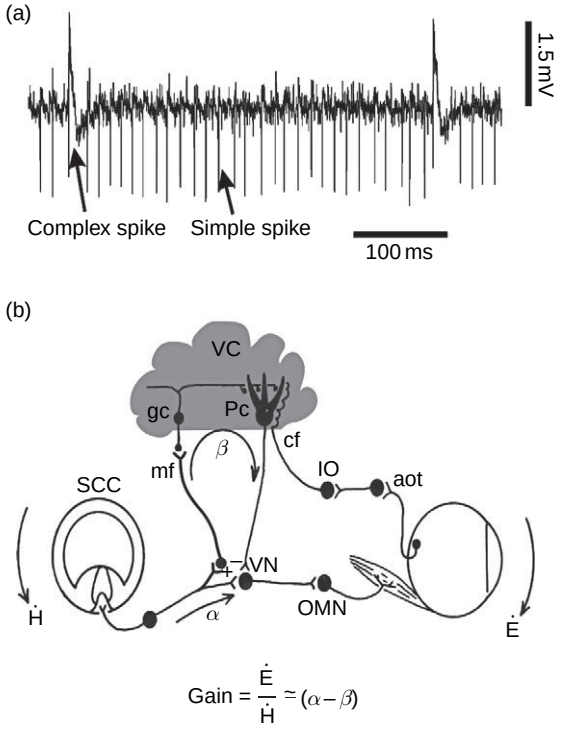

Figure 2 (a) Extracellular recording from an example floccular Purkinje cell showing its high-frequency simple spike (SS) activity as well as complex spike activity (CS) which is due to the climbing fiber input. (b) Two pathways control the gain of the VOR. The main reflex path of gain is paralleled by an inhibitory side branch through the vestibulocerebellum with a gain (beta) so that total gain is proportional to (alpha-beta). Abbreviations: CF, climbing fibers; GC, granule cells; IO, inferior olive; MF, mossy fibers; OMN, oculomotor nuclei; PC, Purkinje cells; VN, vestibular nuclei; aot, accessory optic tract; SCC, semicircular canal; $\dot{E}$, eye velocity; $\dot{H}$, head velocity. From (a) Courtesy of Simpson J and Maruta J. (b) Modified from Robinson DA (1976) Adaptive gain control of vestibuloocular reflex by the cerebellum. *J. Neurophysiol.* 39:954–969.

3.20.3.2 Two Historically Influential Models of Motor Learning in the VOR

The results of single recording and more confined lesion studies have more precisely established that the flocculus and ventral paraflocculus (herein called the floccular complex) of the vestibulocerebellum mediate motor learning in the VOR (e.g., Ito et al., 1974, 1982; Robinson, 1976; Nagao, 1983; Lisberger et al., 1984). Mossy fiber projections from the vestibular nuclei provide a source of head movement-related information to the floccular complex. In turn, the Purkinje cells of the neurons of the floccular complex send monosynaptic inhibitory projections back to neurons in the vestibular nucleus that mediate the VOR (Fukuda et al., 1972; Highstein, 1973; Ito et al., 1977; Sato et al., 1988). Effectively, this vestibular–cerebellar–vestibular pathway provides a parallel inhibitory side loop that can modulate the gain of the direct VOR pathway (**Figure 2(b)**).

To change the gain of the VOR response, there must be adaptive adjustment(s) of the synaptic efficacy between the neuronal elements that mediate the reflex. The question of where and how this adaptation occurs has been debated, and in

particular two hypotheses of motor learning in the VOR have dominated the literature. The principal difference between these two models is the location of the modified synapses that underlie motor learning.

First, in 1972, Ito introduced an influential theory of VOR adaptation based on the Marr–Albus model of cerebellar motor learning. In Ito's adaptation of the Marr–Albus model to VOR learning, the climbing fiber input from the inferior olive provides an error signal that alters the parallel fiber (i.e., mossy fiber-related) Purkinje cell synaptic efficacy. This error signal modifies the head velocity-related modulation of Purkinje cells to change the gain of this cerebellar loop of the VOR circuitry so that the VOR is compensatory (**Figure 3(a)**; red star). Consistent with this theory, climbing fiber inputs to the floccular complex chiefly encode visual slip information, which provides an indication of the reflex performance (Maekawa and Simpson, 1973; Simpson and Alley,

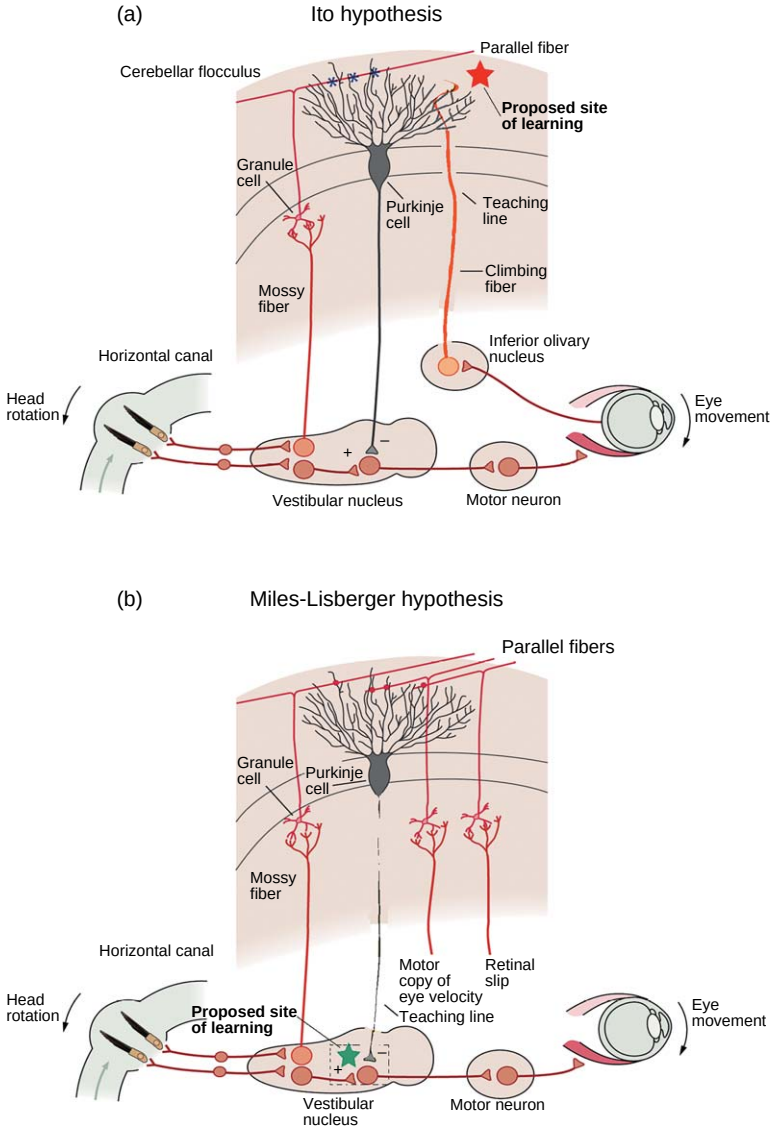

Figure 3 Two models of VOR motor leaning. (a) In Ito's model, climbing fibers encode a visual error signal, which induces learning at the synapses of vestibular parallel fibers onto the Purkinje cells. (b) In the Miles–Lisberger model, floccular Purkinje cells encode an error signal, which supports the modification of synapses in the target neurons of the vestibular nuclei. See text for additional details. From Kandel ER, Schwartz JH, and Jessell TM. *Principles of Neural Science,* 4th edn. Copyright © 2000 by The McGraw-Hill Companies; Chapter 41.

1974; Ghelarducci et al., 1975; Graf et al., 1988). According to Ito's theoretical framework, learning continues until the visual slip signal (which is a measure of performance error) encoded by the climbing fibers becomes zero. At this point, the VOR would be fully compensatory and so no further adaptation would be required.

Alternatively, Miles and Lisberger (1981) proposed that the floccular complex provided an instructive signal to the vestibular nuclei, to guide plastic changes that took place exclusively in the brainstem (**Figure 3(b)**; green star). This hypothesis incorporated the finding that the Purkinje cells of the floccular complex receive significant eye as well as head movement-related information from their mossy fiber inputs via projections from the vestibular, reticular, raphe, and perihypoglossal nuclei. These investigators hypothesized that when the VOR is in the normal state (i.e., when there is no retinal slip during head movements), eye and head movement signals would be equal and opposite and thus would cancel each other out. As a result, no net drive would be encoded by Purkinje cells, and thus no instructive signal would be sent to the vestibular nuclei. However, when retinal slip is present, as would be the case after donning magnifying or minimizing lenses, visual tracking responses (i.e., pursuit) would be recruited to adjust the eye movement response. As a result a significant eye movement signal would be sent back to the floccular complex, and so the output of the Purkinje cells would code an error signal that represents the difference between eye and head movement. In this schema, the error signal guides plastic changes at the level of neurons in the vestibular nuclei, so that the modified VOR pathways will produce stable gaze.

3.20.3.3 More Recent Evidence and the Emergence of the Multisite Hypothesis of Motor Learning

More recently, substantial evidence has accumulated to support an alternative view, namely that the site of motor learning is not exclusively restricted to either the cerebellar cortex of the floccular complex nor to the vestibular nuclei. Evidence for this proposal has been provided by the results of single-unit recording experiments as well as lesion and transgenic studies. These findings are discussed in the sections titled 'Neuronal networks and single-unit recording studies' and 'Current models of long-term VOR modulation' in relation to the Ito and Miles–Lisberger models of motor learning in the VOR.

3.20.4 Neuronal Networks and Single-Unit Recording Studies

3.20.4.1 Review of Direct VOR Pathways

The three-neuron arc responsible for mediating the direct VOR pathway consists of projections from vestibular afferents to interneurons in the vestibular nuclei, which in turn project to extraocular motor neurons. Because it is experimentally less challenging to rotate an alert subject in the yaw axis than in the pitch or roll axes, the circuit that mediates the horizontal VOR has been best characterized. Hair cells within the horizontal semicircular canals are activated by ipsilaterally directed head rotations. In turn these receptor cells excite the vestibular afferents, which project via the VIII nerve to neurons within the vestibular nuclei. In particular, neurons in the rostral medial and the ventrolateral subdivisions of the vestibular nuclei receive direct inputs from horizontal semicircular afferents (Fuchs and Kimm, 1975; Keller and Daniels, 1975; Chubb et al., 1984; Scudder and Fuchs, 1992; Cullen et al., 1993). These neurons in the vestibular nuclei in turn project to the extraocular motor neurons that project to the lateral and medial recti. To date, single-unit studies have focused on the responses of vestibular afferents and neurons in the vestibular nuclei, but not the motor neurons.

3.20.4.2 Changes in Neural Responses in the Adapted State: Vestibular Afferents

In addition to their centrally projecting connections, vestibular receptors receive innervation from centrifugally projecting efferent neurons located near the abducens nucleus (Rasmussen and Gacek, 1958; Gacek and Lyon, 1974; Goldberg and Fernandez, 1980). Electrical activation of the vestibular efferent pathway results in an increase in resting discharge and decrease in sensitivity of vestibular afferents in toad fish and squirrel monkeys (Goldberg and Fernandez, 1980; Highstein and Baker, 1985). Thus, in theory, the vestibular efferent system could be used to alter the dynamic range of the input that is available at the level of the nerve to guide changes in VOR gain.

Miles et al. (1980a) investigated this possibility in monkeys following VOR learning. No change in

afferent responses was observed after motor learning was induced by having the animals wear magnifying or minimizing prisms for more than a month. Neuronal responses were tested over a limited range of frequencies 0.1–1 Hz (peak velocity of 20 deg/s). A more recent study (Sadeghi et al., 2006) has extended these findings to show that the responses of vestibular afferents are similarly not altered following contralateral vestibular damage. In this latter study rotational frequencies up to 15 Hz were used, thus extending the range of rotational frequencies to match those produced during natural head movements. Taken together, these investigations show that changes in responses of vestibular afferents do not appear to play a significant role in supporting long-term adjustments of the VOR gain.

3.20.4.3 Changes in Neural Responses in the Adapted State: Vestibular Nuclei

The second-order neurons in the rostral medial and ventral lateral subdivisions of the vestibular nuclei can be grouped into distinct classes based on idiosyncratic constellations of discharge properties in response to voluntary eye movements and passive whole-body rotations. Of these, two neuron classes contribute to the direct three-neuron arc that mediates the VOR, namely: (1) position-vestibular-pause (PVP) neurons, and (2) eye-head (EH), which are also called floccular target neurons (FTNs).

3.20.4.3.1 PVP neurons

PVP neurons are thought to constitute most of the intermediate leg of the direct VOR pathway; they receive a strong monosynaptic connection from the ipsilateral semicircular canal afferents and project directly to the extraocular motor neurons (McCrea et al., 1987; Cullen et al., 1991; Scudder and Fuchs, 1992; Cullen and McCrea, 1993). These neurons derive their name from the signals they carry during head-restrained head and eye movement paradigms; their firing rate increases with contralaterally directed eye position; they are modulated in response to ipsilaterally directed head velocity during passive whole-body rotations; and they stop firing or pause during ipsilaterally directed saccades and vestibular quick phases.

To address whether changes in the direct VOR pathway mediate motor learning, single-unit recordings were made from PVP neurons in monkeys before and after they had worn magnifying or minimizing spectacles (Lisberger and Miles, 1980, Lisberger et al., 1994a, b). After wearing these spectacles, head movements will evoke larger/smaller eye movements (i.e., an adapted VOR) relative to control conditions to facilitate stabile vision. Thus, it is important to differentiate changes in neuronal modulation that result from the altered movement from those that genuinely reflect changes in a neuron's sensitivity to head movement. To explicitly address this concern, neuronal responses were characterized using a paradigm in which the monkey 'cancels' its VOR by tracking a target that moves with the head. The resulting vestibular stimulation does not lead to eye motion in the opposite direction to the head motion because trained subjects can accurately follow the target at frequencies < 1.5 Hz. Because the PVP responses to VOR cancellation were comparable before and after motor learning, it was concluded that the vestibular nerve synapse on the PVP neurons is not a primary site of plasticity during visually induced motor learning.

Taken together these results have been taken as evidence that PVP neurons receive feedback signals that are related to the adapted eye movements. It is important to note, however, that cancellation of the VOR is largely accomplished via visual pathways that drive a pursuit signal (reviewed in Cullen and Roy, 2004). These pathways are of cerebellar origin and function to cancel the input from the vestibular nerve at the level of the vestibular nuclei. Because PVP neurons are sensitive to smooth pursuit eye movements as well as head velocity, it is important to note that the strength of PVP responses during VOR cancellation will not provide a completely unbiased estimate of their actual sensitivity to vestibular nerve inputs.

3.20.4.3.2 Floccular target neurons

Integration of the results of more recent studies support the idea that changes occur in pursuit as well as VOR pathways after VOR learning (Miles et al., 1980a, b; Lisberger et al., 1994b; Blazquez et al., 2003, 2006). A subset of neurons in the rostral medial and ventral lateral subdivisions of the vestibular nuclei receive direct inhibitory projections from the floccular complex (Lisberger and Pavelko, 1988; Broussard and Lisberger, 1992; Lisberger et al., 1994a, b). These neurons are distinct from PVP neurons and are called floccular target neurons. Their responses largely correspond with those of a distinct physiological subclass of cells, termed

eye-head (EH) neurons, which have been well characterized during eye and head movements in the head-restrained monkey (Tomlinson and Robinson, 1984; McFarland and Fuchs, 1992; Scudder and Fuchs, 1992; Cullen et al., 1993; McCrea et al., 1996; Chen-Huang and McCrea, 1999; Gdowski and McCrea, 1999, 2000; Gdowski et al., 2001; Roy and Cullen, 2003). EH neurons are the most significant premotor input to the extraocular motor neurons of the abducens nucleus during smooth pursuit eye movements (McFarland and Fuchs, 1992; Scudder and Fuchs, 1992; Cullen et al., 1993; Lisberger et al., 1994a, b).

The primary characteristic of EH neurons is that they respond to eye and head movements in the same direction during horizontal smooth pursuit and cancellation of the VOR, respectively. Many EH neurons receive monosynaptic projections from the ipsilateral vestibular nerve (Broussard and Lisberger, 1992; Scudder and Fuchs, 1992), as well as from the floccular complex. EH neurons that show increased firing for eye and head movements away from the side of recording (cEH neurons) can also send direct projections to extraocular motor neurons (Scudder and Fuchs, 1992). Thus, cEH neurons work together with PVP neurons to support the intermediate leg of the direct VOR pathways. Single-unit recordings, made from EH neurons in the brainstems of monkeys before and after wearing magnifying or minimizing spectacles, show that changes in the VOR gain are accompanied by corresponding changes in the head-velocity related modulation of FTNs during cancellation of the VOR (**Figure 4**, Lisberger et al., 1994b). These changes in response gain are more

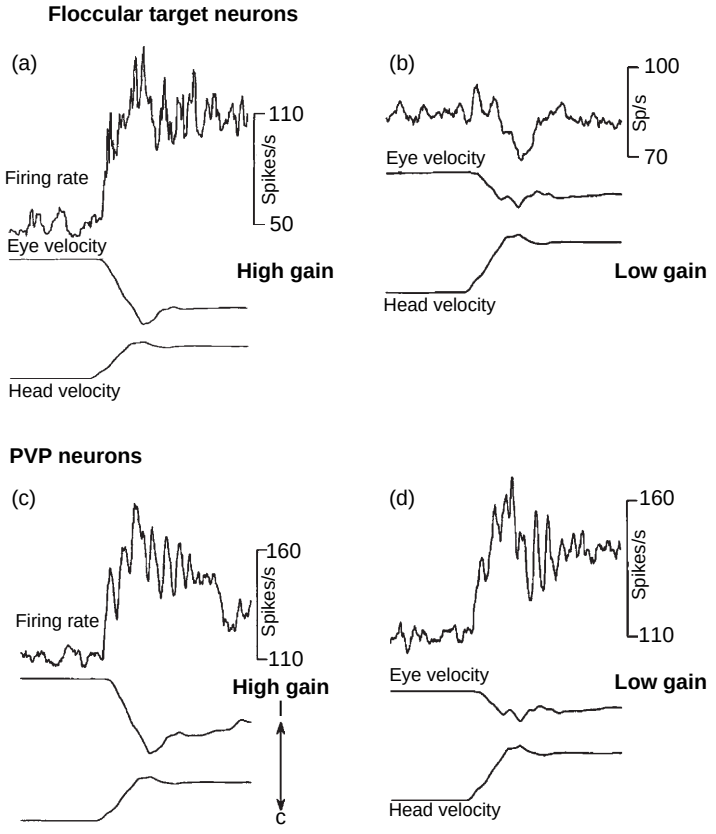

Figure 4 Responses of FTN (a,b) and PVP (c,d) neuron to rapid changes in head velocity after motor learning. Typical response are shown for ipsiversive head motion when the gain was high (a and c) and low (b and d). Upward deflections of the eye and head velocity traces indicate ipsiversive motion. On average the modulation of FTN neuron was significantly different for the two gain states (2.0 versus −0.8 sp/s per deg/s, respectively). In contrast, the modulation of PVP neurons was unchanged. From Lisberger SG, Pavelko TA, and Broussard DM (1994) Neural basis for motor learning in the vestibuloocular reflex of primates. I. Changes in the responses of brain stem neurons. *J. Neurophysiol.* 72: 928–953.

marked for neurons that are activated by the contraversive eye during head-restrained pursuit (i.e., the cEH cells, which contribute to the direct VOR pathway).

EH neurons are sensitive to orbital eye position, as well as smooth-pursuit eye movements and head movement. Thus, as discussed earlier in relation to PVP neurons, changes in an EH neuron's modulation during the VOR or even during cancellation of the VOR do not provide an unbiased estimate of neuronal sensitivity to vestibular nerve inputs. Nevertheless, comparison of the results of the analyses of different groups of brainstem neurons during these conditions does indicate that VOR-related modulation of the cEH neurons is the most altered following motor learning. Furthermore, the responses of these neurons cannot be fully explained by the changes that are seen in the flocculus following learning. In particular their response latencies, unlike those of the floccular Purkinje cells, are appropriate to cause the earliest component of motor learning in the VOR (Lisberger et al., 1994a, b). More recently, the idea that changes at the level of the EH neurons underlie VOR motor learning in the horizontal VOR has been furthered by the finding that the responses of FTNs in the subdivisions of the vestibular nuclei that mediate the vertical VOR (i.e., the y group) are similarly modified during learning in the vertical VOR (Blazquez et al., 2005).

3.20.4.4 Changes in Neural Responses in the Adapted State: Flocculus and Ventral Paraflocculus

Floccular Purkinje cells show both short-term and long-term changes in their responses following VOR learning (Miles et al., 1980a; Watanabe, 1984, 1985; Nagao, 1989; Lisberger, 1994; Raymond and Lisberger, 1996, Blazquez et al., 2003). Work by several laboratories, using different time courses of gain adaptation, demonstrated that changes in Purkinje cell responses are appropriate to induce VOR adaptation either over the course of hours (Watanabe, 1984, 1985; Raymond and Lisberger, 1997; Hirata and Highstein, 2001) or weeks (Miles et al., 1980a; Lisberger et al., 1994a; Blazquez et al., 2003). Because Purkinje cells, like neurons in the vestibular nuclei, are sensitive to eye as well as head movements, these results are difficult to interpret. VOR adaptation will alter the eye movements that are produced in response to head movement, and so it follows that changes in Purkinje cell responses can be a consequence of the altered eye movement-related inputs that are sent to the flocculus.

A number of different approaches have been used in an effort to isolate the vestibular input to the Purkinje cells so that their head velocity sensitivity could be measured following VOR adaptation. First, as described earlier for the vestibular nuclei, neuronal responses were compared during cancellation of the VOR before and after VOR motor learning. Using this approach, changes in Purkinje cell modulation appeared to be in the wrong direction to support the current VOR gain state (Miles et al., 1980a; Lisberger et al., 1994a; Hirata and Highstein, 2001). Accordingly, this finding was originally used in support of the proposal that the floccular complex was not the site of plasticity in VOR motor learning, but instead that changes in the vestibular nuclei were responsible for VOR adaptation (i.e., see Miles et al., 1980a). More recently, it has been established that models of VOR learning that incorporate gain changes at the level of both the brainstem and cerebellum can account for the results of these single-unit recording experiments. In particular, the results of systems identification-based analyses, which incorporate the feedforward and feedback connectivity of the visual and vestibular pathways in the brainstem and floccular complex, indicate that Purkinje cells not only change their head velocity sensitivities, but also their eye position and eye velocity sensitivities after chronic learning (Blazquez et al., 2003). The resultant responses of these combined effects at the level of floccular Purkinje cells provide a modulation of the brainstem pathways (see earlier section titled 'Changes in neuronal responses in the adapted state: vestibular afferents') that is appropriate to support the new VOR gains.

3.20.5 Current Models of Long-Term VOR Modulation

3.20.5.1 Support for a Multiple-Site Hypothesis

As reviewed earlier, evidence from single-unit recording experiments indicates that the site of VOR motor learning is not exclusively restricted to the floccular complex or the vestibular nuclei. Immediately following learning, changes in the simple and complex spike activity of Purkinje cells are appropriate to drive this learning in both the horizontal (Raymond and Lisberger, 1997) and vertical

(Hirata and Highstein, 2001) systems. Moreover, the responses of floccular neurons (Miles et al., 1980a; Watanabe, 1984; Lisberger et al., 1994b; Partsalis et al., 1995a, b; Hirata and Highstein, 2001) as well as FTNs in the vestibular nuclei (Lisberger et al., 1994a; Blazquez et al., 2005) remain modified once a new VOR gain state has been firmly established. Analytical solutions of simple models of the brainstem and cerebellar pathways further indicate that gain changes at the levels of both the cerebellum and vestibular nuclei are required to ensure that the eye movements produced by both the visual tracking (pursuit and optokinetic) and VOR pathways remain accurate after VOR motor learning (Lisberger and Sejnowski, 1992; Lisberger et al., 1994a,b; Blazquez et al., 2003, 2006).

The results of lesion studies have furthered the proposal that the site of VOR motor learning is not restricted to either the floccular complex or the vestibular nuclei. These studies provide strong evidence that the gain changes required for VOR adaptation are initially stored in the floccular complex and in turn drive the formation of long-term synaptic changes at the level of the vestibular nuclei such that long-term memory is chiefly consolidated in the brainstem rather than the cerebellum (reviewed in Broussard and Kassardjian, 2004). This process has been termed the transfer or consolidation hypothesis (Galiana, 1986; Peterson et al., 1991; Raymond and Lisberger, 1996; Broussard and Kassardjian, 2004).

Consistent with this proposal is the finding that learned changes in VOR gain are completely abolished by inactivation of the floccular complex immediately following learning (McElligott et al., 1998; Nagao and Kitazawa, 2003), while inactivation of the floccular complex does not completely abolish long-term changes in VOR gain (Luebke and Robinson, 1994; Partsalis et al., 1995a; Broussard and Kassardjian, 2004; Shutoh et al., 2006). Behavioral and single-unit recording studies have provided further evidence for the proposal that memory storage is transferred from the cerebellum to the vestibular nuclei, but only in the long term. This is consistent with the recent observation that chronically acquired VOR gain changes are better retained than acutely acquired VOR gain changes (Kuki et al., 2004). In addition, the relationship between the head velocity sensitivity of floccular Purkinje neurons and VOR gain after learning differs following short-term versus long-term training (**Figure 5**; Hirata and Highstein, 2001; Blazquez et al., 2003). The cellular mechanisms that are thought to mediate short-term versus long-term changes in VOR gain are considered in more detail in the section titled 'Cellular mechanisms of VOR motor learning: evidence for LTD versus LTP.'

3.20.5.2 The Role of the Flocculus versus Ventral Paraflocculus in VOR Learning

In primates, the flocculus proper is defined as the four most medial lobules caudal to the posterolateral fissure. Adjacent to the fissure is a lobule that constitutes a transition zone termed the medial extension, which is then followed by the five to six more rostral lobules, which constitute the ventral paraflocculus. The ventral paraflocculus is particularly well developed in primates, and most single-unit recording experiments have focused on it rather than the flocculus proper. Selective lesions of these different portions of the floccular complex suggest differences in their relative contributions to the generation of smooth-pursuit eye movements and VOR adaptation (Rambold et al., 2002; Nagao and Kitazawa, 2003). Surgical or irreversible chemical lesions of the ventral paraflocculus results in deficits in both behaviors (Rambold et al., 2002). On the other hand, permanent bilateral lesions, which remove only the flocculus proper, do not produce major deficits in smooth pursuit or changes in gain after long-term VOR motor learning (Rambold et al., 2002). In contrast, acute bilateral inactivation of the flocculus proper immediately following VOR short-term adaptation impairs learned VOR gains (Nagao and Kitazawa, 2003; Shutoh et al., 2006). Taken together, these findings have led to the suggestion that the flocculus makes a greater contribution to the acquisition of VOR motor learning than to its long-term consolidation or retention.

3.20.6 Cellular Mechanisms of VOR Motor Learning: Evidence for LTD versus LTP

3.20.6.1 Cellular Mechanisms for VOR Motor Learning in the Flocculus

As described earlier in the section titled 'Current models of long-term VOR modulation,' there is now general agreement that the gain changes required for VOR adaptation are initially stored in the floccular complex, and the modulation of the Purkinje cell response in turn drives the formation

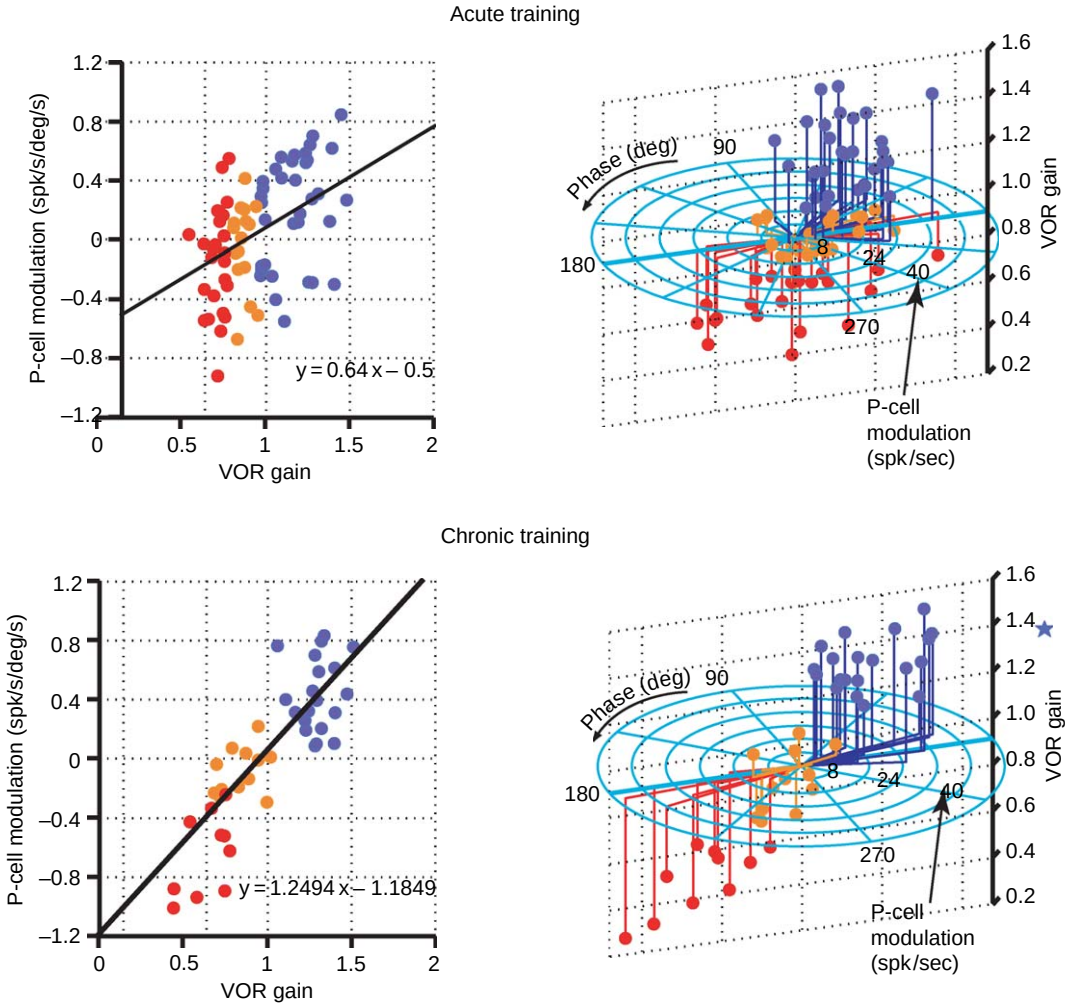

Figure 5 The effects of acute (top row) and chronic (bottom row) training on Purkinje cell responses during VOR for normal (yellow circles), versus low gain (red circles) and high gain (blue circles) adapted animals. Plots on the left show Purkinje cell response sensitivity during head rotation (i.e., (sp/s) per (deg/s)) as a function of VOR gain. Figures on the right are three-dimensional representations where the modulation amplitude for each cell is the length of the line running flat along the circle. The phase of modulation is the degree of the circle, where zero degrees is in phase with head velocity. VOR gain is plotted along the vertical axis. Courtesy of Steve Highstein.

of long-term synaptic changes at the level of the vestibular nuclei. Much recent work has focused on the cellular mechanisms that underlie VOR motor leaning at the level of the flocculus and vestibular nuclei.

The existence of long-term depression (LTD) at the Purkinje cell-parallel fiber synapse was first established by Ito et al. (1982) using electrophysiological techniques. Stimulation of the climbing fiber input to the flocculus reduced the strength of the Purkinje cell-parallel synapse when parallel fibers were simultaneously activated. Subsequent to Ito's original experiments, substantial additional evidence has accumulated in support of the proposal that cerebellar LTD plays a critical role in VOR motor learning. Inhibition of the signaling pathways that are required for induction of cerebellar LTD in normal animals prevents short-term motor learning in the VOR (Nagao and Ito, 1991; Li et al., 1995). Moreover, transgenic mice that express an inhibitor of protein kinase C, an enzyme that is involved in LTD, cannot adapt their VOR gain during short-term motor learning (de Zeeuw et al., 1998; van Alphen et al., 2002). Similarly, transgenic mice

lacking the $\delta 2$ subunit of the glutamate receptor (GluR$\delta 2$), which is required for LTD, do not show VOR motor learning (Katoh et al., 2005).

3.20.6.2 Cellular Mechanisms for VOR Motor Learning in the Vestibular Nuclei

The results of recent *in vitro* experiments have provided insights into the cellular mechanisms that underlie VOR motor learning at the level of the vestibular nuclei. High-frequency stimulation of vestibular nerve can evoke both LTD and long-term potentiation (LTP) in the vestibular nuclei (Caria et al., 1996, 2001; Grassi et al., 2001). The induction of either form of synaptic plasticity requires the activation of *N*-methyl-D-aspartate (NMDA) (Capocchi et al., 1992; Grassi et al., 1995) as well as metabotropic glutamate (Grassi et al., 1998, 2002, 2005) receptors. Interestingly, an animal's past visual or vestibular experience can alter the mechanisms that underlie cellular synaptic plasticity in the vestibular nucleus. For example, neurons in the ventral vestibular nuclei normally exhibit a shift from LTD to LTP during development (Grassi et al., 2004). This shift does not occur in animals that have experienced early visual deprivation or limited vestibular stimulation. Moreover, lack of visual input early in maturation alters the balance of mGluR1 versus mGluR5 receptors (Puyal et al., 2003). Accordingly, it is possible that the presence of visual signals such as retinal slip error (**Figure 3**) might induce changes in the strength of vestibular afferent–vestibular nuclei synapses to facilitate VOR motor learning.

3.20.6.3 Cellular Mechanisms Underlying Increases versus Decreases in VOR Gain

The results of behavioral analysis of VOR learning provide support for the idea that learned increases versus decreases in VOR gain are achieved by means of different plasticity mechanisms. Following learning, increases in VOR gain decay far more rapidly (Miles and Eighmy, 1980) and can be reversed more easily (Boyden and Raymond, 2003) than decreases in VOR gain. This has been furthered by recent studies that have addressed the underlying mechanisms of these differences using genetic manipulations and pharmacological approaches (reviewed in Boyden et al., 2004). Increases and decreases in VOR gain appear to be mediated by plastic changes in common locations because cerebellar lesions have comparable effects in both directions (Michnovicz and Bennett, 1987; Luebke and Robinson, 1994; Pastor et al., 1994; Partsalis et al., 1995b; McElligott et al., 1998). Ito's original model of VOR motor learning (1972) assumed that increases and decreases in VOR gain are governed by a single synaptic plasticity mechanism in the cerebellum, namely LTD. Most recently, however, the results of electrophysiological experiments that have shown that LTP as well as LTD can be induced at parallel fiber–Purkinje cell synapses (Coesmans et al., 2004; Lev-Ram et al., 2003). Thus, it has been suggested that cerebellar LTD at the parallel fiber–Purkinje cell synapse mediates increases in VOR gain, whereas LTP of the same synapse mediates decreases in VOR gain (**Figure 6**; Boyden and Raymond, 2003).

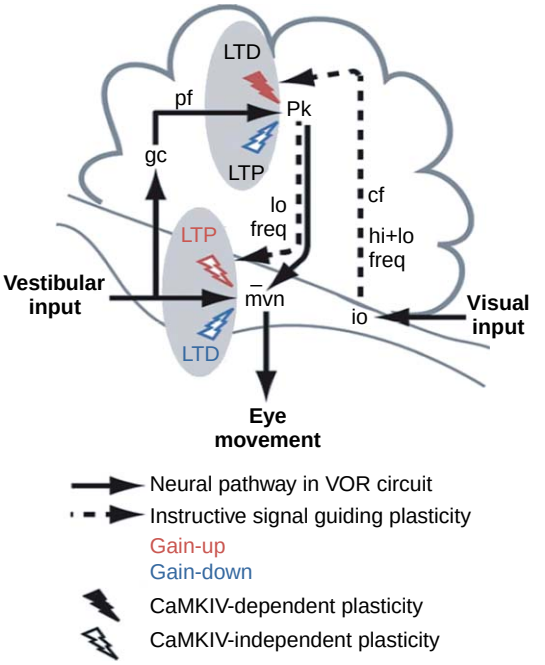

Figure 6 A model that explains differences in gain-up versus gain-down learning in the VOR. Purkinje cells carry only information about the required direction of learning for low-frequency training, whereas climbing fibers carry instructive signals during both high- and low-frequency training. As a result, during low-frequency training Purkinje cells induce plasticity (open lightning bolts) in the vestibular nuclei. In contrast, climbing fiber activity in the cerebellum (filled lightning bolts) also contributes to plasticity during high-frequency training. Learning in the cerebellum that requires LTD could increase VOR gain (red), whereas that which requires LTP could decrease VOR gain (blue). Abbreviations: cf, climbing fibers; gc, granule cells; io, inferior olive; pf, parallel fibers; Pk, Purkinje cells; mvn, medial vestibular nuclei. From Boyden ES, Katoh A, Pyle JL, Chatila TA, Tsien RW, and Raymond JL (2006) Selective engagement of plasticity mechanisms for motor memory storage. *Neuron* 51: 823–824.

3.20.6.4 Cellular Mechanisms: Open Questions

Although both LTD and LTP can also be induced in the vestibular nuclei, it is unclear whether the firing of a Purkinje cell induces depression and/or potentiation at these synapses (Babalian and Vidal, 2000). When LTD is induced in floccular Purkinje cells in an isolated whole-brain preparation, traces of flocculus-dependent plasticity cannot be detected in the FTNs within vestibular nuclei (Babalian and Vidal, 2000). Moreover, recent studies in transgenic mice have further shown that LTD is not required for all forms of VOR plasticity. As discussed earlier in the section titled 'Cellular mechanisms for VOR motor learning in the flocculus,' when LTD is blocked via inhibition of protein kinase C, neither short- nor long-term learning can be induced by visual-vestibular mismatch training. In contrast, vestibular compensation following unilateral damage to the vestibular sensory organs is not altered by the absence of LTD (Faulstich et al., 2006). Thus it appears that non-LTD-dependant pathways can mediate compensation. One possibility is that the synaptic plasticity of excitatory mossy fiber inputs to cerebellar nuclear neurons (Pugh and Raman, 2006; Zhang and Linden, 2006) contributes to non-LTD-dependent motor learning. Moreover, noncerebellar pathways can make a significant contribution to long-term changes in VOR gain following vestibular compensation (Cullen et al., 2006). Further studies will be required to fully understand the mechanisms that underlie VOR plasticity, particularly for learning that occurs following vestibular damage.

3.20.7 Context-Dependent VOR Motor Learning

3.20.7.1 Stimulus-Dependent VOR Motor Learning: Behavior

VOR adaptation can be specific for the stimulus parameters that are used during the induction of motor learning. Numerous studies have established that the amount of adaptive gain change exhibited by the angular VOR is related to the frequency of head rotation that was used to induce motor learning during training (Lisberger et al., 1983; Raymond and Lisberger, 1996; Kramer et al., 1998). The VOR shows the greatest changes at the adapting frequency, and gain changes induced by adaptation at higher frequencies are less frequency specific (i.e., more generalized) than those induced using lower frequencies. This idea has been furthered by the demonstration that the dominant linear component of the VOR response and a frequency-dependent nonlinearity (a rise in gain with increasing velocity of rotation at frequencies more than 2 Hz), which is observed only at higher frequencies (Minor et al., 1999) can be differentially adapted (Clendaniel et al., 2002). The nonlinear component of the VOR was only modified by the training protocols that evoked this component of the response.

The mechanism underlying these frequency-dependent differences in generalization of VOR adaptation are not yet well understood but several possibilities (see discussion by Boyden et al., 2004) can be reconciled with the results of behavioral investigations. On the one hand it is possible that a single plasticity mechanism underlies this frequency-specific adaptation. This could be the case if most neurons in a given structure (i.e., floccular Purkinje cells and/or vestibular nuclei neurons) respond to high-frequency stimulation, but only a subset of these are also sensitive to lower frequencies of stimulation. In this condition, more generalized plasticity would be induced in the circuit by higher-frequency stimulation because it would recruit most neurons. On the other hand, it is tempting to consider the alternative possibility that the dependence of generalization on training frequency results from the existence of two or more distinct plasticity mechanisms.

Evidence that blocking LTD alters the ability to adapt to high- versus low-frequency training protocols is consistent with the latter idea. Knockout mice that lack a protein kinase (CaMKIV) required for LTD (Boyden et al., 2006) show that VOR learning induced by higher-frequency (1 Hz) training is impaired, whereas adaptation induced by lower-frequency stimulation is not altered (0.5 Hz). The results further suggest that increases in gain induced with high-frequency training are mediated by different cellular/molecular plasticity mechanisms than those recruited by decreases in gain or increases in gain induced with low-frequency training. Findings from previous single-unit recording from floccular Purkinje cells provide additional support that different mechanisms guide learning for high- versus low-frequency training (Raymond and Lisberger, 1998). Climbing-fiber responses contained the information required to guide learning only at high-stimulus frequencies, whereas at lower frequencies both

climbing-fiber and simple-spike signals contained the information required to appropriately guide learning. This has led to the proposal that changes in the cerebellum (i.e., changes in the efficacy of the parallel fiber Purkinje cell synapse) specifically induces VOR gain changes at higher frequencies, whereas changes at the level of the vestibular nuclei (driven by the simple spike output of Purkinje cells) can induce gain changes during low-frequency training.

3.20.7.2 Stimulus-Dependent VOR Motor Learning: Neuronal Pathways

The VOR is capable of remarkable adjustments in response to environmental challenges that include lesions of the vestibular system as well as the use of magnifying or minimizing optical lenses. Immediately following unilateral labyrinthectomy, there is a marked asymmetry in gain characterized by diminished responses to rotations toward the lesioned side. Although the VOR shows nearly complete functional recovery for head rotations at lower frequencies (<4 Hz) and velocities (<50 deg/s) the VOR never fully compensates in response to rotations with higher frequencies and/or velocities (reviewed in Sadeghi et al., 2006).

Previous work in squirrel monkeys has demonstrated the presence of linear and nonlinear components to the horizontal vestibulo–ocular reflex (VOR). The nonlinear component is a velocity-dependent gain enhancement (see earlier discussion in the section titled 'Stimulus-dependent VOR motor learning: behavior'). In normal squirrel monkeys, the nonlinear pathway makes only a small (10–15%) contribution to the overall VOR response. The influence of this pathway, however, increases significantly following adaptation to unilateral vestibular damage or motor learning magnifying spectacles, suggesting it plays an important role in VOR adaptation and compensation (Lasker et al., 1999, 2000). Recent work provides support for this idea in old world monkeys and humans (Della Santina et al., 2001; Sadeghi et al., 2006).

Combined *in vivo*/*in vitro* studies have shown that neurons in the vestibular nuclei can be roughly separated into two groups (Type A and B) based on the shape of their action potentials and the subsequent after hyperpolarizations (Serafin et al., 1991a, b). Analysis of the intrinsic membrane dynamics of each cell class suggests that Type B neurons function as active filters, which promote high-frequency responses, whereas Type A neurons behave more like low-pass filters (Ris et al., 2001; Sekirnjak and du Lac, 2002; Beraneck et al., 2003). Thus, it has been proposed that Type A and Type B neurons can be considered channels for encoding low- and high-frequency signals, respectively (Av-Ron and Vidal, 1999; Ris et al., 2001).

Interestingly, the responses of Type A and B neurons resemble the dynamics of the linear (tonic) and nonlinear (phasic) VOR pathways, respectively, described by Minor and colleagues (1999). In addition, some Type B neurons preferentially receive inputs from the flocculus (Babalian and Vidal, 2000; Sekirnjak et al., 2002). Thus, the Type B cells that have been described in *in vitro* studies correspond to the FTN/EH neurons that have been shown to play an important role in lens-induced adaptation in *in vivo* studies (see discussion earlier in the section titled 'Changes in neural responses in the adapted state: vestibular afferents'). Taken together, these findings provide support for the idea that neurons with more phasic membrane properties play the principal role in mediating vestibular compensation and adaptation at the level of the vestibular nuclei.

3.20.7.3 Context-Specific Changes in VOR Gain

A number of recent studies provide firm evidence that subjects can store more than one VOR gain state, where each state is associated with a particular context. Eye position, vergence angle and otolith signals (i.e., head orientation) have all been shown to provide cues that can be used for inducing contextually dependent changes in VOR gain. Shelhamer and colleagues (1992) showed that when the angular VOR was adapted using magnifying and minimizing prisms with subjects' eyes looking up and down, respectively, the gain of the VOR following the adaptation was consistently reduced or increased when subjects looked downward or upward. Comparable results were shown for the translational VOR by the same group (Patel et al., 1998). Similarly, the angular VOR can be trained to store two different gain states by training that requires different gains for two vergence angles (i.e., diverged versus converged conditions; Lewis et al., 2003). The adapted VOR is characterized by different gain states, which are immediately accessed in a vergence specific manner that corresponds to the training context.

Similarly, several studies have shown that static otolith signals can provide strong contextual cues for gating the expression of different VOR gain states.

When the VOR is adapted with the head in a specific orientation relative to gravity, gain changes following adaptation of the angular VOR (Baker et al., 1987; Tiliket et al., 1993; Yakushin et al., 2000) and translational VOR (Shelhamer et al., 2002) are maximal when the head position is in the same position in which the gain had been adapted. These VOR gain changes are stored in a manner that is linked to the context of the head orientation in which changes were induced and fall off to zero when the head is in the opposite position (**Figure 7**; Yakushin et al., 2005). Gravity-specific adaptation of the VOR, like vergence-specific adaptation, can also be adapted to so that the VOR is adapted to two or even three specific gain states, each of which will be optimal for a different specific head position (e.g., Shelhamer et al., 2002, Xiang et al., 2006).

The context-specific VOR adaptation described appears to be strongly associated with the specifics of the stimulus parameters that are used during VOR adaptation (e.g., frequency of stimulation or eye movements that are induced during the training, see the section titled 'Stimulus-dependent VOR motor learning: behavior'). For example, the context-specific adaptation of translational VOR is greatest for head movement stimuli that are similar to those used during training (Shelhamer and Zee, 2003), and this frequency dependency is even more striking than for animals trained to a single gain state (Shelhamer et al., 2000). Other recent studies have

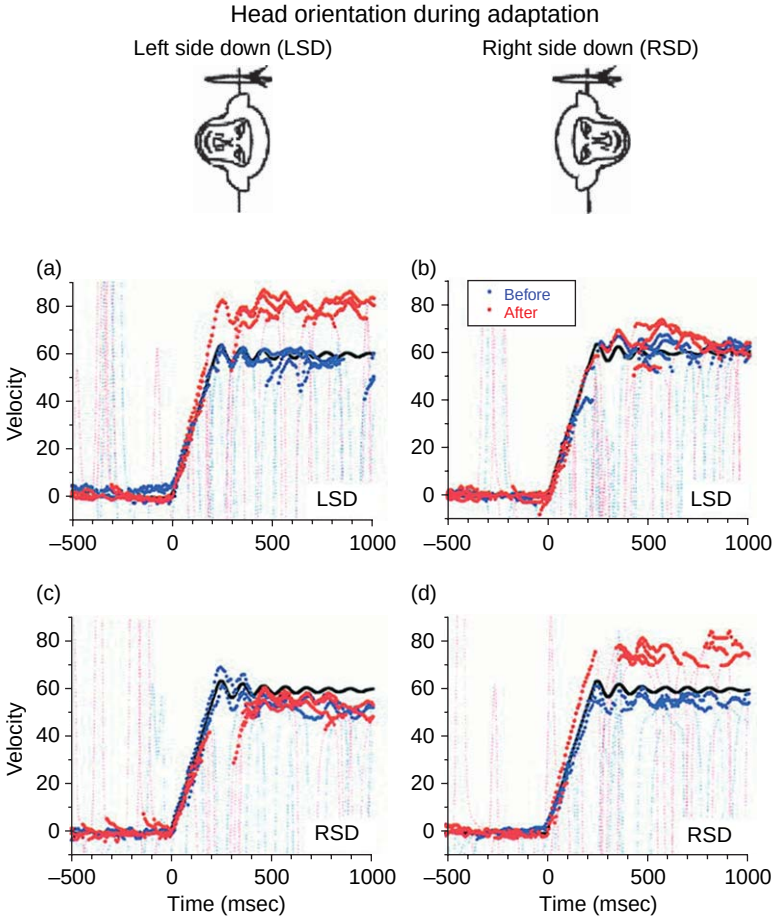

Figure 7 Step responses of the VOR when the animal was adapted left side down (a and c), and right side down (b and d). Eye velocities evoked by rotation before and after adaptation are shown in blue and red, respectively. The head velocity stimulus is shown in black. The direction of the stimulus was reversed to facilitate comparison. When the animal was adapted on one side, increases in eye velocity were significant when the animal was tested with the same side down (a and d), but there were no increases in eye velocity when the contralateral side was down (b and c). From Yakushin SB, Raphan T, and Cohen B (2000) Context-specific adaptation of the vertical vestibuloocular reflex with regard to gravity. *J. Neurophysiol.* 84: 3067–3071.

shown that motor learning can be specific to the particular combination of head motion and evoked eye movement that occurred during training. For example, when one eye is aligned with direction of head movement during adaptation of the translational VOR, it will remain motionless during training (Zhou et al., 2003). In this condition, VOR adaptation is only expressed in the eye that moved during the training.

3.20.8 Conclusions

The results of recent behavioral, single-unit recording and lesion studies have established that VOR motor learning induced by visual-vestibular discrepancy passes through distinct stages. Synaptic changes in the floccular complex underlie the initial induction of VOR adaptation. These changes, in turn, drive the formation of long-term synaptic changes at the level of the vestibular nuclei such that long-term memory is, for the most part, consolidated in the brainstem rather than in the cerebellum. Significant progress has also been made toward understanding the cellular mechanisms that underlie VOR adaptation in both the floccular complex and vestibular nuclei. Experiments in *in vitro* and isolated brain preparations as well as transgenic animals have shown that LTD and LTP can be induced at the parallel fiber–Purkinje cell as well as vestibular afferent–vestibular nuclei synapses. This has been furthered by recent studies that provide support of the idea that different cellular mechanisms induce changes at the parallel fiber–Purkinje cell synapse to induce increases versus decreases in VOR gain. Further investigation will be needed to address many important open questions. For example, we do not yet understand the mechanisms that ultimately drive the formation of long-term synaptic changes at the level of the vestibular nuclei. In addition, the mechanisms that underlie another form of VOR motor learning, namely compensation of the VOR following vestibular damage, are not fully understood.

Although we have gained considerable insights into the neural mechanisms that induce and encode gain changes in the VOR circuitry to support its adaptation and compensation, recent findings by several laboratories have highlighted another key feature of VOR adaptation. Current vergence angle or eye position, otolith-derived signals (i.e., head position), as well as attributes of the head velocity stimulus itself provide cues that can be used for inducing contextually dependent changes in VOR gain. This implies that, at a given instant in time, more than one VOR gain state is stored, and that the particular context will determine which state is retrieved.

Context-specific adaptation has similarly been demonstrated in other motor systems, for example, during ocular pursuit (Takagi et al., 2000), as well as reaching (Lewis and Tamargo, 2001), pointing (Welch et al., 1993), and throwing (Martin et al., 1996) movements. The ability to retrieve motor memories in a context-dependent manner is important for everyday activities. For example, during head rotation, the eyes translate as well as rotate relative to space because they cannot both be perfectly aligned with the axis of rotation. Consequently, a larger VOR gain is necessary to stabilize a near than a far earth-fixed target as a result of the differences in the translation of the target relative to the eyes. Thus, vergence-specific adaptation of the angular VOR is required to ensure gaze stability over a wide range of viewing conditions. Similarly, people who wear bifocal spectacles require a different VOR gain state for each lens magnification, each of which could be retrieved on the basis of current vertical eye position. It remains a significant challenge to understand the mechanisms that underlie context-specific adaptation; nevertheless, the relative simplicity of the vestibular system and the pathways that mediate the VOR make it an excellent model system for bridging the gap between brain and behavior.

3.21 Neurophysiology of Motor Skill Learning

R. J. Nudo, University of Kansas Medical Center, Kansas City, KS, USA

3.21.1 Introduction

Motor performance improves with practice. Movements are initially slow, variable, uncoordinated, and fractionated. After numerous repetitions, movements become fast, stereotyped, coordinated, and smooth, so that individual joint contractions blend into a single, transitionless action. Several aspects of cognitive and motor processing must be refined in order for such high levels of motor performance to be attained. Over the past several years, neurophysiological studies in experimental animals, especially in nonhuman primates, as well as neuroimaging studies in humans, have provided a wealth of data, which has helped to clarify the neural processes and structures underlying the development of skilled motor behavior. It now appears that a broad network of structures in the cerebral cortex, striatum, and cerebellum coordinate their activity to enable skilled motor behavior. Each of these structures probably plays a different role in either motor planning or execution, and some of these structures are critical to the learning of new motor tasks. This is evident since activity patterns are correlated with specific phases of learning, and this activity is altered as tasks are practiced and become highly skilled. In this chapter, we review the evidence from

neurophysiological, neuroanatomical, and neuroimaging studies that shed light on brain mechanisms underlying motor skill learning.

3.21.2 Definition of Motor Skill Learning

As used in this chapter, motor skill refers primarily to fine motor skill, such as might be required in picking up small objects, writing, typing, and so on, and not gross motor skill, such as might be required to sit upright, crawl, or walk. While the learning of gross motor skills is important during development, during activities of daily living, and during recovery from certain severe neurological disorders, the current chapter focuses on fine motor skill and its acquisition. Skill learning is sometimes referred to as habit learning, defined as the process of successive adaptation of behavioral responses to contingencies in environmental stimuli (Mishkin et al., 1984). Habit or skill learning is one of several forms of implicit learning thought to be mediated by neural networks in the cerebellum, frontal cortex, and basal ganglia. Implicit learning is contrasted with declarative learning, which involves the temporal lobe (Squire, 2004).

Although a general sense of what is meant by motor skill exists among researchers, there is no general agreement regarding what constitutes the acquisition of motor skill. In our view, motor skill learning is operationally defined as a change in motor behavior, specifically referring to the increased use of novel, task-specific joint sequences and combinations, resulting from practice and/or repetition. Others have argued that changes in the speed of movement, even if not accompanied by reciprocal changes in the accuracy of movement, indicate skill learning (Fitts, 1954; Hallett et al., 1996). However, it should be cautioned that speed as the sole criterion for evidence of skill learning may, at least in some situations, be confounded, as they may occur as a function of motivational state, also called dispositional learning (Amsel, 1992).

3.21.3 Central Nervous System Structures Involved in Motor Skill Learning

It is now clear that the motor cortex does not execute motor tasks in isolation. A broad network minimally involving the primary and secondary motor areas, the dorsolateral prefrontal cortex, the posterior parietal cortex, the striatum, and the cerebellum is involved in both skill acquisition and in motor execution. One goal of recent research has been to differentiate the role of various structures in the actual movement execution versus the role of the structure in learning the task (usually a movement sequence) or storage of the learned motor program. While both cortical and subcortical structures are clearly involved in motor learning, this chapter focuses on cortical motor areas and their role in skill learning.

Classically, motor skill was viewed as a serial process. Premotor areas were thought to be critical for the learning and storage of motor sequences. Premotor areas were thought to send information to the primary motor cortex for execution of motor behavior via descending pathways to the spinal cord. While certain neuroanatomical and neurophysiological features of premotor and primary motor areas support this concept, the more modern view recognizes that each of the cortical motor areas are, to some extent, involved in motor learning and the storage of motor commands, and that motor skill does not reside in any one place. However, these areas may differ in their degree of involvement in skilled motor behaviors, depending upon various task demands (e.g., role of visual or somatosensory guidance, cognitive demands, bimanual involvement, etc.). Here we review both the basic anatomy and physiology of these various motor areas and evidence for their differential roles in motor skill learning.

3.21.3.1 Cortical Motor Areas in Nonhuman Primates

It is generally accepted that no single feature is sufficient for characterizing an area as a distinct region. Features used to define cortical motor fields include cytoarchitectonics, patterns of afferent and efferent connections, features of intrinsic connectivity, chemoarchitectonics, behavioral effects of ablation, and, particularly for motor cortical areas, the ability to elicit movements upon electrical stimulation.

A differentiated motor field has a unique cytoarchitecture, traditionally defined by stains for Nissl bodies and myelin. Additionally, areas have been examined and characterized based on cytochrome oxidase staining, acetylcholinesterase staining, neurofilament antibody staining, and receptor binding. Unique characteristics of cell types, laminar organization, cell density, fiber density, and various staining densities

are all used for characterization. Extensive tract tracing studies have been used to identify subareas of motor cortex based on differential afferent and efferent connections with the thalamus, basal ganglia, and other cortical areas, as well as their projections to the spinal cord. Physiological criteria have also been used for differentiation. Intracortical microstimulation mapping procedures have helped to define somatotopic organization within each motor area, with attention paid to minimal threshold requirements for initiation of movements, as well as the characterization of the movements themselves. The relationship of single-unit activity to behavioral aspects of motor tasks in awake, freely moving animals has also been an important approach to distinguishing motor fields. Finally, motor areas have been characterized based on functional differences in ablation-behavior studies in nonhuman primates and functional imaging studies in humans.

The nomenclature used for subdivisions of primate motor areas has varied across laboratories. The generalized current scheme includes M1 (or Brodmann's area 4); four subdivisions of the lateral premotor cortex (PMd-c, PMd-r, PMv-c, and PMv-r, or F2, F7, F4, and F5, respectively); two premotor subdivisions on the mesial surface of the hemisphere (SMA and pre-SMA, or F3 and F6), and three subdivisions of the cingulate motor area within regions lining the cingulate sulcus (CMAr, CMAd, and CMAv, or area 24c, area 6c, and area 23c). M1 is the most easily recognizable area in histological stains, as it contains very large pyramidal neurons in layer V, the so-called Betz cells. Also, it contains a greatly reduced layer IV, compared with sensory cortex that contains a thick layer IV with substantial numbers of granule cells. For this reason, M1 is sometimes referred to as agranular cortex. **Figure 1** illustrates the location of the main cortical motor areas.

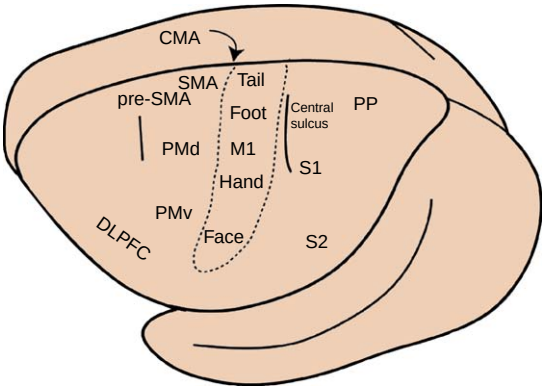

Figure 1 Location of cortical areas involved in motor skill learning and execution. Cortical areas are depicted on the brain of a squirrel monkey, a primate with few convolutions in its cortex. The areas depicted can be subdivided further on the basis of anatomical and physiological criteria. For example, SMA can be divided into a caudal component (SMA proper) and a rostral component (pre-SMA). CMA, cingulate motor areas; SMA, supplementary motor area; PMd, dorsal premotor cortex; PMv, ventral premotor cortex; DLPFC, dorsolateral prefrontal cortex; M1, primary motor cortex; PP, posterior parietal cortex; S1, primary somatosensory cortex; S2, second somatosensory area.

3.21.3.2 Cortical Motor Areas in Rodents

Because rodents are often used to study the role of motor cortex in motor skill learning, a brief comparative account of cortical motor areas in rodents is instructive. (While motor cortex in cats is also frequently a focus of motor learning experiments, this species will not be discussed in this review.) Intracortical microstimulation studies of sensorimotor cortex in the rat have shown a complete motor representation that is cytoarchitectonically defined as agranular cortex (Hall and Lindholm, 1974; Donoghue and Wise, 1982) and commonly called M1 based on its similarities to primate M1. In rodents, the portion of the agranular cortex in caudal portions of frontal cortex that is devoted to forelimb movements is referred to as the caudal forelimb area (CFA). In addition, a second motor representation of the forelimb has been identified in more rostral portions of the frontal cortex. This second forelimb representation, referred to as the rostral forelimb area (RFA), is smaller than the CFA (Neafsey et al., 1986). The RFA is separated from the CFA by a zone where intracortical microstimulation elicits vibrissa or neck movements.

Because the presence of a secondary motor area in rats would appear to parallel the differentiation of motor areas in primates, suggestions have been made that the RFA is a homolog of one of the primate secondary motor areas. Tract tracing studies of motor cortical connections in rat have shown differences in the thalamic, striatal, and cortical connections of CFA and RFA (Rouiller et al., 1993). Comparison of these connections to the pattern of connections of primate motor areas suggests that RFA has some similarities to primate premotor areas. Overall, based on its connections, CFA is more similar to the M1 forelimb area in primates, and RFA in some ways appears to be more similar to nonprimary motor cortex in primates. It is not currently possible to

decide whether RFA is a homolog of primate premotor cortex, supplementary motor areas, or a combination of secondary motor areas in primates (Rouiller et al., 1993). A more comprehensive review of primate and rodent motor areas can be found in Nudo and Frost (2006).

3.21.3.3 Role of Somatosensory Cortex in Motor Skill Learning

While the present chapter focuses on motor output structures, it should be recognized that sensory information plays a critical role in the learning of new motor skills. For example, the somatosensory system is critical for skilled motor behavior. Various somatosensory regions in the parietal lobe of the cerebral cortex are intimately interconnected with motor cortical regions in the frontal lobe. Somatosensory information can be recorded from neurons in M1, and this information is segregated by submodality. Cutaneous inputs arrive in the more caudal aspects of M1, while proprioceptive inputs arrive in the more rostral aspects. Focal experimental lesions in rostral or caudal M1 result in distinct sensory-related deficits in skilled use of the hands. Lesions in either primary somatosensory cortex or M1 in nonhuman primates result in similar deficits. Thus, while there are clear structural and functional distinctions between M1 and S1, they are functionally codependent with regard to skilled motor behaviors.

3.21.4 Organization of Primary Motor Cortex and Its Role in Motor Skill Learning

The vast majority of studies examining the neurophysiological bases for motor skill learning have been performed in the primary motor cortex, or M1. The reasons for this bias are numerous: M1 is very accessible because of its location in the precentral gyrus. The portion of M1 that is most often examined, the M1 hand representation, is located on the dorsolateral surface. In most primates, however, a large portion of the M1 hand representation is buried in the anterior banks of the central sulcus, rendering accurate reconstruction of two-dimensional topographic maps more challenging. Nevertheless, neuronal population studies, especially from cells within the more rostral portions of M1, and to a lesser extent, the caudal portions of M1 within the depths of the central sulcus, are numerous. Thus, from the first functional localization studies in the 1800s to cellular responsivity studies of the present day, M1 is the primary focus of most cortical studies of motor control.

In primates at least, M1 is equivalent to Brodmann's area 4, based on cytoarchitectonic criteria. M1 contains a complete representation of skeletal and orofacial musculature organized in a topographic fashion, but with an exaggerated representation of the hands and face. This organization has been known since the late 1800s, primarily because of muscular contractions evoked from electrical stimulation of the cortical surface and, more recently, by more direct stimulation of the output neurons located in layer V, demonstrated by intracortical microstimulation. The most direct access to motor neurons in the spinal cord is via the corticospinal tract, originating in layer V pyramidal cells and terminating in intermediate and deep laminae of the spinal cord. In many primate species (and possibly other mammalian species), a subset of corticospinal neurons, so-called corticomotoneuronal cells, terminate monosynaptically onto spinal motor neurons. It is now known that corticomotoneuronal cells diverge to innervate multiple (on average, about four or five) motor neuron pools (**Figure 2**). Furthermore, corticomotoneuronal cells with different projection patterns intermingle within each local zone within M1 (Rathelot and Strick, 2006). Thus, the highly organized topographic arrangement inferred from electrical stimulation studies is valid only on a macroscopic scale. Substantial divergence and convergence exist in the connections between M1 and spinal cord motor neurons at a more focal level. It is possible that this anatomical arrangement confers on M1 a certain capacity for functional plasticity, since, depending upon the subset of neurons in a given zone that is activated, a different motor output might result.

M1 can access motor neurons in the spinal cord via more indirect routes also. For example, corticofugal neurons project monosynaptically to the red nucleus, which in turn projects monosynaptically and disynaptically to spinal cord motor neurons. These pathways are topographically organized on a macroscopic scale, much like the direct corticomotoneuronal pathway. Somewhat more diffuse access can be accomplished via M1 projections to the pontine and medullary reticular formation, which in turn projects to the spinal cord.

M1 also contains a rich array of intracortical connections that are thought to modulate the output of corticofugal cells. The role of local corticocortical fibers in shaping responses in the execution of skilled motor tasks is not well known. However, this

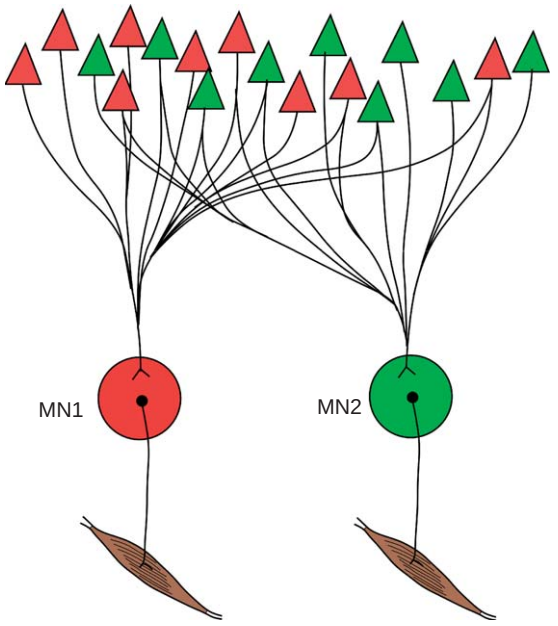

Figure 2 Divergence and convergence of corticospinal neurons in M1. Corticospinal neurons diverge to form monosynaptic connections with up to four or five motor neuron pools. Two such pools, MN1 and MN2, are shown in the figure. Corticospinal neurons projecting to a single motor neuron pool are represented over a large territory within M1. Thus, different corticospinal neuron populations (red and green triangles) are intermixed across the spatial domain of M1.

modulatory influence may provide another important substrate for plasticity in the output properties of motor cortex.

Virtually all mammalian species contain a cortical structure analogous (if not homologous) to primary motor cortex. Corticospinal neurons originating in layer V exist in every mammalian species studied to date, including primates, carnivores, rodents, insectivores, and marsupials. However, the number of corticospinal neurons, their penetration into the cord, their trajectory in the cord, and the proximity of their terminals to motor neuron cell bodies vary widely across species. A motor cortex, as defined by an area of the cerebral cortex whose stimulation results in movements of muscles of the body, seems to be universal among mammals.

3.21.4.1 Neurophysiological Changes in M1 Associated with Motor Skill Learning

Historically, it has been thought that since M1 is so intimately connected to motor neurons in the spinal cord, its role in motor behavior was concerned primarily with low-level execution of muscular contractions. However, several lines of evidence now suggest that it plays a very important role in skill acquisition and motor learning.

Neurophysiological studies in animal models, especially nonhuman primates, provide unique insight into the role of various cortical and subcortical networks in motor skill learning, since the activity of neuronal populations can be tracked over time in the same animals, as they perform a specific task. However, until recently, the most common paradigm was to examine neuronal activity in relation to movement only after an animal had been highly trained for several weeks to months. While this paradigm allows examination of the relationship of neuronal activity to control of movements, it does not provide much insight into the actual learning of the task. This is important since the acquisition of various aspects of motor skill might be mediated by different neuronal structures and processes.

Several human studies using transcranial magnetic stimulation have demonstrated that increased use of muscles expands their motor representations (Pascual-Leone and Torres, 1993; Tyc et al., 2005). Even simple movements repeated over a short period of time are effective in inducing cortical representational changes (Classen et al., 1998). Recent experiments in nonhuman primates have demonstrated that motor representations of hand movements expand in concert with the acquisition of new motor skills (Nudo et al., 1996). In these studies, monkeys were trained on an operant task requiring retrieval of food pellets from small wells. Behavioral performance was initially poor based on timing of retrievals and numbers of digit flexions required per retrieval. Behavioral performance increased asymptotically and reached plateau in about 10 days. At the end of the training period, both individual joint movements and specific joint movement combinations and sequences used by individual animals became represented over larger cortical territories (**Figure 3**). As digit skills were acquired, very little expansion of the total hand representation occurred. Instead, digit and wrist representations became redistributed. These effects were reversible, to some extent, though not completely. This suggests that once a novel motor task is learned, certain aspects of cortical topography are altered for an extremely long period of time. Changes in face motor cortex have also been

Figure 3 Alterations in motor representations in M1 as a result of motor skill training. After several days of practice at a novel motor task (pellet retrievals from small wells), monkeys display larger representations of the fingers and wrist. In addition, representations of multijoint movements (fingers + wrist) emerge. Current thresholds required for activating movements at multijoint sites are particularly low compared with at single-joint sites. From Nudo RJ, Milliken GW, Jenkins WM, and Merzenich MM (1996) Use-dependent alterations of movement representations in primary motor cortex of adult squirrel monkeys. *J. Neurosci.* 16: 785–807.

demonstrated after learning a novel tongue protrusion task (Sessle et al., 2007).

One of the more interesting aspects of these results is that movement combinations that were used in the task became represented over a larger cortical territory. This suggests that temporal correlation of movements (and presumably muscles) drives changes in cortical motor organization. It is possible that local intracortical connections couple various separate modules together to form muscle or movement synergies. After training, at sites where multiple joints are represented (as defined by similar thresholds for activation), the current levels required for evoking the multijoint movements are significantly lower than those required to evoke single-joint movements. Recently, analogous results have been demonstrated using functional magnetic resonance imaging after motor training in humans (McNamara et al., 2007). Thus, training may in some way prime specific intracortical connections to enhance the excitability of subsets of corticomotoneuronal cells that must fire concurrently for skilled tasks to be completed.

Subsequent microelectrode stimulation studies in monkeys and rats confirmed these initial findings and further suggested that skill acquisition was a necessary feature of the behavioral experience for neurophysiological map plasticity to occur, rather than simple movement execution alone. Monkeys that retrieve food pellets from larger wells than those used in the study described do not exhibit the slowly developing asymptotic learning curve compared with monkeys trained on the small-well task. Even though they execute the same number of digit movements, these animals demonstrate no systematic change in motor map topography in M1 (Plautz et al., 2000). Similar findings have been found in rodents. Rats trained in a novel task to retrieve food pellets from a rotating platform demonstrate expansions of distal forelimb representations in M1. However, rats trained to press a bar repeatedly with their distal forelimb show no map changes (Kleim et al., 1998). Presumably, the large-well pellet retrieval task in the monkey and the bar pressing task in the rat are skills that had already been acquired in the normal behavior of the animal. Only when novel tasks are taught that require the acquisition of new joint movement combinations is the motor cortex topography altered significantly.

Another paradigm for motor training, strength training, also does not appear to alter motor maps in M1. In comparison to nontrained control animals, rats that are trained to repetitively grasp and break a strand of dried pasta show expanded representations of the distal forelimb, presumably due to the novel skill required by the task. However, if rats are trained to break progressively larger bundles of pasta strands, a similar task that simply requires more force, the same expansions occur. That is, no further reorganization in distal forelimb representations occurs with strength training (Remple et al., 2001).

At the cellular level, both long-term potentiation (LTP) and long-term depression (LTD) can be generated in somatosensory and motor cortex of rats under specific conditions (Castro-Alamancos et al., 1995; Rioult-Pedotti et al., 2000). It has been suggested that extensive intracortical connections in superficial layers of motor cortex might undergo changes in synaptic efficacy that underlie neurophysiological changes in motor cortex during motor learning. In rats, when one limb is trained on a motor task, the amplitude of field potentials contralateral to the trained limb is significantly increased relative to the cortex opposite the untrained limb. Further, the trained cortex is less amenable to subsequent LTP induction (Rioult-Pedotti et al., 1998; Hodgson et al., 2005). However, others have argued that learning motor skill acquisition produces bidirectional changes in synaptic strength distributed throughout the intracortical networks of motor cortex. Unidirectional changes in the population of neural elements are suggested to occur during certain behavioral states not directly related to the learning process (i.e., stress; Cohen and Castro-Alamancos, 2005).

3.21.4.2 Neuroanatomical Correlates of Motor Skill Training in M1

Skill training is also associated with changes in the microanatomy within motor cortex, including dendritic reorganization, synaptogenesis, and changes in

synapse morphology. Training rats on an acrobatic task that requires them to traverse a series of obstacles (horizontal ladder, grid platform, rope, barriers) results in increases in synapse to neuron ratios and dendritic processes in motor cortex (Jones et al., 1999; Bury and Jones, 2002). Similar synaptic and dendritic changes occur with reach training in rats (Withers and Greenough, 1989; Kleim et al., 2002). Training-induced structural reorganization is limited to the motor cortex region that undergoes neurophysiological reorganization (Kleim et al., 2002). More recent immunohistochemical studies have attempted to determine the proteins that are involved in these morphological changes. In rats, synaptophysin and GAP-43 expression appear to be correlated with the first 5 days of motor skill learning. However, microtubule-associated protein 2 (MAP-2) was not influenced by learning (Derksen et al., 2006). Brain-derived neurotrophic factor (BDNF) appears to be involved in learning-related plasticity in motor cortex. If BDNF is inhibited by injection of antisense oligodeoxynucleotides, receptor antagonists, or BDNF receptor antibodies, motor skill is impaired and neurophysiological organization is disrupted (Kleim et al., 2003; Adkins et al., 2006).

While studies at the genetic and molecular level of analysis are still few in number, recent studies suggest a time-dependent change in corticostriatal expression patterns of immediate early genes during motor training (Hernandez et al., 2006).

3.21.5 Secondary Motor Areas and Their Role in Motor Skill Learning

In addition to M1, there are several secondary motor areas (SMAs) recognized in the primate cortex (**Figure 1**). These areas have been defined as having direct connections to both M1 and the spinal cord. The premotor cortex, the SMA, and the cingulate motor cortex have been identified in all primate species examined, including prosimian primates. Each of these secondary areas has been divided into subareas based on differences in cortical architecture that are related to hodological and functional differences. The lateral premotor area is divided into ventral and dorsal areas (PMv and PMd, respectively), the SMA into SMA proper and pre-SMA, and the cingulate motor cortex into rostral (CMAr) and caudal (CMAc) divisions. As many as 10 motor fields emerged early in primate evolution (Wu et al., 2000).

The premotor and supplementary motor areas appear to be involved in different aspects of movement compared to M1. This has been suggested simply from the timing of activity in the various cortical motor regions. Using time-resolved fMRI during a delayed cued finger movement task, activity in M1 was substantially weaker during movement preparation compared with during movement execution. However, activity in PM and SMA was equally high during both phases of the task (Richter et al., 1997).

3.21.5.1 Role of the SMA in Motor Skill Learning

A significant role in the planning, preparation, and initiation of voluntary movement has been ascribed to the secondary motor areas on the medial wall of the hemispheres, especially the supplementary motor area. Early stimulation studies demonstrating complex movements evoked at higher currents from stimulation of SMA first suggested that the medial motor areas are involved in more complex aspects of motor behavior (Thickbroom et al., 2000). Later, neuroimaging studies implicated the role of SMA in higher-order processes. In one very influential study examining cerebral blood flow, for example, the SMA was the only area activated when subjects mentally rehearsed a finger tapping sequence without actually executing it (Roland et al., 1980).

Based on these early results, the focus for SMA studies has been on its role in complex aspects of motor behavior, such as movement planning and sequencing. In daily activities, discrete movements must be coordinated in the proper sequence, and transitions from one movement to the next must be accomplished smoothly and rapidly. As movement sequences are practiced, the individual movements become more stereotyped (i.e., with decreased variability in kinematics and kinetics), and the time between different movements decreases. Eventually, one movement component blends into the next, and a smooth, coordinated action results. The SMA is thought to participate in this sequencing function. But it should be recognized that sequence learning requires several neural systems that are involved in cognitive, perceptual, motoric, and temporal aspects of learning (Grafton et al., 1998). Motor behaviors are controlled by a distributed network, and it may be too simplistic to think in terms of compartmentalized units that have mutually exclusive functions. For example, a recent 2-deoxyglucose study in nonhuman primates

showed substantial metabolic activity in both SMA and pre-SMA associated with visually guided reaching movements. The intensity of activation was comparable to that of M1 in the same animals (Picard and Strick, 2003). Most neurons in SMA are active in relation to effector-related variables. However, a modest number appear to represent target direction independent of reach direction. Further, the largest number of neurons in SMA appears to be context-dependent, that is, activity is directional in one visuomotor mapping condition, but not others (Crutcher et al., 2004). While it is now clear that these areas are involved in diverse aspects of movement control, planning and timing are the major focus of investigations.

Many studies in nonhuman primates have demonstrated that the supplementary motor area is important in the control of sequential movements. Early studies demonstrated that SMA neurons are active during movements of either extremity (Brinkman and Porter, 1983), and SMA lesions result in deficits in bimanual coordination (Brinkman, 1981). More recent studies demonstrated that removal of SMA in monkeys does not cause paralysis or akinesia. However, monkeys were impaired at performance of a simple learned task in which they were required to raise their arm to obtain a food reward below (Thaler et al., 1995). They were less impaired if the task was paced by an external cue (tone). These deficits are similar to those observed in humans with damage to SMA. Patients with lesions involving the SMA, but sparing the lateral hemispheric surface, demonstrated difficulties in producing rhythmic motion unless the task was guided by auditory pacing (Halsband et al., 1993). These data have been cited as evidence for the role of SMA in self-initiated actions.

SMA is thought to play a role in modulating motor output based on kinesthetic inputs. A large percentage of neurons in SMA respond differentially to different instructions during a preparatory state (Tanji et al., 1980; Passingham, 1987). Also, neuronal discharge within SMA typically precedes activity in M1 (Deecke et al., 1985), but SMA response properties differ from those in M1 in that SMA activity is related to factors other than the execution of movement to a greater extent than neurons in M1 (Kurata and Tanji, 1985).

Neuronal activity in SMA is also thought to reflect internal models of movement dynamics, or the forces exerted by contracting muscles. Dynamic related signals are nearly comparable in SMA and M1 (Crutcher and Alexander, 1990). Movement dynamics are significantly represented in SMA during both motor planning and execution. This property is likely to play a particularly important role in motor learning, as SMA neurons shift their preferred direction in the direction of an external force when monkeys adapt to a perturbing force field, and back in the other direction when the monkeys readapt to the nonperturbed direction. This shift occurs during the instructed delay and during the movement-related time window (Padoa-Schioppa et al., 2004).

3.21.5.2 Two SMAs: Different Roles for SMA and Pre-SMA

Two SMA representations can be differentiated in primate species based on distinct cytoarchitecture, intracortical microstimulation, neuronal response properties, and connection patterns. These two areas, located on the mesial aspect of the frontal cortex, are referred to as SMA proper (or simply SMA; also called F3) and the pre-SMA (also called F6), situated more rostrally (Wu et al., 2000). Typically, in human neuroimaging studies, the SMA is differentiated from pre-SMA based their location relative to the anterior commissure, with the SMA proper lying caudal to the level of the commissure, and the pre-SMA lying rostral to the commissure. However, diffusion tensor imaging studies have revealed different patterns of connections in SMA and pre-SMA, and thus, more refined identification methods in humans are now available (Lehericy et al., 2004).

3.21.5.2.1 Basic differences in physiology and anatomy of SMA/pre-SMA

SMA contains a complete motor representation with the face-arm-leg regions arranged rostrocaudally (Luppino et al., 1991). Movements are elicited at low current thresholds. Arm movements can be elicited from pre-SMA, though larger currents are required (Matsuzaka et al., 1992). Compared to SMA, pre-SMA has only sparse spinal projections but connects more heavily with prefrontal cortex. For this reason, some investigators consider pre-SMA (as well as pre-PMd) to be a prefrontal cortical region rather than a premotor area. In general, SMA proper is thought to be involved primarily in simple tasks, while pre-SMA is activated during relatively complex tasks (Picard and Strick, 2001).

3.21.5.2.2 Role of SMA/pre-SMA in learning of motor sequences

Many cells in SMA and pre-SMA fire preferentially during the performance of new sequences (Nakamura et al., 1998). Studies of the role of SMA and pre-SMA in sequence learning have focused primarily on either movement sequences with the upper extremity or sequences of saccades (Muri et al., 1994). Neuronal responses to visual stimuli predominate in pre-SMA, while responses to somatosensory stimuli predominate in SMA proper (Matsuzaka et al., 1992). However, the current review focuses exclusively on movements of the upper extremity, and not on saccades.

Neurons in SMA/pre-SMA that are related to sequence learning start discharging after the illumination of the stimuli for each set; the discharge rate increases until the monkey presses the first button. As learning proceeds, these neurons discharge progressively less, so that in highly learned sequences, almost no activity is evident. Such neurons that preferentially are activated during new sequences are more common in pre-SMA. This role has often been referred to as reprogramming. In fact, neurophysiological studies in monkeys demonstrate that many pre-SMA cells are preferentially active only during the single trials where the animals are required to update to a new movement sequence (Shima et al., 1996). The activity is not related to a new association, since the sensory stimuli and the associations with different movements are already well learned. This suggests that pre-SMA is involved in updating motor plans or reprogramming.

Many SMA neurons display a gradual change in activity related to experience with a particular movement sequence. This suggests that activity in SMA is dynamically reorganized by experience (Lee and Quessy, 2003). It is possible for learning about motor tasks to occur in the absence of motor performance changes, for example, as measured by reaction time. This might occur during the observation of a motor task. The subject later demonstrates more rapid improvements in performance since some perceptual/cognitive aspect of the task was learned during the observation. It has been argued that SMA may play a role in sequence learning independent of the relationship with performance changes (Lee and Quessy, 2003).

One behavioral paradigm that is popular for studying motor sequence learning in nonhuman primates is the sequential button task, in which monkeys are required to press pairs of buttons in the proper sequence. This task has been used extensively by Hikosaka and colleagues, who generally train monkeys in sets of five consecutive pairs of button presses. Using a similar task in a PET study of cerebral blood flow in humans, SMA was more active (more blood flow) during the performance of a prelearned sequence compared with a new sequence (Jenkins et al., 1994). In contrast, pre-SMA is active during the process of learning the sequence (Hikosaka et al., 1996).

These results may explain the earlier lesion results. If SMA is more active after a motor sequence is learned (and thus, after external cues are no longer necessary to pace the task), damage to SMA would then result in deficits in performing the learned sequence. However, if external cues are then provided, the lateral premotor areas are engaged and can compensate for the deficit.

But many brain regions are active during new learning, such as dorsolateral prefrontal cortex, parietal cortex, lateral premotor area, cerebellum, and basal ganglia (Nakamura et al., 1999). Are either SMA or pre-SMA necessary for learning new sequences? In monkey studies, these areas can be differentially and temporarily inactivated using muscimol, a GABA agonist. Inactivation of either area increases reaction time of button presses for both novel and learned sequences. However, inactivation of pre-SMA, but not SMA, increases errors for novel sequences, but not learned sequences (Nakamura et al., 1999). These data provide further support that pre-SMA is more involved in the learning of new motor sequences. What specific factors related to new learning are disrupted by the inactivation (novelty detection, selective attention, decision making, error correction, switching motor plan, memory coding, retrieval, etc.) are not completely known.

Cells have also been found in SMA that appear to be responsive to a particular order of forthcoming movements (Tanji and Shima, 1994), supporting the view that SMA is particularly important in the relational order of sequence components (i.e., neurons fire during movement A only if movement A is preceded or followed by movement B). In addition, both SMA and pre-SMA neurons show selectivity for the numerical order of sequence components, although the incidence of such neurons is higher in pre-SMA. That is, these neurons may fire during movement A only if movement A is the second movement in the sequence (Clower and Alexander, 1998).

Before leaving this discussion of motor sequence learning, it should be emphasized that SMA and pre-SMA are probably not the only cortical motor

areas involved in coding movement sequences. Recent data from monkeys have demonstrated that after long-term training on a sequence task, a large proportion of neurons in M1 were differentially active during a repeating sequence versus a random sequence (Matsuzaka et al., 2007). A large number of M1 neurons are active during the instruction period, similar to findings in premotor areas. When cells were sought that showed an interaction between movement direction and serial order (sequence-related cells), such cells were the most common type (40%). Only 17% of these cells were related to movement direction alone (Lu and Ashe, 2005). This suggests that M1 may represent sequential movements, as has been suggested for SMA and pre-SMA. It would appear that M1 participates in motor skill learning beyond the simple kinematic level, and thus, the neural network participating in more cognitive aspects of motor tasks may be broadly distributed.

A model for a more global network view of sequence learning has been proposed by Ashe and colleagues (2006). The basic principle of this model is that motor sequences involve both implicit and explicit learning depending upon the stage of the learning process (**Figure 4**). These two forms of learning are thought to employ somewhat different neural structures. Much of motor sequence learning is implicit, as elements of the movements are made in sequential order without specific awareness about the sequence. Ashe's model suggests that in these conditions, implicit processes originate in M1 and propagate to premotor areas. With repeated practice, learning may become explicit, as the subject is aware of the instructional set. In this case, explicit processes originate in prefrontal cortex and then propagate to premotor areas. In reality, both implicit and explicit processes probably interact, and thus neural correlates can be found across broad neuronal networks.

3.21.5.2.3 Role of SMA/pre-SMA in self-initiated versus externally guided movements

One of the central issues concerning the role of SMA/pre-SMA in movement is its role in self-initiated movements as opposed to movements triggered by external stimuli, or externally guided movements. While a large percentage of neurons in SMA are active during IG movements, approximately 90% of task-related neurons are active before or during EG movements (Mushiake et al., 1991).

Both self-initiated and externally guided movements activate a common network of cortical areas including SMA, pre-SMA, cingulate cortex, M1, superior parietal cortex, and insular cortex. Neurophysiological data in animals seem to indicate that the mesial motor areas are more involved in self-initiated movements, while lateral premotor areas are involved in externally guided movements (Romo and Schultz, 1987; Thaler et al., 1988; Mushiake et al., 1991; Cunnington et al., 2002). Motor preparatory activity appears to arise primarily from mesial motor areas, supporting this view. Neuroimaging studies have demonstrated that mesial motor areas show greater activation with self-initiated compared with externally triggered movement (Rao et al., 1993; Wessel et al., 1997; Deiber et al., 1999; Jenkins et al., 2000; Hoshi and Tanji, 2006), and greater activation of lateral premotor areas for externally triggered (EG) movements.

Activity increases in both mesial motor areas and lateral premotor areas during a movement preparation period (Richter et al., 1997). M1 shows weak activation

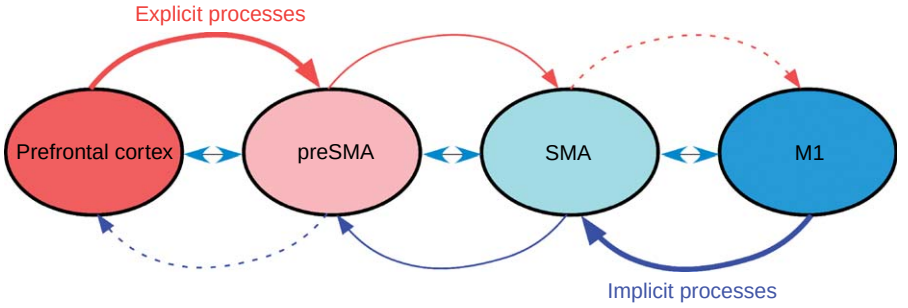

Figure 4 Cortical structures involved in the control of motor sequences. In this model, both explicit and implicit processes operate in the learning and execution of movement sequences. The degree of involvement of the two processes, and the underlying neural structures participating in the behavior, are a function of the stage of the learning process. Adapted from Ashe J, Lungu OV, Basford AT, and Lu X (2006) Cortical control of motor sequences. *Curr. Opin. Neurobiol.* 16: 213–221.

during this preparation period, and follows that of premotor areas in time (Wildgruber et al., 1997). Using rapid event-related functional magnetic resonance imaging that allows the timing of different motor cortical areas to be examined, activity has been examined using a finger sequence movement task. Using this approach, activity in SMA does not differ between self-initiated and externally guided sequences during movement, or between self-initiated premovement and movement. Both self-initiated movements and externally cued movements show strong activation in mesial motor areas. However, the timing of the activity in pre-SMA was significantly earlier for self-initiated compared with externally triggered movements. (Cunnington et al., 2002). Sequence complexity had a greater effect on SMA before rather than during movement, suggesting that SMA is more involved in preparatory processes (Elsinger et al., 2006).

Pre-SMA appears to be preferentially involved in self-initiated movements. Pre-SMA also appears to be activated when a mental representation of a movement is engaged, in the absence of actual movement (Koski et al., 2003). However, imagined movements are also correlated with activation in SMA, but the SMA was more active during movement execution (Cunnington et al., 2006).

Whether the SMA is involved in self-initiated movements is subject to debate (see discussion in Deiber et al., 1999), but other variables may modulate activity of SMA, in addition to the mode of movement initiation. Pre-SMA (as well as PMd) and not SMA was activated preferentially during an auditory conditional motor task, in which two different tones triggered different movements (Kurata et al., 2000). Pre-SMA activity appears to be rate dependent, with more extensive activation with faster movements. SMA is preferential for sequential rather than fixed movements, that is, the type of movement (Deiber et al., 1999).

One interesting aspect of the timing of movements focuses on whether motor areas are concerned with ordinal or interval properties of the timed movements. Timing control appears to be independent of sequence representation. That is, timing can be changed without changing the sequential order. During a sequential movement task, subjects had to attend to either the interval or the ordinal information of a sequence of visually presented stimuli. While the same motor areas were activated in both conditions, pre-SMA, lateral PMC, frontal opercular areas, basal ganglia, and left lateral cerebellar cortex were activated more strongly by interval information, while SMA, frontal eye field, M1 and S1, cuneus, and medial cerebellar cortex were more active for ordinal information. (Schubotz and von Cramon, 2001). Thus, different aspects of impending movement sequences may be processed by different areas.

3.21.5.2.4 Shift-related cells in pre-SMA

In monkeys, activity in response to visual cue signals during a preparatory phase that indicates the direction of an upcoming arm movement is abundant in pre-SMA. Also, pre-SMA contains an abundance of shift-related cells that respond when monkeys are instructed to shift the target of a future reach from a previous target to a new target (Matsuzaka and Tanji, 1996). Relatively few shift-related cells are found in SMA. The majority of SMA neurons are time-locked to movements.

3.21.5.2.5 Role of SMA in kinetics and dynamics of movement

Two aspects of reaching movements have been described based on kinematics versus dynamics of the action (Padoa-Schioppa et al., 2002). Kinematics refers to the evolution in time of the joint angles and hand position. Dynamics refers to the set of forces exerted by the muscles. The accomplishment of skilled reaching can be defined from a neural perspective as the generation of appropriate forces (dynamics) for a desired hand trajectory (kinematics). Thus the role that the central motor structures plays in the transformation of desired kinematics into dynamics is critical to our understanding of motor skill learning. Dynamics-related neural activity has been found in several motor structures including dentate and interpositus nuclei in the cerebellum, M1, SMA, PMd, PMv, and putamen. Neurophysiological studies suggest that dynamics-related activity in SMA occur during the motor planning phase. Thus, SMA is likely to participate in this kinetics-to-dynamics transformation (Padoa-Schioppa et al., 2002).

3.21.5.3 Lateral Premotor Cortical Areas and Their Role in Motor Skill Learning

3.21.5.3.1 Comparative aspects of lateral premotor areas

Recent studies indicate that premotor areas play an important role in sensory guidance of movement and some aspects of motor preparation. Premotor areas probably first appeared with the divergence of

prosimian primates, as evidenced by lateral premotor representations coincident with distinct cytoarchitectonics rostral to the M1 representation. Two major subdivisions, PMd and PMv, have been identified in the prosimian Galago (Wu et al., 2000). PMd has been further subdivided in Galago into rostral and caudal components (PMd-r and PMd-c, respectively). These two PMd areas appear to be functionally distinct, as saccades are evoked from stimulation of PMd-r, and forelimb and body movements are evoked from PMd-c (Fujii et al., 2000). To the extent that Galagos represent a primordial state of primate motor cortex, it is likely that PMd-r, PMd-c, and PMv are homologs in all extant primates. Intracortical microstimulation studies have also identified PMv and PMd in New World and Old World monkeys (Gould et al., 1986; Stepniewska et al., 1993; Preuss et al., 1996; Frost et al., 2003; Hoshi and Tanji, 2004). The PMd has been shown to consist of representations of both hindlimb and forelimb (He et al., 1993; Ghosh and Gattera, 1995; Preuss et al., 1996; Raos et al., 2003), while PMv contains representations of the forelimb and orofacial muscles (Stepniewska et al., 1993; Preuss et al., 1996).

In addition to the areas noted that have been identified in prosimian primates and New World monkeys, the PMv is further differentiated in Old World monkeys. A total of four subareas of lateral premotor cortex are identifiable in macaques: PMd-c, PMd-r, PMv-c, and PMv-r (or F2, F7, F4, and F5, respectively) based on cytoarchitectonics and intracortical microstimulation results and connections (Rizzolatti and Fadiga, 1998; Rouiller et al., 1998; Morel et al., 2005).

Unlike macaque monkeys, there have been no delineations of subareas F4 and F5 (Pmv-c and Pmv-r) in PMv of prosimian primates or New World monkeys. In macaques, PMv is subdivided into caudal and rostral divisions based on cytoarchitectonic, connectional, histochemical, and physiological distinctions (Matelli et al., 1985, 1991; Luppino et al., 1999; Rizzolatti and Luppino, 2001; Rizzolatti et al., 2002; Morel et al., 2005).

Since direct corticospinal projections originate from dorsal and ventral premotor areas (as from M1, SMA, and CMA), it is possible that all frontal cortical areas may participate in movement dynamics.

3.21.5.3.2 Role of the ventral premotor cortex in motor control

The ventral premotor cortex was first characterized functionally by its involvement in visually guided motor behavior as its neurons discharge during preparation and execution of movements under visual guidance (Godschalk et al., 1981). PMv neurons also respond to tactile and proprioceptive stimulation (Graziano et al., 1997; Graziano, 1999). Thus, PMv has been implicated in the initiation and control of limb movements based on visual and somatosensory information (Kurata and Tanji, 1986; Gentilucci et al., 1988; Rizzolatti et al., 1988; Mushiake et al., 1991, 1997). PMv is important for the integration of visual information derived from extrapersonal three-dimensional space and involved in the spatial guidance of limb movements (Kakei et al., 2001). PMv neurons respond to somatosensory stimuli applied to either face or arm and to visual stimuli corresponding to peripersonal space (Gallese et al., 1996; Graziano et al., 1997). PMv neurons are selective for the three-dimensional shape of objects to be grasped (Murata et al., 1997), the direction or movement trajectory in visual/extrinsic space (Kakei et al., 2001; Schwartz et al., 2004), the attention to visuospatial stimuli (Boussaoud et al., 1993), and decisions making based on somatosensory signals (Romo et al., 2004).

Specific lesions of PMv in the area responding to visual object presentation (F5) result in deficits in visually guided grasping movements. Hand preshaping preceding grasping is markedly impaired. Monkeys were able to grasp objects, but only after compensation based on tactile correction (Fogassi et al., 2001). Animals show a reluctance to use the affected hand (Rizzolatti et al., 1983; Schieber, 2000), though the ability to make a precision grip appears unaffected (Schieber, 2000). During conditional visuomotor association tasks, movements have smaller amplitudes and slower velocities, but few direction errors are made (Kurata and Hoffman, 1994). Monkeys appear to lose the ability to perform a prism adaptation task after muscimol injection in PMv (Kurata and Hoshi, 1999). Lesions of the periarcuate region of frontal cortex (premotor cortex, probably primarily PMv) result in deficits in selecting the proper response to a conditional cue (Petrides, 1986).

In macaques, F4 appears to code goal-directed actions mediated by spatial locations (Rizzolatti et al., 2002), while F5 has been shown to be involved in motor-action recognition (Umilta et al., 2001). Human area 44 has been shown to be involved in sensorimotor transformations for grasping and manipulation (Binkofski et al., 1999) and is thought

to be homologous to F5 in macaques (Rizzolatti et al., 2002).

Neurons in PMv reflect processes in extrinsic coordinates more often than neurons in M1 (Kakei et al., 2001). Effector-independent activity is more frequent in PMv than in PMd (Hoshi and Tanji, 2002). Premovement activity is less frequent in PMv than PMd (Boudreau et al., 2001). Activity of neurons in PMv co-varies with external force in a precision grip task (Hepp-Reymond et al., 1994, 1999). Dynamics of movement appear to be coded in both PMd and PMv (Xiao et al., 2006).

3.21.5.3.3 Role of dorsal premotor cortex in motor control

PMd is involved in movement parameters (Fu et al., 1993; Kurata, 1993; Crammond and Kalaska, 2000) and in the integration of internal body representation and target information for the preparation of motor actions (Kurata, 1994; Hoshi and Tanji, 2004). PMd neurons are active during a preparatory motor-set period (Weinrich and Wise, 1982) and in relation to visuomotor-association tasks (Kurata and Wise, 1988; Mitz et al., 1991). Neurons in PMd are active before expected visual signals (Mauritz and Wise, 1986) and during motor preparation (Wise and Mauritz, 1985; Kurata and Wise, 1988). Target-related activity prior to and during movement is more abundant in PMd than in M1 (Shen and Alexander, 1997). However, there is considerable overlap in function (Riehle and Requin, 1989; Kalaska et al., 1997).

Like SMA, neurons in PMd appear to reflect dynamics during motor planning, or the dynamics of upcoming movement. PMd may also be involved in the kinetics-to-dynamics transformation, though not to the degree that SMA is. During the premovement period, neurons in PMv are mostly not directionally tuned, which is more like M1.

Monkeys with PMd lesions exhibit increased direction errors during conditional visuomotor association tasks. However, movement amplitude and velocity are normal (Kurata and Hoffman, 1994). This contrasts with effects of PMv lesions.

3.21.5.3.4 Direct comparison of ventral and dorsal premotor cortex response properties

In a few studies, direct comparisons have been made between these two premotor areas. The results show that set-related activity is mainly found in PMd, while movement-related activity is found in both PMd and PMv (Kurata, 1993). PMv neurons mainly respond to visual target location, while PMd neurons respond to target location and arm direction (Hoshi and Tanji, 2004). PMv neurons predominantly reflect locations of visuospatial signals (Hoshi and Tanji, 2002, 2006). About half of PMd neurons reflect motor instructions about the cue (arm or target to be selected) (Hoshi and Tanji, 2006).

3.21.5.3.5 Role of dorsal and ventral premotor cortex in motor skill learning

Based on the response properties of premotor neurons and the effects of lesions to PMd and PMv, it would appear that premotor cortex plays a role in retrieval of movements from memory based on environmental context (Mitz et al., 1991). This would suggest an important role for premotor cortex in learning conditional associations between sensory stimuli and appropriate motor actions. When monkeys were trained to learn new conditional motor associations, over half the neurons tested in PMd changed their activity during the learning of the association (Mitz et al., 1991). As learning progressed, the activity of novel associations began to resemble familiar ones (Buch et al., 2006). Interestingly, after the response choice had been made, but prior to any feedback, activity increased in the putamen, but not in PMd (Buch et al., 2006). In an auditory conditional association task in humans, PMd and pre-SMA exclusively showed preferential activation, suggesting that these are sites where general sensorimotor integration for learning new associations takes place (Kurata et al., 2000).

In another popular paradigm for motor learning, neuronal activity is recorded in motor areas as animals learn to adapt to a novel force field. In this task, premotor neurons display plasticity related to learning of kinematic, dynamic, or memory properties (Xiao, 2005). A progressive change in movement-related representations have been reported in PMd in an instructed-delay paradigm (Messier and Kalaska, 2000).

3.21.5.3.6 Learning through observation: role of premotor cortex

There is now considerable interest in the role of motor cortical areas in learning new motor skills through observation. While motor skills are typically learned through physical practice, it is well known that motor performance can be improved simply by observing a skilled motor task (Vogt, 1995; Mattar and Gribble, 2005). It has been suggested that observing the movements of another

individual is not simply the observation of visual patterns but the generation of an image of oneself for performing the action (Petrosini et al., 2003). Thus, it is likely that the same structures that are involved in motor execution are active during the observation.

The neural basis of imitation is becoming increasingly clear. In macaque monkeys, so-called mirror neurons located in the ventral premotor cortex (area F5) and posterior parietal cortex (area PF) fire not only when the monkey performs a particular motor action but also when the monkey observes someone else performing the same action (Rizzolatti et al., 1996). This phenomenon has been implicated in the human ability to imitate. Functional magnetic resonance imaging studies in humans confirm that similar regions may be active during both observed and executed actions (Koski et al., 2003). Further, these regions appear to be more active during specular imitation (i.e., the actor moves the left hand and the imitator moves the right hand, as if looking in a mirror), more so than during anatomic imitation (i.e., the actor and imitator move the right hand) (Koski et al., 2003).

3.21.5.4 CMAs and Their Role in Motor Behavior

The primate cingulate cortex, buried in the cingulate sulcus, has traditionally been divided into rostral and caudal architectonic subdivisions (areas 24 and 23). More recently, in the macaque, the caudal CMA has been further differentiated into three distinct areas – rostral (CMAr), dorsal (CMAd), and ventral (CMAv) – based on cytoarchitectonics and neuronal response properties (Walsh and Ebner, 1970; Vogt et al., 1987; Takada et al., 2001; Hatanaka et al., 2003). Because the CMAs are in close proximity to SMA and pre-SMA, it is likely that in many older studies in both nonhuman primates and humans, neuronal activation anywhere on the medial wall was attributed to SMA. Thus, caution should be taken when interpretating findings in which this distinction is not made clear. In general, the rostral cingulate zone is activated by complex tasks, while the caudal cingulated zone is activated during simple tasks (Picard and Strick, 1996).

CMAv receives proprioceptive input from the arm and hand (Cadoret and Smith, 1995). As with other secondary motor areas, the CMA areas send somatotopic projections directly to M1 and the spinal cord (Muakkassa and Strick, 1979; Dum and Strick, 1991, 1996; Luppino et al., 1993; He et al., 1995; Wang et al., 2001). The somatotopy of CMA has been examined using intracortical microstimulation, demonstrating at least a forelimb representation in each of the three subareas (Mitz and Wise, 1987; Luppino et al., 1991, 1994; Takada et al., 2001; Wang et al., 2001; Hatanaka et al., 2003). CMA also receives prominent afferent input from limbic structures and the prefrontal cortex, conveying information regarding motivation. Functional studies examining CMAs suggest that CMAr plays a unique role in the cognitive control of voluntary movements, while the caudal CMA (CMAd and CMAv) is directly involved in the execution of voluntary movement (Devinsky et al., 1995; Picard and Strick, 1996, 2001; Carter et al., 1999; Tanji et al., 2002).

Both the rostral and caudal cingulate areas are more active for self-initiated as opposed to externally triggered movements. In the caudal cingulate zone, activation is greater for sequential rather than for fixed movements, much like SMA proper (Deiber et al., 1999).

On the basis of deoxyglucose labeling techniques in monkeys, it has been suggested that CMAd is highly active during the preparation for and/or execution of a highly rehearsed, remembered movement sequence but is less active if the movement sequence is performed under visual guidance (Picard and Strick, 1997). In the same remembered movement sequence task, the CMAr and CMAv were not active. Instead, these areas are active during simple motor tasks (Shima et al., 1991).

CMAs are likely to play a role in motor learning. A learning paradigm that is popular in rabbits is trace eyeblink conditioning. Lesions of the caudal anterior cingulate cortex in rabbits prevent trace eyeblink conditioning (Weible et al., 2000). However, based on inputs from limbic and prefrontal structures, the role of cingulate areas in motor learning is likely to be related to transmitting information regarding motivation and memory of previous events, rather than simple sensorimotor transformations.

3.21.6 Phases of Motor Learning and Differential Activation of Motor Structures

Significant improvements in reaching accuracy occur in rats after less than 1 week of training. However, significant expansion of movement representations does not occur for at least 10 days after training is initiated (Kleim et al., 2004). This

mismatch between behavioral and neurophysiological endpoints suggests that plasticity in cortical maps reflects only certain aspects of the motor learning experience. Therefore, it is important to differentiate the various phases of motor learning.

Memory has often been described in terms of a short-term memory that is labile and susceptible to interference and a long-term memory that is more stable. The process of transferring information from short-term to long-term memory is referred to as consolidation. It has been argued that motor learning proceeds through similar stages and that different neural mechanisms may account for the two distinct functional stages (Shadmehr and Brashers-Krug, 1997). Stages of motor skill learning have also been described as consisting of a fast, within-session phase that occurs on a time scale of minutes and a second, slowly evolving phase that takes hours to occur. Whether these stages of motor learning that have been proposed based on human experiments have any relationship to neurophysiological and neuroanatomical findings from experimental animal models is still unclear. While the human studies are typically conducted over the course of several hours or a few days, the cortical plasticity demonstrated in animals takes place over 1 week or more. It is possible that the stages of motor learning described in human studies are the initial events in a much more protracted process.

Early and late phases of motor learning have been associated with different neuronal networks. In motor sequence learning, the early phase is thought to involve the corticostriatal and corticocerebellar networks, while the late phase is attributed to the corticostriatal network (see Doyon and Benali, 2005). In a pursuit rotor task requiring human subjects to track a moving target with a stylus, positron emission tomography studies have shown increased blood flow involving a large distributed network in cortex, striatum, and cerebellum during the execution of the task (Grafton et al., 1992). These included motor areas (M1, SMA, putamen, substantia nigra, anterior lobe, and inferior vermis of the cerebellum) and visual association areas (fusiform gyrus and extrastriate area 18). However, sequential positron emission tomography scans over the course of learning the pursuit task demonstrated increased cerebral blood flow in a smaller subset of motor structures including contralateral SMA, M1, and pulvinar thalamus. Thus, procedural motor learning is accomplished by a subregion of the larger network that is critical to the movement execution.

3.21.7 Summary

Significant advances have been made in the past several years in understanding the role of the various cortical motor areas in motor learning. It is clear that motor skill acquisition is associated with alterations in topographic maps of motor representations, structural changes in neuronal elements (synapses, dendrites, etc.), and differential expression of growth-related proteins. We now recognize that motor learning is a distributed process. While differentiation in the response properties of various cortical areas demonstrates their unique functions, there is considerable overlap. Primary motor cortex is most associated with movement-related aspects of learning motor tasks. The mesial areas are more related to learning motor sequences, especially when they are self-initiated. The lateral motor areas are more related to externally guided movements and the integration of sensory cues with motor commands, especially in forming conditional motor associations. Finally, the CMAs are involved in more cognitive and motivational aspects of motor learning.

3.22 Cerebral Cortex: Motor Learning

J. N. Sanes, Brown University, Providence, RI, USA

Published by Elsevier Ltd.

3.22.1 Introduction

The proposition that mechanisms in the cerebral cortex contribute to motor skill learning seems relatively straightforward. A learning-related role for motor related structures of the frontal lobe, including the primary motor cortex (M1), the premotor area (PMA), and the supplementary motor areas (SMA) might once have generated significant controversy. However, inspection of the historical and recent record provides considerable evidence that many neocortical regions, even those with clear roles in supporting motor performance, exhibit plasticity (Brown and Sherrington, 1912; Lashley, 1923; Sanes and Donoghue, 2000). The observations of plastic phenomena in these regions and their highly organized intracortical network suggest that adaptive modifications are a feature of motor structures, and that they operate in parallel with mechanisms that control movement output parameters. Significant recent advances have occurred in detailing how the neocortex contributes to motor skill learning, and these are reviewed here with a focus on human physiology and related work for experimental animals. Subcortical structures have key roles in various aspects of motor learning, such as the vestibular-ocular reflex, but these are not discussed in extensive detail.

Despite long-standing indications that motor structures of the brain exhibit plastic changes, traditional views hold that neocortical regions such as M1, PMA, and SMA function only to mediate the kinematics and dynamics of voluntary skeletal movements. To be sure, the interconnected afferent and efferent neocortical and subcortical targets of these regions form a highly integrated neural network that emits precise neural commands to mediate limb positions, velocities, and forces needed to implement the fluid movements that humans (and other mammals) readily perform. The range of interconnections among neocortical and subcortical motor-related areas that include inputs from so-called association areas (Wise et al., 1997) suggests that motor cortical regions should express functions beyond motor control. The diffuseness of intrinsic connectivity and the functional representation pattern in M1 could also provide a ready substrate for roles in motor learning for M1 and other nearby related neocortical motor areas (Sanes and Donoghue, 2000; Sanes, 2003). This chapter reviews the static and dynamic organization of motor-related neocortical areas with a view that this organization supports their participation in acquisition, retention, and expression of motor skills. The chapter in particular reviews evidence that processing in motor-related neocortical and selected subcortical regions contributes to motor learning and reviews recent studies on the possible cellular mechanisms of motor learning.

Any discussion of motor learning necessarily commences with its definition. Motor learning entails acquiring novel movement patterns, which can occur simply by repeating a simple action when the muscles that generate the movement(s) develop a stereotyped pattern of agonist and antagonist activity, either gradually or emergently (Corcos et al., 1993). Developing expertise for more complex skills such as for numerous sport or artistic activities that involve multiple joint actions and across-limb coordination likely entails

developing novel simultaneous and sequential action patterns. Motor learning also includes the acquisition of pairings between external events and voluntary actions – sometimes the events and actions are common and perhaps part of an individual's normal experience, but they have not been previously combined. Examples are learning to manipulate a newly found tool or responding for the first time to a sensory stimulus that directs movement. The constituent actions, such as grasping, applying forces, and the sensory cues that stimulated the actions have already been acquired or experienced but not necessarily connected in a new context. Independently of whether the motor learning requires adaptation or forming new sensory-motor links, new patterns of neural activity or activation must accompany these changes. Understanding the behavioral and neural concomitants of sequential actions has been an active area of recent motor learning research and is considered here.

3.22.2 Motor Cortical Representations

Following upon pioneering observations from the late nineteenth and early twentieth centuries (e.g., Fritsch and Hitzig, 1870; Ferrier, 1876; Jackson, 1884; Sherrington, 1911), researchers working in the middle of the twentieth century used focal application of electrical stimulation to map output functions of M1. These studies collectively revealed a somatotopically ordered movement map that represented the body; the representational form of this map resembled a distorted cartoon of the body (Penfield and Rasmussen, 1950; Woolsey et al., 1952), with body-part joints or movements laid out upon the surface of M1. The principal organizing feature of this representation incorporated a topographic ordering of the leg (hindlimb in quadrupedal mammals), arm (forelimb, including digits), and head and face from the medial convexity to more lateral and inferior sections of the cerebral hemisphere.

While the general rubric of a medial to lateral, leg, arm, and face representation has appeared consistently in all early and current studies, significant commentary exists that casts doubt upon the notion that the homunculus cartoon ever represented the actual findings (Schott, 1993; Sanes and Schieber, 2001). Indeed, Penfield and Woolsey merely used the cartoon and figurine representations to depict in summary form some aspects of orderly patterning of the body superimposed upon the neocortical surface. Referring to the homunculus cartoon for M1, Penfield and Rasmussen noted that,

> A figurine of this sort cannot give an accurate indication of the specific joints in which movement takes place, for in most cases movement appears at more than one joint simultaneously. (Penfield and Rasmussen, 1950: 56)

Instead, they suggested that the summary illustration should become used as a heuristic for further investigation. With a similar sentiment, Woolsey et al. expressed caution similar to that of Penfield and Rasmussen (1950) by stating that an illustration depicting the results of their electrical stimulation mapping

> *is an inadequate representation of the localization pattern, since in a line drawing one cannot indicate the successive overlap which is so characteristic a feature of cortical representation, not only in the motor but also in the sensory areas.* (Woolsey et al., 1952: 251–252; italics appearing in the original)

Despite these admonitions, the widely adopted corporeal schema has profoundly influenced concepts of motor cortex organization. Specifically, the homunculus plan suggests that representations for each body part have a high degree of order, with a point-to-point plan and without overlap in cortical space. An orderly somatotopic arrangement would suggest dedication of specific brain elements, such as a cortical column, for the control of one body part (Asanuma and Ward, 1971), such as an individual finger, perhaps precluding a flexible arrangement required for plasticity or learning.

While controversy still remains, a critical review of experimental data derived from a variety of sources, including intracranial, surface, and transcranial stimulation methods, lesions, and neuroimaging, upholds the segregation of functional subregions within M1, that is, the separation of representations for head, arm (forelimb in quadrupeds), and leg (hindlimb in quadrupeds). However, the same data resolutely discards precise topography within M1 as an organizing principle. The alternate view holds that each M1 subregion has an organization resembling a network with distributed functions (Sanes and Donoghue, 1997; Sanes and Schieber, 2001); neural elements – actual spiking neurons, local field potentials recorded from neurons, functional magnetic resonance imaging (MRI) voxels, or electroencephalogram sources – within these

subregions may have highly specific functional features, though according to contemporary notions of network properties, the elements can have flexible and shared functions. The most complete data sets to assess whether ordered topography represents voluntary movements have been obtained for the M1 arm region, with the most extensive descriptive maps derived from evoked movements via electrical stimulation techniques. Intracranial electrical stimulation as applied to M1 can reveal the movement or muscle coupling of the stimulated site by current deposited by a microelectrode inserted amongst cortical neurons (Stoney et al., 1968). New movements evoked when the electrode traverses the cortex in small steps suggested the existence of an underlying pattern of organization. However, when assembled into a comprehensive map, sites for any particular body part appear widely distributed, multiple, and overlapping (Kwan et al., 1978; Sessle and Wiesendanger, 1982; Gould et al., 1986; Donoghue et al., 1992; Nudo et al., 1992; Park et al., 2004). It should be noted that even the cruder surface stimulation data derived by Penfield and his colleagues, using much lower resolution than feasible with intracortical stimulation also has supported this form of distributed organization (Penfield and Boldrey, 1937). Additionally, the pioneering studies of Jankowska and coworkers predicted the recognition that M1 has a distributed pattern representation of motor control (Jankowska et al., 1975). The available data for M1 representations other than that for the arm – M1 organization for the face (Huang et al., 1989) and leg areas (Gould et al., 1986) – each show a similar distributed internal organization while maintaining separation from the adjacent arm region.

Reservations about the nonbiological nature of electrical stimulation are clearly warranted when defining the organizing features of the motor map. However, evidence from neural recordings, pharmacological inactivation, and connectional studies all reveal the distributed nature of M1 subregion organization consistent with that identified by intracortical electrical stimulation mapping. Spike-triggered averaging has demonstrated that single neurons in the M1 arm area influence multiple arm muscles (Buys et al., 1986; Fetz et al., 1989), including combinations of proximal with distal muscles (McKiernan et al., 1998; Park et al., 2004). In addition, recordings of single M1 neurons show that they rarely modulate with the action of a single joint or part; each neuron appears to participate in multiple hand motor actions, and neurons influencing different digits or the wrist appeared to have a seemingly random distribution (Schieber and Hibbard, 1993). This pattern does not easily find reconciliation with a discrete, topographically segregated organization for M1. As predicted by distributed functional relationship of M1 to movement and muscle control, focal inactivation of monkey M1 produces more global effects on arm actions but does not block the action of individual parts (Schieber and Poliakov, 1998).

Contemporary neuroimaging methods that detect local changes in blood flow have also allowed exploration of the organization of human motor cortex. Low-resolution studies with positron emission tomography (PET) found overlapping activation patterns for distal and proximal arm movements within the M1 arm area (Colebatch et al., 1991; Grafton et al., 1991). The higher-resolution fMRI method has also revealed overlapping, distributed activation in M1 for distinctive movements of the fingers, wrist, and elbow (Rao et al., 1995; Sanes et al., 1995; Hlustik et al., 2001; Indovina and Sanes, 2001), thus showing consistency with a distributed organization within the M1 arm subregion. Finally, all the functional data appear to have an anatomical correlate insofar as the M1 arm subregion has vast horizontal interconnectivity without an obvious topographic plan for fingers, wrist, or other parts of the arm (Huntley and Jones, 1991).

Taken together, this body of experimental data reveals a pattern of M1 organization having discrete gross subdivisions. However, each subdivision has an internal distributed network in which control emerges from broad activity patterns (Sanes and Donoghue, 1997, 2000). Not only can this organization provide the immense storage capability and richness of function characteristics of distributed networks, but it also provides a basis for flexibility if the organization of this network has modifiability. In the next sections, we provide evidence that M1 representations have plasticity and discuss its implications for a M1 role in motor learning.

3.22.3 Motor Cortical Plasticity

One of the most interesting aspects of behavior of mammals, particularly primates, is their remarkable, seemingly limitless flexibility in motor behavior. The range of skills, precision, and adaptability of motor control evident in animals with a large forebrain seems unmatched. Behavioral flexibility often becomes attributed to the neural mechanisms embedded in the

cerebral cortex, though to be sure, subcortical structures have key roles in motor learning. This connection suggests that some sort of modifiable architecture exists within motor cortical circuitry. The idea of a dynamic organization in motor cortex has a lengthy history and seemingly coexisted with the development of notions that a portion of the neocortex has a movement specialization (Brown and Sherrington, 1912). Furthermore, the concept that M1 circuits have flexibility has appeared throughout the experimental literature of the twentieth century (Lashley, 1923; Gellhorn and Hyde, 1953). In the past 20 years, application of intracortical electrical stimulation mapping, and then related mapping methods using transcranial stimulation in humans, has shown that functional maps within M1 can exhibit rapid and sometimes even long-lasting reorganization. In a series of these electrical stimulation mapping experiments, we demonstrated that transection of the facial motor nerve, which supplies the rat's facial whisker musculature, led to a functional loss of the M1 whisker area. This region was supplanted by representations of the adjacent forelimb or eye/eyelid regions (Donoghue et al., 1990; Sanes et al., 1992). This reorganization emerged abruptly within hours of the nerve lesion, and the basic form of the reorganization that was revealed soon after the lesion persisted for months (Sanes et al., 1990). The ability to evoke movements at similar thresholds in both the reorganized and normal areas of M1 suggested that these areas acquired functions of the normal cortex as part of an expanded representation. In experimental animals, this pattern generalizes to peripheral nerve (Sanes et al., 1990; Franchi and Veronesi, 2006) or central (Nudo and Milliken, 1996) lesions, repetitive M1 stimulation (Nudo et al., 1990), or changes in limb configuration (Sanes et al., 1992). The availability of transcranial stimulation methods has extended M1 mapping to humans. A variety of manipulations including amputations (Hall et al., 1990; Cohen et al., 1991), spinal cord injury (Topka et al., 1991), transient modifications in sensory inputs (Brasil-Neto et al., 1992), immobilization (Liepert et al., 1995), and repetitive M1 stimulation (Berardelli et al., 1998) all have been shown to modify M1 movement representations. This diverse set of results has clearly established the fact that motor maps in humans and nonhuman animals have dynamic and adaptive features.

The demonstrations of motor plasticity with electrical stimulation do not come without controversy. A complex issue of electrical stimulation mapping is defining the site of effect. It is essential to understand the site(s) and underlying basis for reorganized motor representations prior to concluding that changes observed in an M1 output map related to changes in an M1 neural circuit. A key issue concerns understanding that intracortical stimulation applied to M1 activates intrinsic and especially output neurons, such as the pyramidal tract neurons of layer 5 that descend to the spinal cord and via excitation of alpha motor neurons produce the muscular activity with appropriate temporal and spatial summation. However, electrical stimulation also activates intracortical dendritic and axonal processes in and around the vicinity of the stimulating electrode(s), and perhaps most significantly, stimulation activates the recurrent axon collateral system for each neuron brought to threshold. Additionally, the precise location of the stimulating electrode governs, in part, the neural circuits activated; an electrode in layer 5 would predominantly activate pyramidal tract neurons, whereas an electrode in layers 2/3 of M1 would preferentially activate intrinsic and corticocortical circuits. Moreover, a striking feature of neocortical pyramidal neurons is that these projection neurons have extensive local collateral branches in addition to the efferent axon (Ghosh and Porter, 1988). The intracortical M1 branches extend locally and appear to synapse in the immediate vicinity of the neuron and typically have substantial horizontal, or lateral, connection systems that can extend upward of 1 cm within M1 (DeFelipe et al., 1986; Huntley and Jones, 1991; Keller 1993a; Hess and Donoghue, 1994). Thus, one must take into account the fact that projection neurons likely also participate in internal processing within M1 in addition to delivering its output message to subcortical systems. Finally, electrical stimulation of pyramidal tract neurons sends signals not only to the spinal cord but also to a vast set of supraspinal, subcortical targets within the brainstem, striatum, and thalamus (Shinoda et al., 1979; Canedo, 1997).

In humans, transcranial stimulation with electrical and magnetic devices has also been used profitably to study M1 map plasticity (Hall et al., 1990; Cohen et al., 1991; Topka et al., 1991; Boroojerdi et al., 2001). These more global transcranial stimulation methods, in comparison to intracortical electrical stimulation, while essential to study the potential for modification in the human cortex, suffer even more severely from the lack of precise knowledge of which neurons, and their related connections, are activated by stimulation. Transcranial magnetic stimulation (TMS) is assumed to activate neurons superficial to output layer V, while transcranial

electrical stimulation (TES) likely activates neurons mainly in layers V and VI and axons in the underlying white matter (Day et al., 1987). Although the observation that TMS but not TES yields certain types of map reorganization has consistency with an intracortical site for plasticity (Chen et al., 1998; Ziemann et al., 1998; Boroojerdi et al., 2001), both TMS and TES would activate immensely complex sets of cortical and subcortical circuits. Thus, it remains unproven that reorganization observed in the cerebral cortex using any of these forms of stimulation necessarily means that the cerebral cortex is the site of modification.

3.22.4 Substrates for Motor Cortical Plasticity

In the past 20 years, evidence has accrued that directly demonstrates substrates and mechanisms within M1 to implement plasticity. Thus, these findings have placed M1 intrinsic circuitry in a strategic position to mediate and to account for representational organization that stimulation mapping has revealed. The candidate substrate for M1 plasticity is the system of horizontal connections that spans M1. Evidence from several sources demonstrates that horizontal connections in M1 can serve to functionally associate intrinsic neurons into dynamically structured assemblies that can form a flexible set of motor maps. The existence of latent motor output maps in M1 has been revealed using focal and local blockade of GABAergic inhibition that then apparently unmasks existing horizontal connections likely normally blocked by feedforward inhibition (Jacobs and Donoghue 1991). Local GABAergic release yielded map changes parallel to those occurring following facial nerve lesions (Sanes et al., 1990). The results of this experiment demonstrated that M1 contains the intrinsic circuitry necessary to support reorganization. Furthermore, they suggested that the moment-to-moment details of M1 organization likely depended on the precise balance of excitatory and inhibitory influences within the network of M1 connections. Plasticity similar to that observed in experimental animals also occurs in humans using the indirect methods of transcranial stimulation and pharmacological manipulation through systemic application (Ziemann et al., 1998; Di Lazzaro et al., 2006).

Another relevant finding that links M1 map reorganization to modification of the horizontal M1 circuitry relates to the distribution of intracortical connections within M1 and the sites of map changes following nerve damage (Huntley, 1997). In this work, facial nerve lesion in rats resulted in M1 reorganization only at sites that had strong horizontal connections that spanned the reorganized facial whisker area and the forelimb areas. No significant reorganization occurred in M1 zones without any or with only sparse connections between the forelimb and whisker regions. This anatomical-physiological finding indicated that M1 reorganization revealed by electrical stimulation mapping reflected the architectural pattern of the horizontal connection network in M1 and that reorganization could reflect synaptic plasticity of these fibers.

A third important set of results obtained from motor cortex slice preparations has provided additional support for an intracortical substrate that mediates restructuring of M1 maps. Slice preparations can directly evaluate local connections under controlled circumstances using both intracellular and, on a grosser scale, field potential recordings. Field potentials can reveal summed synaptic effects within a small patch of cortex (Aroniadou and Keller, 1993; Donoghue et al., 1996). The studies using slices to investigate the functional architecture of M1 have demonstrated the existence of fairly extensive and functionally strong horizontal pathways in this region that not only spanned superficial layers 2/3 but also traversed the deeper layer 5. Pharmacological manipulations demonstrated that glutamate receptors mediate these horizontal excitatory connections (Keller, 1993b; Hess et al., 1994), consistent with pathways in other systems that might exhibit plasticity. Further, feedforward GABA inhibition likely regulates the strength of excitation, as was predicted by earlier work (Hess et al., 1994, 1996; Donoghue et al., 1996).

While these intracortical connections could provide a basis for dynamic and even instantaneous modulation of the functional architecture of M1, persistent changes in the efficacy of horizontal connections over longer periods likely require a stable form of synaptic modification. Activity-dependent modification through processes leading to long-term potentiation (LTP) and depression (LTD), which has been documented extensively in the hippocampus and other central nervous system (CNS) structures, could also provide a mechanism for long-lasting synaptic modification in the neocortex. The possibility for activity-dependent synaptic plasticity has been long established and well documented in M1

(Baranyi and Feher, 1978; Baranyi et al., 1991). The horizontal pathways in M1 that may mediate formation of new associations among populations of M1 neurons do indeed exhibit the capacity for long-lasting synaptic modification (Hess and Donoghue, 1994; Aroniadou and Keller, 1995). Similar to other systems, the pattern of stimulation regulates the connection strength of the horizontal M1 pathway, either up for LTP with high-frequency stimulation or down for LTD with low-frequency stimulation (Hess and Donoghue, 1996b). As in other systems that exhibit plasticity (Malenka and Bear, 2004), *N*-methyl-D-aspartate (NMDA) receptors appear to mediate the plasticity occurring in M1, thereby suggesting that common mechanisms regulate synaptic efficacy across the CNS.

LTP induction in the mature M1 appears somewhat more constrained than similar mechanisms elsewhere in the adult CNS and processes transpiring during development. LTP in M1 horizontal pathways cannot be induced unless inhibition is transiently reduced during the LTP-inducing high-frequency stimulation (Hess et al., 1996). LTP in the horizontal pathway can occur when tetanization of vertical pathways accompanies horizontal activation (Hess et al., 1996). This vertical activation presumably recruits thalamocortical fibers and a mixture of other inputs and output fibers with recurrent collaterals. These results suggest that modifications in adult M1 representations related to increases in synaptic efficacy require a specific context: Alterations in the level of inhibition or concomitant activity of extrinsic pathways appear to allow a permissive situation for functional restructuring of intracortical connections that can lead to changes in the M1 output map. These permissive relationships raise the possibility that the cerebello-thalamocortical pathway, which forms one important vertical input to motor cortex, provides a gating signal for synaptic reorganization. By contrast to LTP, LTD in the horizontal M1 pathway is readily induced by repetitive low-frequency stimulation independent of contexts (Hess and Donoghue, 1996a). The differences in induction of LTP and LTD in horizontal pathways of M1 suggest a set of complex network relationships that could operate during formation and rehearsal of rules that govern acquisition of motor skills. These results have demonstrated the M1 has a propensity to exhibit plastic phenomena, but they do not provide a direct link between LTP or LTD and behavior. While these linkages are discussed in more detail in the section titled "Learning Mechanisms," it is worth noting here that induction of LTP in a subzone of rat M1 enlarges the output representation for this region of cortex (Monfils et al., 2004).

Through activity-sensitive mechanisms, the synaptic efficacy of the interconnections among M1 neurons can be continuously adjusted up and down, presumably throughout life, as a consequence of their exposure to appropriate activity patterns. The extent of these adjustments is likely strongly regulated by context. These findings seem to place M1 at the center of an arena where functional reorganization of motor representations occurs, since M1 contains both the substrate, that is, the horizontal connection system, and the mechanisms, that is, LTP/D, for reorganization. Nevertheless, one cannot rule out subcortical sites as participants in lesion-induced reorganization of M1 because the potential for synaptic modification is widespread in the nervous system (Randic et al., 1993).

3.22.5 Movement Practice

A simple form of motor learning entails practice-related performance changes. Considerable evidence exists suggesting a neocortical role in both short-term learning, on the order of minutes to hours (Karni et al., 1995), and longer-term learning, from hours to days or months and even beyond (Karni et al., 1995; Pascual-Leone et al., 1995; Pearce et al., 2000; Hlustik et al., 2004). Many of these studies have focused upon learning-related changes in M1, perhaps due to its propensity to exhibit shifts in representation patterns and evidence of plasticity (Sanes and Donoghue, 2000).

A common finding is that practice changes the size of cortical representation of a particular movement (Pascual-Leone et al., 1995) or the size of the motor-evoked potential (Pearce et al., 2000) following transcranial stimulation. In its simplest form, repetitive practice of a known motor sequence appears to increase the area of cortical territory related to individual finger movements (Pascual-Leone et al., 1995). In these studies, participants repetitively performed a task akin to simple piano keying sequence across several days, using only one hand. As expected, performance improved both in speed and accuracy. In parallel to the improved performance, the scalp region over M1 from which TMS elicited motor-evoked potentials (MEPs) from finger flexor and finger extensor muscles increased. These effects do not generalize to the untrained hand, but

interestingly, mere mental practice yielded comparable expansion of the motor cortical representation of digit muscles when compared to actual movement. Numerous groups have replicated these findings (e.g., Classen et al., 1998; Hlustik et al., 2004; Jensen et al., 2005). Hlustik et al. (2004) extended them to functional studies and observed expanded activation with functional MRI in M1 and S1 following extensive practice of a sequential movement. These types of practice effects have been interpreted as indicating plastic processes occurring at the neocortical level, some of which might become consolidated.

The cortical basis of the practice-related modifications in motor cortical output find support from differences in the effects of practice on MEPs evoked by TMS and TES (Classen et al., 1998). In this study, participants repeatedly performed a thumb movement opposite in direction to the movement evoked by TMS over presumed M1. After 30 min of such training, or practice, the movement evoked by TMS had shifted toward the direction of the previously opposite-trained movement; this effect was transitory, enduring, on average, for 20–30 min. The cortical basis of the effect lies in the observations that movements evoked by TES posttraining resembled those evoked prior to training and the differences between the effects of TES and TMS. TES is generally thought to activate neurons and fibers in deep cortical layers and the white matter, whereby neurons and fibers activated by TMS are located more superficially (Day et al., 1987); therefore, while TES yields its effects on muscles directly through activating M1, TMS exerts its spinal effects indirectly by first activating layer II/III neurons and then transsynaptically activating M1 output layers.

In general, M1 appears to figure prominently in development of practice-related motor skills, as might be predicted from its propensity to exhibit rapid shifts in output representation patterns (Sanes and Donoghue, 2000). As noted, simple repetitions of finger movements can yield modifications of M1 output for tens of minutes (Classen et al., 1998), though in this study the specificity of the modified M1 output pattern was not established. More recent data have extended these findings to indicate that M1 practice-related plasticity occurs for rapid but not slow-ramp movements, suggesting a functional specialization for M1 (Muellbacher et al., 2001). Furthermore, it appears that M1 has a role in early consolidation of practice-related changes in motor skills (Muellbacher et al., 2002). Disruption of M1 processing by repetitive transcranial magnetic stimulation (rTMS) substantially reduced performance practice-related improvements. These effects did not seem to have relation to M1 output, since it appeared normal upon testing with standard TMS evaluation and was restricted to disruption of M1, since rTMS delivered to prefrontal cortex (PFC) or occipital cortex had no effect. Other studies, however, have noted, not surprisingly, that the role of M1 networks in consolidation may not extend to all motor learning tasks, such as learning novel limb dynamics (Baraduc et al., 2004). In this study, rTMS delivered to M1 did not disrupt a participant's ability to retain previously learned adaptations to modifications in limb dynamics.

Practice-related effects occur in situations other than repetition of simple movements and in structures other then M1. Humans readily perform rhythmic movements paced by a metronome in a syncopated or synchronized mode, though syncopation degrades as the beat frequency increases beyond a critical threshold and transforms into a synchronized sensory-motor rhythm. Humans improve their syncopation ability with practice, as demonstrated by an elevation of the threshold, allowing it to occur at higher rhythmic frequencies; therefore, the transition from syncopation to synchronized pacing can become a useful tool to evaluate brain mechanisms of practice. Using magnetoencephalographic methods, Jantzen et al. (2001) found that syncopation training reduced differences in magnetic field power in the alpha and beta bands recorded over M1 when comparing syncopation and synchronized rhythm production. The same group assessed neocortical network activation patterns with functional MRI, using the same behavioral assay (Jantzen et al., 2002). Prior to practice-induced improvements in syncopation performance, syncopation activated a wider set of structures, including SMA, the inferior frontal gyrus, superior temporal gyrus, and subcortical structures, than occurred during the synchronization task. The greater network of activation might have related to the increased complexity of the syncopation task, which would seem to require greater need to attend to sensory-motor timing. Analogous to findings in other domains, speech in this case (Raichle et al., 1994), and practice on the syncopation task, reduced activation in SMA and the inferior frontal gyrus, yielding a more similar activation pattern between the two tasks. Practice-related changes in neocortical activation also occurred with improvements in accuracy on a targeted movement

task. In an event-related potential (ERP) study, the amplitude of frontal ERPs decreased while parietal ERPs increased with improvements in accuracy (Staines et al., 2002), a finding reminiscent of the frontal-to-parietal shift in activation pattern found with acquisition of motor sequences by trial-and-error learning (Sakai et al., 1998; Eliassen et al. 2003) or motor adaptation (Shadmehr and Holcomb, 1997). In summary, it appears that practice yields convergent neocortical processing resembling that occurring for the simplest possible action, a process that might be described as finding the lowest common denominator coupled with a shift in activation from frontal to parietal regions.

Much of the prior discussion focused mostly on short-term changes in M1 output and neocortical networks related to discrete bouts of practicing movement-tasks. Plasticity in motor-related areas of neocortex has also been observed in groups of individuals who practice specific motor tasks for years; these groups include professional and semiprofessional musicians, athletes, and blind individuals using Braille for reading. Both stimulation and imaging methods have been used to document effects of long-term practice on cortical physiology. Long-term musical training clearly changes a variety of the brain's anatomical features, some subtly. Morphometric methods based on anatomic MRI have revealed increased volume of M1 parietal motor areas and the cerebellum of both professional and amateur musicians compared to controls (Gaser and Schlaug, 2003; Hutchinson et al., 2003). Prolonged musical training also appears to increase the volume of the pyramidal tract, as assessed with the noninvasive MRI method of diffusion tensor imaging (Bengtsson et al., 2005). Musical training and extensive athletic performance also influence the size of MEPs evoked by TMS applied to M1 (Sparing et al., 2007), extent of cortex activated (Tyc et al., 2005), and intracortical facilitation and inhibition using paired-pulse TMS (Nordstrom and Butler, 2002), again supporting a role for localizing plasticity to M1. Functional MRI studies with musicians have also revealed substantive changes in activation related to motor tasks; a common result is that musicians exhibit less movement-related activation than nonmusicians in neocortex and cerebellum (Jancke et al., 2000; Koeneke et al., 2004; Meister et al., 2005). These results supported the general concept that prolonged practice improves the efficiency of brain processing.

3.22.6 Movement Sequence Learning

Investigating the brain correlates and mechanisms related to learning and performing movement sequences has generated considerable interest, undoubtedly related to the recognition that motor behavior commonly involves performing and coordinating a highly organized set of independent movements that become precisely sequenced in space and time. Learning movement sequences can occur explicitly or implicitly and may or may not observe rules established for declarative learning (Rosenbaum et al., 2001). Researchers have most commonly used a specialized task – the serial reaction time task (SRTT) – that has implicit and explicit components to investigate the neurobiology of motor sequence learning (Nissen and Bullemer, 1987); other sequential movement situations have also been used, but less frequently than the SRTT, to assess brain mechanisms of sequential movements (Hikosaka et al., 2002). The SRTT typically requires discrete responses to cues presented visually and sequentially. Commonly, reaction time (RT) decreases as an ordered sequence repeats, with evidence of learning occurring in about 100–200 trials. While repetition alone would also yield performance improvements, the decreases in RT can be shown to reflect learning, and this sequence learning is not purely perceptual (Willingham, 1999), as might be conjectured from a task that presents a set of ordered visual cures. Additionally, since the improvements in RT initially occur without explicit knowledge of the ordered sequence, these early RT improvements ostensibly index implicit knowledge. As exposure to the order sequence continues, participants develop explicit knowledge of the sequence that can become probed by specially designed generation tasks or verbal query. Thus, the SRTT can assess brain changes occurring during both the implicit and explicit phases of motor acquisition.

Prior work using the SRTT has found widespread neocortical activation, as assessed with PET and functional MRI, during both the implicit and explicit phases of the task. Subcortical structures, including those in the basal ganglia and cerebellum, also become activated during the learning that occurs during the SRTT. Despite the wealth of information about neural substrates of the SRTT, numerous questions remain unanswered. These uncertainties include whether the same areas mediate learning

and expression of implicit and explicit knowledge and whether brain areas implicated in mediating SRTT have a general or specific role in variants of the task, that is, sequence learning for spatial, temporal, or object attributes.

Different brain networks become activated during development of implicit and explicit knowledge during performance of the SRTT (Grafton et al., 1995; Hazeltine et al., 1997; Honda et al., 1998). Accrual of implicit knowledge activated neocortical motor-related areas, including M1 and SMA; these data had consistency with observations of expansion of finger movement representations in M1, as assessed with TMS, during development of implicit knowledge (Pascual-Leone et al., 1994). By contrast, development of explicit knowledge yielded activation in PFC, PMA, and posterior parietal cortex, among other areas. Activation related to acquisition of implicit knowledge during motor sequence performance may extend beyond M1 and SMA, since recent data indicated activation in ventral PMA, midcingulate, PFC, and posterior parietal cortex when implicit sequence knowledge developed (Seidler et al., 2002). Consider though the findings of Nitsche et al. (2003), who extended earlier results of Pascual-Leone et al. (1994) of an M1 role in mediating development of implicit knowledge. In this work, Nitsche et al. (2003), also using TMS, confirmed a role for M1 in acquisition of implicit knowledge during the SRTT but failed to find any effect of TMS to PMA or PFC in modifying decreases in response time, the marker for development of implicit knowledge. Subsequent work by Seidler et al. (2005) provided support for a differential role of neocortical and basal ganglia during the encoding of procedural knowledge of the ordered sequence. In this work, M1 activation, as indexed with functional MRI methods, showed increases in the earliest phases of learning; by contrast, the putamen, the motor component of the striatum, exhibited activation during the later phase of implicit learning. The involvement of parietal and frontal networks during rapid development of explicit knowledge has been confirmed (Eliassen et al., 2001; Muller et al., 2002). The Eliassen et al. (2001) work has particular importance, since it provided indirect evidence of interactions between the implicit and explicit phases of the SRTT task. The data from that study provided clear evidence for prefrontal and parietal involvement in explicit learning. The experiment used a variant of the SRTT to address brain activation patterns during acquisition of explicit knowledge without the possibility of interactions with development of implicit knowledge. Participants were informed that a sequence existed, but not its pattern, and learned this sequence while functional MR images were obtained. Prefrontal and posterior parietal cortical areas became active during acquisition of explicit knowledge, without involvement of the implicit system. Evidence from neuropsychology also suggests segregation of neural mechanisms for implicit and explicit motor sequence learning. Patients with damage to the left parietal lobe fail to exhibit implicit knowledge in standard versions of the SRTT even when provided with extensive practice and failure to gain explicit knowledge (Boyd and Winstein, 2001).

Despite indications of independence of implicit and explicit knowledge systems for motor sequence learning, evidence from behavioral and neuropsychological sources provides clues that these systems have interactions. For example, providing explicit knowledge to patients with a variety of neocortical damage in the frontal and parietal neocortical regions, basal ganglia regions, or the cerebellum prior to performing the SRTT yields a decreasing RT time profile as the sequence progresses that resembles development of implicit knowledge (Molinari et al., 1997; Boyd and Winstein, 2001, 2004, 2006). These data suggest that neocortical–cerebellar loops, with likely mediation of the basal ganglia, have key roles in how the implicit and explicit knowledge systems interact during learning of sequential actions. Behaviorally, RT advantages occur for elements of explicitly trained sequences covertly imbedded in a skein of random response elements, even though participants evince no awareness of the explicitly trained sequence elements (Willingham and Goedert-Eschmann, 2002). The results of this study appear to provide evidence that dorsal PFC has a specific role for developing knowledge about spatial sequences. Temporary inactivation of the PFC with rTMS prevented response time decrements that accompany repeated exposure to a covert motor sequence. PFC inactivation did not prevent improvements in motor performance to sequences cued by colored visual stimuli. The only caveat about this work is that the baseline response time for the spatial sequence may have been too low to reveal further response time decrements. Further work should be done to clarify this point. A functional MRI study using analogous methods provided clear evidence of interactions between mechanisms related to implicit and explicit sequence knowledge (Willingham et al., 2002). Activation related to implicit knowledge and covert-explicit knowledge occurred in portions of the left inferior

parietal lobule, left inferior frontal gyrus, and right putamen. Performance of an overt-explicit task activated these same areas and many more in neocortex and subcortical regions, including thalamic areas and the cerebellum. The activation occurring for the covert-explicit task and accompanying reduced response time, even when participants had no awareness of the sequence elements, indicates that explicit knowledge can improve performance (and activate the same brain areas), even without awareness. Brown and Robertson (2007) provided additional evidence of interactions between the explicit and implicit systems for accrual of sequence knowledge, though they did not localize the site of these interactions. In this study, Brown and Robertson (2007) followed up on prior work showing that the procedural skill of improved response times becomes enhanced with sleep, but not during wakefulness, if and only if the declarative (or explicit) aspects of the sequence also were learned (Robertson et al., 2004; Spencer et al., 2006). They hypothesized that disruption of explicit sequence knowledge would enhance response time, a marker for implicit knowledge; the results supported the hypothesis, supplying support to claims that mechanisms for developing implicit and explicit knowledge interact.

A neocortical involvement in motor sequence learning extends beyond development of implicit and explicit knowledge for discrete movements cued by visual-spatial stimuli. In addition to disrupting SRTT performance, PFC damage impairs learning of continuously performed movement sequences (Gomez Beldarrain et al., 2002), as does low-level rTMS (Pascual-Leone et al., 1996). This impairment appears to occur independently of processes underlying learning of discrete movements sequences – as in the SRTT – and has a relationship to overall planning abilities (Gomez Beldarrain et al., 2002). Additionally, the more superior portions of the PFC, perhaps homologous to the dorsal-lateral PFC of monkeys, seems to have a specific role in development of motor sequence learning cued by spatial stimuli. Reversible inactivation of this PFC area by rTMS disrupted development of implicit knowledge when responding to spatial cues, as assessed by response times; comparable stimulation when participants responded to color cues or rTMS delivered over the posterior parietal cortex when participants responded to spatial or color cues had no effect on response times (Robertson et al., 2001). Explicit knowledge development was not assessed with this protocol, but rTMS of PFC might be expected to disrupt explicit sequence knowledge. These data have consistency with a working model of PFC functional domains (Levy and Goldman-Rakic, 2000).

Two additional findings have clarified the neocortical role in motor sequence learning beyond the 'standard' discrete visual-spatial responding required for the SRTT. Sequences performed by continuous tracking yield neocortical activation related to improved performance in a region spanning the precentral and postcentral gyri, the precuneus, and a region spanning the parietal–occipital fissure (Grafton et al., 2001). Since the improvements in tracking performance can be considered development of implicit knowledge, the pre- and postcentral activation has consistency with implicit knowledge-related activation occurring during the standard SRTT (Grafton et al., 1995; Hazeltine et al., 1997; Honda et al., 1998). Discrete sequence tasks have typically evaluated visuospatial cuing and responding, yet accurate performance of sequential movements also requires precise timing. Ramnani and Passingham (2001) found that progressive acquisition of temporal sequences yielded increasing activation in lateral and medial sections of the posterior parietal cortex, preSMA, and PMA in neocortex and also in the posterior lateral cerebellum. Decreasing activation in connection with temporal sequence acquisition occurred in inferior temporal cortex (IT) and prestriate cortex. Direct comparison of spatial with temporal sequence learning yielded overlapping activation in the parietal lobe, but only the cerebellum and inferior temporal gyrus became active during learning of timed sequences (Sakai et al., 2002). Combined learning of spatial and temporal sequences yielded novel activation in PMA and PFC, suggesting that these frontal areas participated in coordinating choice of effector (the spatial component) and when to start a sequence element (the temporal component).

3.22.7 Arbitrary Sensory-Motor Associative Learning

Neocortical structures also appear to participate in learning arbitrary relationships between sensory events and voluntary movements. Lesion, neural recording, and neuroimaging data have all provided evidence of involvement of PMA and PFC and, more recently, IT, basal ganglia, and the hippocampus in forming and maintaining arbitrary sensory-motor

associations (Wise and Murray, 2000). Neural recording studies in monkeys have found linkages to the dorsal portions of PMA and PFC to forming visual-motor associate rules (Mitz et al., 1991; Asaad et al., 1998; White and Wise, 1999), though evidence exists that other cortical areas, such as frontal and supplementary eye fields (Chen and Wise, 1995) and hippocampus (Cahusac et al., 1993; Wirth et al., 2003) also participate in this type of learning. Since visual-motor rule formation and expression typically requires object identification, it has plausibility that ventral visual pathways involved in visually based object identification should also participate in forming learned relationships between visual stimuli and voluntary movements. Bussey et al. (2001) tested this hypothesis more extensively by assessing whether bilateral lesions in the ventral and orbital PFC in monkeys affected formation and retention of arbitrary visual-motor associations. Bilateral damage to this region, an efferent target of IT, abolished rapid acquisition of new association, and impaired association retention. However, the ventral and orbital PFC lesion did not prevent new learning, indicating that PFC alone does not have a critical role in establishing or retaining visual-motor associations. A subsequent study, using the cross-disconnection procedure (staged unilateral damage in different hemispheres to two neocortical structures), revealed that unilateral ventral and orbital PFC damage had little or no effect on rule formation. The addition of an IT lesion in the opposite hemisphere severely impaired learning of visual-motor association (Bussey et al., 2002). This lesion study in monkeys provides clear evidence of the important roles of IT and ventral PFC in forming visual-motor associative rules. Unilateral lesion of PFC did not alter retention of acquired or learning of new arbitrary visual-motor associations. Addition of a contraversive lesion of IT, an input structure to PFC, impaired retention and learning. The results suggest that information processed in IT and passed to PFC is critical in learning new visual-motor rules. These data indicate the necessity of a functional pathway between IT and PFC to form and retain visual-motor associations.

Neuroimaging work has reinforced these views by showing that the human homologue of monkey IT and ventral PFC exhibit dynamic activation changes during sustained performance of initially (and then learnt) visual-motor couplings (Toni et al., 2001). Further support for interactions between temporal and frontal structures during rule formation derive from studies showing learning-related changes in effective connectivity in a processing stream originating in occipital regions then to the middle temporal gyrus through the anterior striatum ending in the superior PMA (Toni et al., 2002). Effective connectivity related to visual-motor associative learning also changes in other pathways, with increases occurring between regions of the inferior frontal sulcus to the anterior striatum. By contrast, decreasing effective connectivity occurred in a frontal pathway from the inferior frontal gyrus to the opercular region of the precentral gyrus, as mediated by a presumed connection through the anterior striatum. Despite the emphasis on a temporal-striatal-ventral frontal pathway on forming and maintaining sensory-motor associations, other neocortical areas of humans also participate in these processes, particularly interconnected regions in the parietal and frontal cortex (Eliassen et al., 2003; Grol et al., 2006). Different structures in these regions participate in early, later, and over-learned aspects of visual-motor mappings.

The basal ganglia also participate in development and retention of arbitrary sensory-motor associations. Neural recording from various nuclei in the basal ganglia have shown that spiking changes during the acquisition of visual-motor associations (Hadj-Bouziane et al., 2003; Brasted and Wise, 2004). Buch et al. (2006) have provided evidence of a key role for putamen neurons in the process of forming such associations. They examined population activity of neurons in putamen and dorsal PMA, comparing the firing rates of these two areas between the stimulus and feedback cues during trial-and-error learning of stimulus-response mappings. Early in learning, the population discharge of putamen neurons became differentiated from that of dorsal PMA neurons after behavioral selection occurred but before the feedback signal appeared. Putamen neurons exhibited sustained spiking in this interval, whereas dorsal PMA discharge rates fell to baseline. Additionally, putamen neurons showed selectivity for particular mappings. The maintenance of selective ephemeral information about stimulus response mappings by the putamen until reinforcement occurs suggests that this brain region operates to first form and likely also to maintain arbitrary sensory-motor associations. As noted previously, functional connectivity between the temporal and frontal cortex, as mediated via the anterior striatum, exhibits learning-related changes during formation and rehearsal of visual-motor associations. These results provide support for a key role of the striatum in development of sensory-motor mappings.

3.22.8 Learning Mechanisms

A remaining question concerns how use-dependent and sensory-driven motor learning occurs. Similar to the mechanisms discussed for M1 plasticity, candidate mechanisms include fundamental modification in neural spiking properties, formation of new intrinsic or extrinsic synaptic contacts, LTP (LTD) of network synapses, and changes in intracortical processing (Sanes and Donoghue, 2000). Support for each of these mechanisms having a role in supporting motor learning exists, and therefore they should not be considered as a feature only for motor plasticity, or even learning, but complementary processes. Understanding mechanisms for motor learning have commonly focused upon M1 and relatively simple motor tasks, though similar mechanisms likely mediate a wide range of motor learning phenomena across a variety of neural structures.

A useful tool to examine how M1 might participate in learning is to characterize potential changes in the firing profiles of M1 neurons. Cells in M1 commonly exhibit a preferential increase in spiking related to movement in a particular direction (Georgopoulos et al., 1982). The preferred direction can index changes in M1 coding in response to a monkey adapting movements when exposed to an artificial force field (Gandolfo et al., 2000). A more systematic treatment of these data revealed that a substantial fraction of M1 neurons exhibited memory-like changes in a neuron's preferred direction (Li et al., 2001); a subsequent study by the same group (Padoa-Schioppa et al., 2004) found similar results for neurons in SMA. About half of these memory-like cells retained a profile similar to that developed during exposure to the new force field after it was removed, while the remaining half changed the preferred direction only after the new force field was removed but in a direction consistent with the novel force field. The difference between these two memory-like cells is that one expressed (and then retained) modification in the preferred direction upon exposure to the change in force field, whereby the second type expressed the modified preferred direction only after the novel force field was removed. The results provide important insights into a M1 role in fundamental processes of memory and consolidation. However, a weakness of these studies relates to an inability to determine the durability of these shifts in preferred direction; recalling the findings of Classen et al. (1998) on only short-term changes in M1 output due to practice, one might expect that the changes observed by this group of researchers (Gandolfo et al., 2000; Li et al., 2001; Padoa-Schioppa et al., 2004) might not endure. Therefore, it remains an important issue to resolve in determining how M1 and SMA code motor learning.

Another feature of M1 physiology is synchronous firing between nearby or even relatively distant neurons (Murthy and Fetz, 1996; Donoghue et al., 1998), a property that can be revealed in the characteristics of post-spike averages recorded in skeletal muscles (Smith and Fetz, 1989). Recent data indicate that the probability of synchronous firing of M1 neurons, as determined from examining spike-triggered averages in hand muscles, increases with longevity and complexity of training (Schieber, 2002), suggesting that within-area communication, as well as between-area connectivity, likely has importance as an important mechanism underlying development of motor skill. Future work should likely address whether synchrony within the cortex is an antecedent or a consequence of motor skill acquisition. Recent work provides evidence that enhanced functional connectivity between M1 and spinal targets parallels development of motor skills (Kargo and Nitz, 2003, 2004). First, Kargo and Nitz (2003) demonstrated a change in the correlation between M1 neural spiking and muscle synergy patterns as reach-to-grasp learning improved in rats. Second, they showed that the signal-to-noise ratio of M1 neurons improved as motor skill learning progressed and that M1 firing more reliably recruited muscles related to task performance (Kargo and Nitz, 2004). The improved recruitment of muscles by M1 indicated that learning improved, albeit by a currently unknown mechanism, the excitatory transmission from M1 to spinal cord.

LTP and LTD have been proposed as mechanisms for learning and memory functions throughout the brain, though definitive proof of the relationship between synaptic plasticity and learning often is lacking (Martin and Morris, 2002). As noted, modification of internal circuitry and synaptic plasticity has been amply demonstrated in M1 (Jacobs and Donoghue, 1991; Hess and Donoghue, 1994). Motor skill learning and the amount of LTP and LTD induced in M1 appear associated (Rioult-Pedotti et al., 1998, 2000; though see Cohen and Castro-Alamancos, 2005) to suggest that synaptic plasticity mediates motor skill acquisition. Induction of LTP in M1 can increases the size of M1 output representations (Monfils et al. 2004). In this study, LTP was induced in the caudal forelimb zone of the rat M1 by high-frequency stimulation of the

corpus callosum across multiple days. Intracortical stimulation mapping revealed an expansion of the caudal forelimb representation and local changes in dendritic morphology. Other work from this group has demonstrated modifications in synaptogenesis (Kleim et al. 2004) following prolonged motor training; however, the increased synaptogenesis preceded map reorganization, suggestion that synaptic rearrangement stimulated the functional consequences of motor skill learning.

In addition, work in humans paralleling that in experimental animals has suggested the possibility of LTP-like mechanisms in human M1 (Stefan et al., 2000; Ziemann et al., 2004). In this work, peripheral nerve stimulation can induce lasting enhancement – for tens of minutes – of motor-evoked potentials from M1 TMS. Systemic pretreatment of human participants with pharmacologic agents that block NMDA receptors reduces this LTP-like phenomena (Stefan et al., 2002). Practice-related changes in TMS-induced M1 output can also be modified by GABA transmission blockade (Ziemann et al., 2001; McDonnell et al., 2007), as can agents that generally reduce cortical excitability (Sohn et al., 2002). Modification of GABA and NMDA function also impairs adaptation to novel sensory-motor environments but not recall of already-learned sensory-motor perturbations (Donchin et al., 2002). In this work, the authors provide additional information that modifications in GABAergic and glutaminergic neurotransmission affected motor learning, in particular sensory-motor adaptation. Coupled with earlier studies showing that manipulation of GABAergic and glutaminergic neurotransmission affects learning of simple movements, the results of this study suggest that these neurotransmitter systems have a general function across a variety of motor skill situations. Thus, it appears that manipulation of neurotransmitter systems, albeit via systemic routes, that foster LTP or LTD affect the underlying physiology of human motor learning.

3.22.9 Concluding Remarks

The understanding of how neocortex and its associated subcortical structures contribute to generating motor learning and its expression has advanced significantly in the past 20 years. Neuroimaging, novel approaches using neural recording in experimental animals, and interventional studies that use transcranial stimulation have provided new insights into how a variety of cerebral cortical and subcortical targets contribute to performance-related improvements of voluntary movements following practice, development of implicit and declarative knowledge of movement sequences, and how sensory-motor rules become formed and retained. The learning-related changes in activation history or even neuronal spiking cannot directly address underlying synaptic mechanisms that drive motor learning. Not unlike other learning systems, LTP and LTD have been proposed as mechanisms of motor learning, as have changes in neural synchrony within and across structures. In M1, horizontal connections show plastic phenomena that correlate with improvement in skilled performance, an example of procedural motor learning. Since neural plasticity occurs in many brain sites, balancing LTP and LTD could represent a mechanism for the synaptic modifications that may underlie many forms of motor learning. Thus, while procedural motor learning might mostly involve M1, associative motor learning might involve cortical regions other than M1, even though LTP and LTD or perhaps neuronal synchrony might mediate both forms of motor learning, with the inputs to the involved cortical areas determining the form of motor learning.

3.23 Neurophysiology of Birdsong Learning

R. Mooney, J. Prather and T. Roberts, Duke University, Durham, NC, USA

3.23.1 Synopsis

Songbirds are one of the few nonhuman animals that learn to vocalize. Juvenile songbirds first memorize a tutor song and then match this memorized model using auditory feedback. The close parallels between song learning in birds and speech learning in humans have piqued interest in the mechanisms of song learning. The neurobiological analysis of birdsong was revolutionized by the discovery of a specialized constellation of brain nuclei necessary to singing. Part of this 'song system' includes a basal ganglia pathway necessary to song plasticity, providing an important insight into neural mechanisms of song learning. Other important issues, such as where tutor song memories are stored and how and where auditory feedback registers in the brain of the singing bird, are now beginning to be addressed, with many of the most exciting results about to unfold. This chapter discusses song's function as a communication signal, the role experience plays in song development, peripheral and central song mechanisms, and neural mechanisms of song learning. *See* Chapter 1.17 for additional discussion of bird song learning.

3.23.2 The Song Behavior

3.23.2.1 Taxonomy of Songbirds

Oscine songbirds (Aves, Passeriformes, Oscini) comprise over half of the approximately 8000 extant avian species. Oscine songbirds learn to sing, which distinguishes them from most other birds – and indeed almost all nonhuman animals. Most neurobiological studies of singing and song learning have focused on a few domesticated or partially domesticated songbirds that breed readily in captivity. These include zebra finches (*Taeniopygia guttata*), a colonial and nomadic species native to the Australian Outback, Society finches (*Lonchura domestica*), which have been fully domesticated for centuries, and canaries (*Serinus canaria*), a seasonally breeding cardueline finch native to the Canary Islands (**Figure 1**). Although these species will continue to be useful, the great diversity of singing-related behaviors in other wild songbirds provides a vast and currently underexploited resource for comparative analysis of song learning mechanisms.

3.23.2.2 Calls versus Songs

Birds utter both calls and songs (Marler, 2004b; Williams, 2004). Calls are brief sounds (~100 ms) with relatively simple acoustic structure. Songs are longer in duration (typically 1–3 s) and typically more complex in structure, often consisting of extensive and rapid frequency and amplitude modulations. Song complexity does not always reflect learning: The songs of some suboscine birds (Aves, Passeriformes, Tyranni) are complex but innate. Moreover, although calls are simpler than songs, some fine acoustical features of calls also may be learned.

3.23.2.3 Song Nomenclature

Songs can be visualized with a sonogram, which plots frequency as a function of time (**Figure 1**). The smallest song unit is the note, a short burst of sound (~5–100 ms) that is separated by brief (5–10 ms) silence and that appears as a continuous trace on a

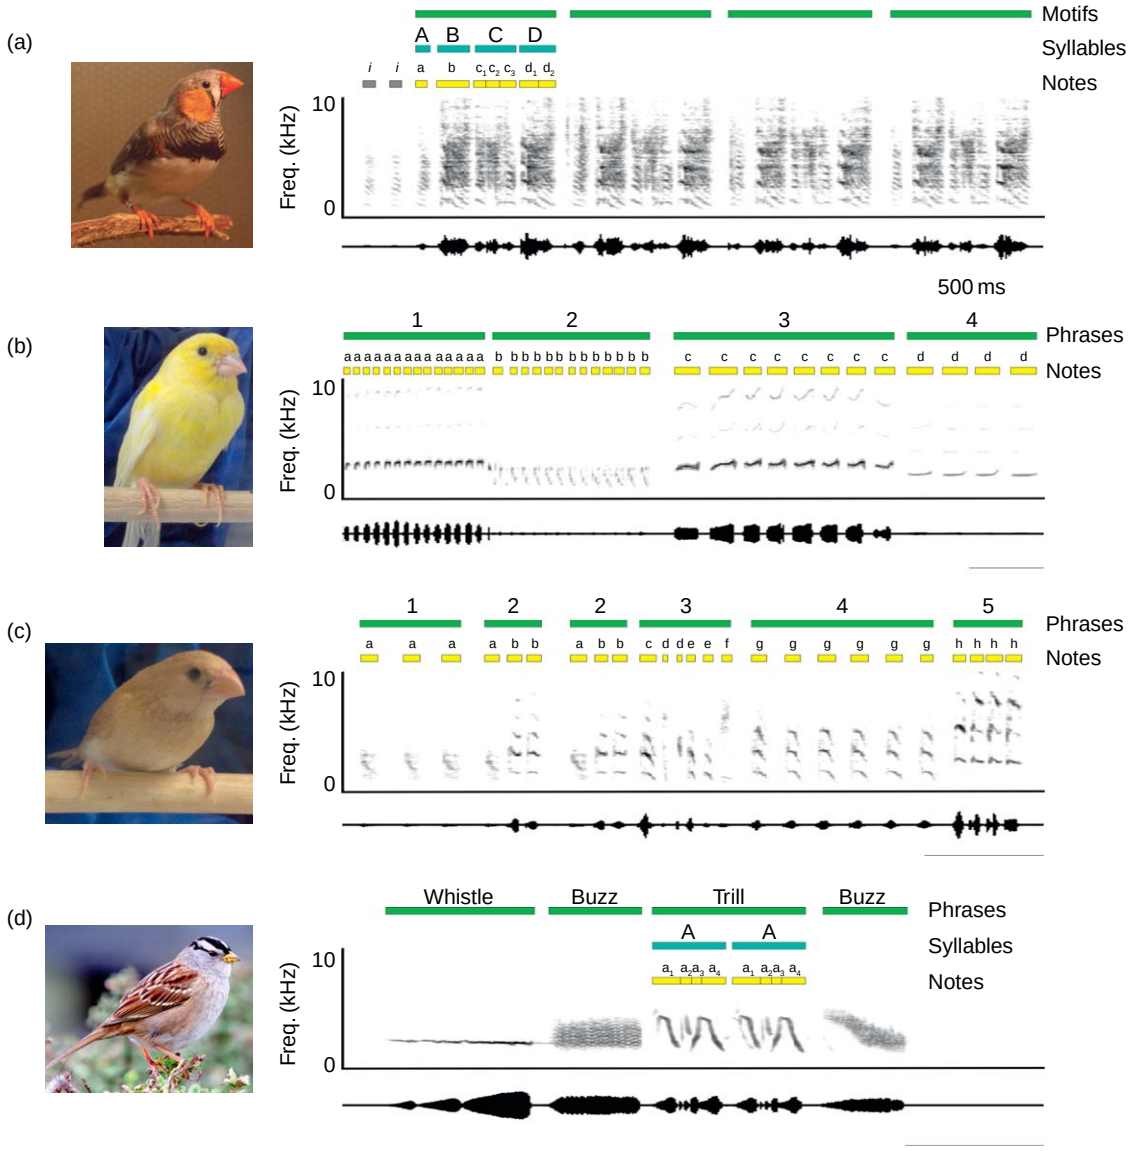

Figure 1 Four male songbirds and their crystallized songs, depicted by an oscillogram (bottom) and a sonogram (top). Colored boxes above each sonogram delineate song components for each exemplar. (a) Zebra finch (*Taeniopygia guttata*) song bouts begin with a series of brief introductory notes (denoted by '*i*' and gray boxes) followed by one or more identical motifs (green boxes). Each motif consists of a stereotyped sequence of syllables (blue boxes), with each syllable comprising one or a few notes (yellow boxes). (b) Canary (*Serinus canaria*) song consists of a series of phrases (green boxes), each of which consists of a trilled single-note (yellow boxes) or multinote syllable (not shown). Male canaries can sing a large number of different phrases, which can be combined in different sequences to produce a large repertoire of songs. (c) Society finch (*Lonchura domestica*) song is characterized by phrases (green boxes) consisting of a sequence of notes or syllables (yellow boxes). Although the note sequence that defines each phrase is typically stereotyped, the phrase sequence can vary across song bouts. (d) White-crowned sparrow (*Zonotrichia leucophrys*) song begins with a whistle phrase (green boxes) a combination of other phrases referred to as buzzes and syllables (a repeated sequence of one or more notes). Zebra finch image courtesy Daniel D. Baleckaitis, canary and bengalese finch images courtesy of David Kloetzer and Jon Prather, white-crowned sparrow image courtesy Vladimir Pravosudov (University of Nevada Reno).

sonogram. One or more notes are grouped to form syllables, which are arranged in specific sequences known as motifs, phrases, or songs, depending on the species (**Figure 1**) (Marler, 2004a). In those birds that produce several distinct songs, each song is referred to as a song type. Song typically lasts ~2 s, but it can be as long as 30 s in canaries and European starlings. Songs are uttered one to several times in quick

succession to form a bout, which can be separated from the next bout by many seconds or even minutes.

3.23.2.4 Function of Song as Communication Signal

3.23.2.4.1 Territorial defense

In most songbirds, song is produced by males, primarily during breeding season. Song serves two primary functions: territorial defense and mate attraction (Catchpole and Slater, 1995). Song's role in territorial defense can be shown by poking a small hole in one of the air sacs in the bird's specialized respiratory system. Such air sac rupture temporarily mutes the bird, and he quickly loses his territory to neighboring males (McDonald, 1989). In a similar vein, neighboring males are reluctant to invade territory vacated by a fellow conspecific bird if the absent male's songs are played through speakers positioned in the vacant territory (Krebs, 1977). Thus, song is necessary to enable a bird to defend his territory against other males and can even serve this function in the absence of visual displays or physical combat.

Distinguishing neighbors from strangers also is important to territorial defense. During the breeding season, a male will aggressively approach and even attack speakers broadcasting unfamiliar songs (Catchpole and Slater, 1995). These territorial displays habituate when the male is repeatedly exposed to several 'virtual neighbors' simulated by songs played through separate speakers. However, when the male hears a 'new' bird's song through one of the speakers, he again attacks, indicating he detected a stranger's song on a background of familiar songs (Nelson and Marler, 1989).

3.23.2.4.2 Mate attraction and female song preferences

The other major function of male song is to attract and arouse conspecific females. Song is a powerful acoustic aphrodisiac that can draw in females literally from out of sight. Song's arousing qualities can be revealed by simply playing it through a loudspeaker. For conspecific female birds in breeding condition, this acoustical stimulation is sufficient to evoke a lordotic response, known as a copulation solicitation display (CSD).

The CSD has helped reveal song features females find attractive. Females tend to favor longer songs containing more complex syllables (Clayton and Prove, 1989), features that distinguish learned songs from those produced by untutored birds (Searcy et al., 1985). Moreover, females prefer the highly stereotyped (crystallized) songs of adult males in breeding condition. In swamp sparrows, females favor songs most challenging for males to produce (Ballentine et al., 2004). Finally, although females often do not sing, their capacity for song discrimination can surpass that of males. For example, female redwing blackbirds make CSDs to the songs of a male conspecific but not to a mockingbird's imitations of this song, while male redwing blackbirds attack speakers broadcasting either song (Searcy and Brenowitz, 1988).

From an evolutionary perspective, female songbirds select males partly based on learned features of song (Searcy et al., 1985). Consequently, sexual selection in songbirds has exerted extraordinary selective pressure on brain structures specialized for singing and song learning. As discussed in greater detail later in this chapter, the elaboration of specialized neural circuits for song has proven to be a great boon to neurobiologists interested in vocal learning mechanisms.

3.23.2.5 Acoustic Features of Song Vary with Function and Context

3.23.2.5.1 Broadcast versus local songs

A basic distinction can be made between broadcast songs, which are highly tonal and typically produced by territorial songbirds to propagate over large distances, and local songs intended for a more intimate audience (**Figure 1**). The acoustic energy in broadcast songs is focused in a narrow-frequency band centered at ~3–4 kHz, avoiding interference with lower-frequency environmental sounds. When broadcast songs propagate over long distances, their tones become 'blurred.' Males disregard spectrally blurred songs, even when played at sound pressure levels approximating songs of nearby birds, indicating that the degree of spectral blurring, rather than absolute loudness, is used to estimate the singer's distance (Naguib and Wiley, 2001). In contrast to broadcast songs, the songs of birds that sing only for a local audience, such as male zebra finches, often are broadband signals that propagate only several to a few tens of meters (**Figure 1**).

3.23.2.5.2 The importance of social context

Song can vary with social context. The songs of adult male zebra finches directed to another individual are slightly more stereotyped than undirected songs

(Kao and Brainard, 2006). The functional significance of these context-dependent changes is unclear, but activity in the male's brain changes depending on whether he is singing directed or undirected songs (Jarvis et al., 1998; Hessler and Doupe, 1999b). Dueting songbirds also afford another example of social contributions to song structure. In some tropical wrens (*Thryothorus spp.*), both males and females sing a small repertoire of song types, and breeding partners sing precisely coordinated duets thought to facilitate breeding synchrony in their equatorial environment (Langmore, 1998).

3.23.3 Song Learning

3.23.3.1 General Themes

Songbirds learn to sing during a juvenile sensitive period comprising two distinct phases, both dependent on auditory experience (**Figures 2** and **3**). During the first phase, known as sensory acquisition, the young bird listens to and memorizes one or more tutor songs. During the ensuing phase of sensorimotor learning, the pupil relies on auditory feedback to match its song to the memorized model. Song crystallization, wherein the song becomes highly stereotyped and usually much less dependent on auditory feedback, signals the end of sensorimotor learning.

In seasonally breeding songbirds that populate temperate regions, 6–10 months separate sensory acquisition and sensorimotor learning (**Figure 2**). In contrast, these periods overlap in species such as the zebra finch, which crystallize their songs only 3 months after hatching (**Figure 2**). Regardless of the pace of song learning, young birds evince sensory plasticity, by memorizing one or more tutor songs, and motor plasticity, by vocally imitating one or more song model.

The great diversity of songbird species is paralleled by minor variations on these major song

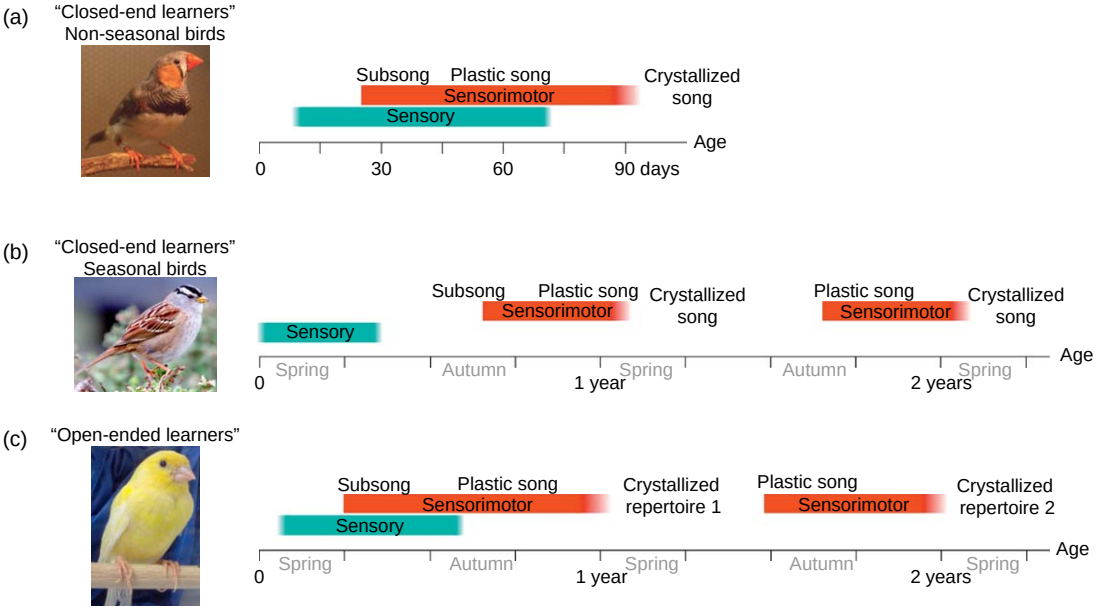

Figure 2 Developmental timelines of song learning in different songbird species illustrate similarities and variations in the song learning process. During sensory acquisition (blue box), the juvenile bird listens to and memorizes one or more tutor songs. During sensorimotor learning (red box), the juvenile matches its own song to the memorized model using auditory feedback. Song crystallization marks the end of sensorimotor learning. 'Closed-end learners,' such as the zebra finch and white-crowned sparrow (a and b), retain the same crystallized song repertoire throughout adulthood, while in 'open-ended learners,' such as the canary, the crystallized repertoire can change from one year to the next. (a) In the zebra finch, the sensory (blue box) and sensorimotor periods (red box) overlap extensively, and song crystallization is complete between 90 and 120 days after hatching. (b) In the white-crowned sparrow, sensory acquisition and sensorimotor learning are separated by many months, indicating that the tutor songs are stored in memory without rehearsal. Song crystallization occurs in the spring, at the end of the first year. Early each ensuing spring, adult male white-crowned sparrows again sing plastic songs, but they recrystallize the same song type as that crystallized in their first year. (c) Canaries are seasonally breeding birds, like white-crowned sparrows, but can exhibit changes in their repertoire of crystallized songs from one year to the next. Zebra finch image courtesy of Daniel D. Baleckaitis, white-crowned sparrow image courtesy of Vladimir Pravosudov (University of Nevada Reno), canary image courtesy of David Kloetzer and Jon Prather.

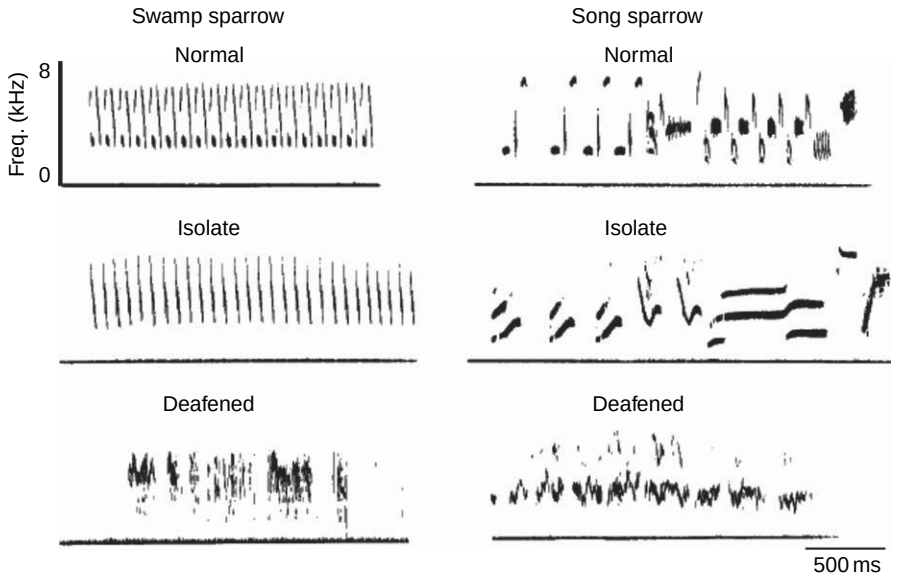

Figure 3 Development of species-typical song structure requires auditory experience of an appropriate song model and experience of singing-related auditory feedback. These sonograms depict songs of adult swamp (left) or song (right) sparrows raised with normal experience of a tutor and with their hearing intact (top row), raised in isolation from others birds' songs with hearing intact (middle) and raised with experience of a tutor song but deafened before sensorimotor learning (bottom). Isolate songs display rudimentary species-typical song features but lack the acoustical complexity of normal wild-type song, underscoring the important role of auditory experience of the tutor song. Songs of deafened birds lack even the rudimentary features of the isolate song, revealing the important role auditory feedback plays in sensorimotor learning Reprinted from Marler P and Doupe AJ (2000) Singing in the brain. *Proc. Natl. Acad. Sci. USA* 97: 2965–2967. Copyright (2000) National Academy of Sciences, U.S.A, with permission.

learning themes (**Figure 2**). 'Closed-ended' learners, which include the white-crowned sparrow and the zebra finch, retain one crystallized song throughout adult life. 'Open-ended' learners, such as the canary, continue to modify their songs as adults, although whether such adult plasticity involves copying of new tutor songs remains uncertain.

3.23.3.2 Sensory Acquisition

3.23.3.2.1 Cross-fostering and isolates

Several lines of evidence show that songbirds learn to sing. First, young songbirds transplanted into the nest of another species develop songs resembling those of their foster parents (Immelmann, 1969; Baptista and Petrinovich, 1984, 1986). Second, local song dialects distinguish different breeding populations of the same songbird species (Marler and Tamura, 1964). Third, birds raised without a tutor subsequently fail to sing species-typical songs and, instead, produce rudimentary 'isolate' songs (**Figure 3**) (Thorpe, 1954, 1958; Immelmann, 1969; Marler, 1970; Price, 1979). This dependence on auditory instruction distinguishes birdsong from most other animal vocalizations that, regardless of their acoustical complexity, develop through innate processes (Konishi and Nottebohm, 1969; Kroodsma and Konishi, 1991).

3.23.3.2.2 Sensory acquisition: born to learn

Young songbirds are prodigious song mnemonists. The number of models that may be memorized during sensory acquisition can range into the hundreds in some species, and the total exposure required for accurate recall can be remarkably limited. In perhaps the most impressive example of this learning capacity, young nightingales accurately learn 10–20 song types (comprising a total of 75–100 syllables) after hearing them fewer than only 20 times (Hultsch and Todt, 1989a,b). Moreover, these memories are stored for many months before the bird actually begins to sing. This astounding feat of auditory memory is reminiscent of other forms of sensory imprinting and suggests that the juvenile songbird is predisposed to memorize certain sounds almost effortlessly.

Cross-fostering experiments show that juvenile songbirds are flexible in the range of songs they will memorize and subsequently copy (Immelmann, 1969; Baptista and Petrinovich, 1984, 1986). Nonetheless, they prefer to learn conspecific songs when given the opportunity. After being tutored on a recorded medley of conspecific and heterospecific songs, juvenile swamp and song sparrows preferentially copy their conspecific songs (Marler and Peters, 1987, 1989; Marler, 1990). Interestingly, these experiments used recorded tutor songs, indicating that juveniles must innately recognize acoustic cues present in the conspecific songs. In the wild, such innate recognition of conspecific song may help naïve juveniles avoid spurious imprinting on heterospecific songs.

3.23.3.2.3 A sensitive period for sensory acquisition

Sensory acquisition closes between the end of the second and third month after hatching in many species (**Figure 2**) (Thorpe, 1958; Immelmann, 1969; Marler and Peters, 1987, 1988). Young birds typically fledge at the end of the first month, so in natural settings juveniles socialize with other potential tutors in addition to their fathers. The timing of sensory acquisition has been mapped most precisely in zebra finches, where juveniles were initially raised with tutors, then removed to an isolated environment at various ages (Bohner, 1990). These controlled tutoring experiments suggest that much of what will be copied can be memorized by the end of the fifth week. Complementary experiments in which birds were sequentially exposed to a series of tutors show that juvenile birds become refractory to further copying from new tutors by about the end of the second month (Eales, 1985). The closure of sensory acquisition is not strictly age limited, because raising birds in isolation extends sensory acquisition 1 to 2 months (Eales, 1987; Morrison and Nottebohm, 1993). Nevertheless, birds subjected to late tutoring copy less extensively than do normally tutored birds, and eventually individuals become totally resistant to learning from a tutor.

3.23.3.2.4 Sensory acquisition results in long-lasting memories of the tutor song

A remarkable feature of sensory acquisition is that the memory of the tutor song can be stored for long periods prior to the first attempts at vocal imitation. In seasonally breeding species, such as swamp and song sparrows, imprinting on the tutor song occurs in the late spring immediately after hatching, but the earliest attempts at vocal imitation do not begin until early in the following spring, a full 8 to 10 months later (**Figure 2**) (Marler and Peters, 1981, 1982b). This capacity to store the tutor song memory for a long period prior to imitation is especially impressive and is one way in which songbirds may differ from humans, where auditory experience of the vocal model and attempts at vocal imitation overlap.

Long-term storage of the tutor song memory may be a general feature of song learning. Despite their normally compressed song learning schedules, juvenile zebra finches briefly exposed to a tutor, then prevented from hearing their own songs for several months by exposing them to a loud masking noise, imitate the tutor song when the noise is turned off (Funabiki and Konishi, 2003). The long delays between tutor song imprinting and subsequent vocal recall afford an opportunity to search for neural correlates of long-lasting auditory memories.

3.23.3.3 Sensorimotor Learning

3.23.3.3.1 General themes including the role of auditory feedback

During sensorimotor learning, the juvenile matches its own song to the memorized tutor model (**Figures 3 and 4**). Although sensorimotor learning typically occurs without ongoing exposure to the tutor, pioneering studies by Mark Konishi showed that juvenile birds deafened after sensory acquisition but before or during sensorimotor learning subsequently developed highly abnormal songs (**Figure 3**) (Konishi, 1965). This observation supports the idea that the juvenile uses auditory feedback to evaluate differences between its own song and a 'template' initially created upon hearing the tutor. Interestingly, Konishi also discovered that birds raised without tutors also develop highly abnormal songs following juvenile deafening (Konishi, 1965). Apparently, even isolate birds use auditory feedback to match their rudimentary songs to an innate 'template.'

Sensorimotor learning comprises several stages (**Figure 4**) (Immelmann, 1969; Marler and Peters, 1982a). Subsong, which constitutes the young bird's earliest song efforts, is a soft and rambling vocalization with little resemblance to the species-typical song. Subsequently, birds produce plastic songs, which contain recognizable notes and syllables that vary in their acoustical structure and sequence from one bout to the next. This bout-to-bout variability is thought to facilitate exploration of the vocal-acoustic space, enabling the pupil to better match the tutor song. In distinction from sensory acquisition, sensorimotor

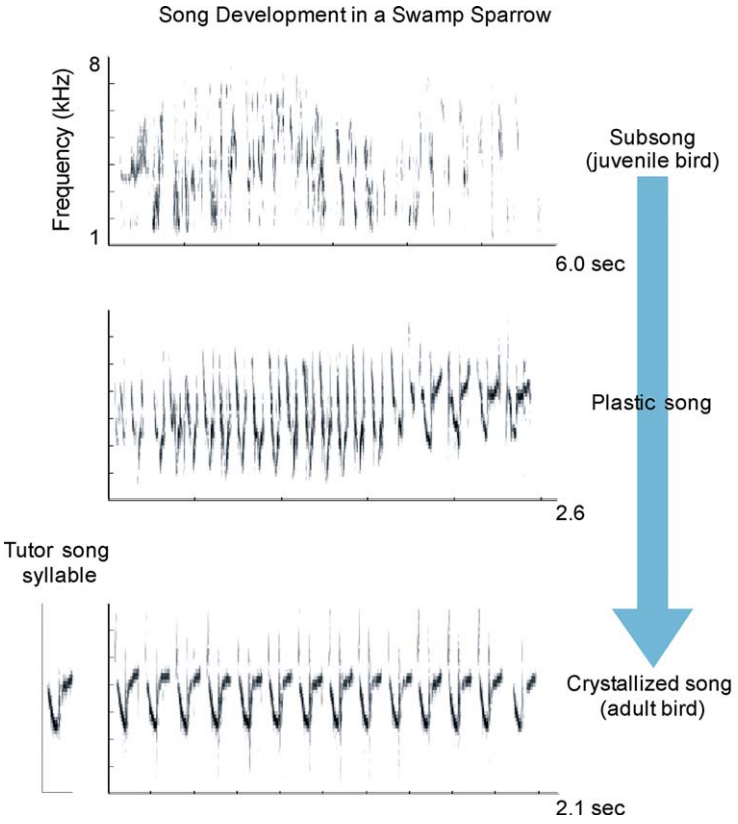

Figure 4 During sensorimotor learning, song progresses from a string of sounds with little recognizable structure ('subsong') to the stereotyped species-typical pattern characteristic of crystallized song. These sonograms depict sensorimotor learning in a male swamp sparrow, a species that in adulthood produces several distinct song types, each consisting of a monosyllabic trill. Subsong contains a variable sequence of notes that bear no obvious resemblance to the tutor song. 'Plastic song' is defined by acoustic features typical of adult song, in this case a trilled syllable similar to one of the tutor songs, and variability in the structure and sequence of notes and syllables. Upon crystallization, the structure and sequence of syllables becomes highly stereotyped. Image created from swamp sparrow data provided by Susan Peters.

learning is a slow process. Over many weeks and tens or hundreds of thousands of vocal renditions, the juvenile's song undergoes plastic changes that render it similar to the tutor model. Thus, juvenile songs display acute variability and adaptive plasticity. Juvenile birds also generate improvised notes and make mistakes in memorization and/or imitation of the tutor song, with the result that their imitations, though highly accurate, are not perfect copies of the tutor. Innate mechanisms also can play a role: juvenile white-crowned sparrows tutored only on overlapping syllable pairs eventually 'stitch' these syllables together to form a complete song phrase (Rose et al., 2004). This interplay between imitation, improvisation, innate constraints, and error yields songs that are unique yet still species typical.

With the onset of sexual maturity, the structure and sequence of notes and syllables becomes highly stereotyped, or 'crystallized.' In contrast to the slow pace of sensorimotor learning, crystallization can occur very rapidly, often in less than 1 week. In many seasonally breeding songbirds, the male sex hormone testosterone is thought to be the catalyst for crystallization (Marler et al., 1988). Because testosterone levels can fluctuate with changes in day length, adult males of seasonally breeding species sing plastic songs early each spring and then recrystallize their songs as spring days lengthen.

3.23.3.3.2 Syllable overproduction and attrition during sensorimotor learning

Much of what we know about sensorimotor learning stems from studying sparrows, songbirds that breed seasonally and that display an 8-month gap between sensory acquisition and the first stages of plastic song. Syllable overproduction and subsequent attrition are major features of sensorimotor learning in these birds

(Marler and Peters, 1982c). In contrast to crystallized songs, plastic songs in sparrows are not only more variable but also contain a wider range of material, much of it learned from various tutors during sensory acquisition. Thus, the juvenile's plastic songs effectively report the numerous tutor songs stored in memory. Upon crystallization, much of this learned material is deleted, with the consequence that the adult crystallized repertoire represents only a subset of what was actually learned.

3.23.3.3.3 Selection-based models of sensorimotor learning

The sequence of syllable overproduction followed by attrition supports a selection-based model of sensorimotor learning (Marler and Peters, 1982c). In this model, overproduction provides a palette of songs from which the young adult chooses its crystallized repertoire. But is this 'choice' random or instead guided by an instructive process? One idea is that slight variations in late plastic songs help the juvenile gain breeding territory by providing it with the necessary behavioral flexibility to match the dialect of the older, more established breeding males in the neighborhood. Indeed, juvenile white-crowned sparrows crystallize a plastic song most like a white-crowned sparrow song broadcast to them repeatedly through a speaker and delete their other plastic songs (Nelson and Marler, 1994).

3.23.3.3.4 A fine time-scale analysis of sensorimotor learning

The pioneering studies of sensorimotor learning relied on tape recordings, which were scanned by human listeners in real time, limiting the numbers of songs that could be analyzed. The advent of cheap mass storage devices coupled with the development of automated song analysis methods, especially those developed by Ofer Tchernichovski and his coworkers, have provided a blow-by-blow account of sensorimotor learning in zebra finches (Tchernichovski et al., 2000, 2001; Deregnaucourt et al., 2005). Such comprehensive analyses have yielded several important insights into vocal learning strategies (Deregnaucourt et al., 2005). First, the match between the pupil's song and the tutor model varies systematically over the course of the day, being poorest in the morning but quickly rising to a plateau by early afternoon. In contrast, daily variations are much more modest following crystallization. Second, the quality of the match partially declines overnight, so that the pupil begins each day slightly worse than it left off the evening before. Third, and perhaps most intriguingly, the greater the night-to-morning song deterioration during sensorimotor learning, the better the final match between the pupil's song and the tutor song. These observations suggest that during juvenile life, sleep triggers song deconsolidation, generating increased variability that enables the pupil to more fully 'search' vocal space in the quest to match the memorized tutor song.

3.23.3.4 Song Crystallization

3.23.3.4.1 A changing role for sensory feedback

Crystallized songs are not only more stereotyped than plastic songs but they also depend less acutely on auditory feedback (Konishi, 1965; Price, 1979). Deafening in juveniles leads to rapid song deterioration, whereas adult deafening in some species can exert little or no effect on the crystallized song (Konishi, 1965; Price, 1979). This implies that crystallization either transforms the song motor program into a feedback-independent 'read-only' system or that crystallized song maintenance is mediated by nonauditory (i.e., proprioceptive) forms of sensory feedback. Notably, when brief puffs of air are injected into the respiratory system of singing birds, respiratory and vocal muscles rapidly (~10 ms) compensate to maintain stable song output; these effects are seen even in deafened birds, indicative of proprioceptive feedback (Suthers et al., 2002). However, whether proprioceptive feedback is used for crystallized song maintenance remains untested.

The degree to which crystallized songs depend on auditory feedback varies across species. Pioneering studies by Mark Konishi indicated that crystallized songs of adult white-crowned sparrows were impervious to deafening (Konishi, 1965). In contrast, crystallized songs of adult zebra finches are maintained actively via auditory feedback: Adult deafening (Nordeen and Nordeen, 1992) or chronic exposure to distorted auditory feedback (Williams and McKibben, 1992; Leonardo and Konishi, 1999) triggers a slow process of song deterioration and plastic changes to the vocal pattern, known as decrystallization. Nonetheless, as with humans, deafening-induced vocal deterioration in zebra finches is slower in adults than in juveniles (Price, 1979; Cowie and Douglas-Cowie, 1992). Notably, adult Society finches, close relatives of the zebra finch, remain acutely dependent on auditory feedback, as their crystallized songs start to deteriorate several days to a week after deafening (Okanoya and Yamaguchi, 1997; Woolley and Rubel,

1997). In both zebra finches and Society finches, one idea is that the neural mechanisms enabling feedback-dependent learning in the juvenile also are employed to maintain stable song patterns in the adult.

3.23.3.4.2 Crystallization can impose innate constraints on song structure

A major insight is that crystallization can impose innate, species-typical constraints on song structure. Juvenile canaries tutored on synthetic songs provide an especially elegant demonstration of this effect (Gardner et al., 2005). In normal adult canaries, short stereotyped syllables are repeated to form phrases, which are linked together in the crystallized song. Synthetic 'phraseless' songs, in which syllables continuously vary in duration and amount of frequency modulation, can be used to tutor young canaries. Remarkably, juveniles first produce faithful imitations of such phraseless tutor songs but then impose phrasing with crystallization. Such innate constraints may explain why the songs of birds deafened early in life still exhibit crude but species-typical song features and why isolate songs are more similar within rather than across species. These innate mechanisms also could account for the conservation of song phenotype across geographically isolated breeding populations of the same species. If the brain of the naïve juvenile was truly a tabula rasa, then songs would randomly diverge across isolated populations, making such song conservation improbable.

3.23.3.4.3 Crystallization and critical periods for motor learning

Most evidence indicates that crystallization is not simply the result of successful learning but is the result of other factors – specifically testosterone. Male swamp and song sparrows castrated as juveniles develop plastic songs containing imitations of tutor songs, but they fail to undergo song crystallization unless implanted with testosterone (Marler et al., 1988). More generally, many seasonal songbirds crystallize their songs as vernal days lengthen and their testosterone levels rise but 'decrystallize' their songs as autumnal days shorten and their testosterone levels drop (**Figure 2**) (Nottebohm et al., 1987; Smith et al., 1997a). Thus, crystallization can be regulated by photoperiod-sensitive endocrine factors rather than the quality of the match to the tutor song.

Some evidence of an age-dependent component of crystallization comes from experiments in which botox injections were used to reversibly paralyze syringeal muscles of juvenile zebra finches (Pytte and Suthers, 2000). When vocal paralysis spanned the period bracketing crystallization, the birds crystallized abnormal songs. In contrast, permanent disruptions in song quality were not observed when reversible paralysis was induced either earlier in sensorimotor learning or after crystallization.

Although this age-dependent effect may point to a critical period for sensorimotor learning, different aspects of this learning process may be regulated independently. As mentioned earlier, juvenile zebra finches can be prevented from copying previously memorized Society finch tutor songs by chronically exposing them to masking noise (Funabiki and Konishi, 2003). Such 'reversibly deafened' birds successfully imitated syllables from the memorized tutor songs when the noise was turned off between 100 to 200 days after hatching, one to several months after crystallization normally occurs in this species. However, the phrase structure of the Society finch tutor song was only imitated if the masking noise was turned off prior to day 80; otherwise, imitations consisted of Society finch notes organized into motifs typical of normal zebra finch songs. These results indicate that the closure of sensorimotor learning is not strictly age limited, at least when auditory feedback is blocked, and also hint that different aspects of sensorimotor learning, particularly note versus phrase imitation, are regulated independently.

3.23.3.4.4 Vocal plasticity following song crystallization

In seasonal birds such as swamp sparrows, syllables 'lost' during the initial round of crystallization may reappear in plastic songs in subsequent years, suggesting that they persist as auditory or motor memories (Marler and Peters, 1982a). Despite transient reexpression of 'lost' syllables, swamp sparrows nevertheless recrystallize the same subset of song types each summer. Those species that never alter their crystallized songs, which include zebra finches as well as North American sparrows, are referred to as 'closed-ended' or 'age-limited' learners (**Figure 2**) (Marler and Peters, 1987). In contrast, 'open-ended' or 'age-independent' learners, such as canaries, change their songs with each round of recrystallization (**Figure 2**) (Nottebohm and Nottebohm, 1978; Nottebohm, 1984). From a neurobiological perspective, this ongoing pattern of vocal 'exuberance' followed by attrition suggests that brain mechanisms engaged during sensorimotor learning in the juvenile can be reengaged in the adult.

3.23.4 Peripheral Mechanisms of Song Production

3.23.4.1 General Themes

Birds and mammals vocalize by inducing pressure waves in the expiratory air column. In general, this is achieved by passing air over vibrating membranes within a vocal organ. In humans, the vibratory elements are the vocal folds in the larynx. Although birds have a larynx, their vibratory element is in the syrinx, a specialized vocal organ unique to birds (**Figure 5**) (King, 1979).

The structure of the syrinx varies greatly across different avian taxa (King, 1979). General features of the syrinx are that it is located in the airway below the larynx, and it can be moved by sets of intrinsic and extrinsic muscles. The syrinx of oscine songbirds is a bipartite structure located at the confluence of the trachea and the two bronchi and contains a larger number of intrinsic muscles than in nonoscines (**Figure 5**). This sophisticated intrinsic musculature, the bipartite structure of the syrinx, and the highly specialized avian respiratory system enable virtuosic song displays.

A current view is that vocal output is determined by expiratory air pressure, syringeal muscle tension as air passes through the bronchial lumen, and filtering by the upper vocal tract (Suthers and Margoliash, 2002; Goller and Cooper, 2004; Suthers and Zollinger, 2004). Indeed, mathematical models indicate that small variations in the timing and magnitude of expiratory pressure and syringeal tension are sufficient to generate many of the acoustic features of birdsong (Mindlin, 2005).

3.23.4.2 The Syrinx: A Vibrating Vocal Organ

3.23.4.2.1 Anatomy and function of the syrinx

The oscine syrinx consists of a group of intrinsic muscles attached to specialized cartilaginous rings in caudal portions of the trachea and/or the primary bronchi (**Figure 5**) (King, 1979). In the upper bronchi, the medial parts of the rings are absent and instead consist of a sheer membrane, known as the medial tympaniform membrane (MTM). The cranial end of each bronchus is characterized by thickenings known as the medial and lateral labia. Over a century ago, Setherwall (1901) suggested that the syringeal labia were functionally analogous to the laryngeal vocal folds. Miskimen (1951) later suggested that the MTM was the primary vibratory source of sound in the syrinx, an idea that dominated for several decades. The highly tonal quality of many birdsongs also led to an alternate, 'aerodynamic' hypothesis (Nottebohm, 1976; Gaunt et al., 1982; Gaunt, 1983; Casey and Gaunt, 1985), namely, that birdsong is not produced by a vibratory source but, instead, by air passing through a constricted bronchial lumen, which would act like a hole-tone whistle. Over the last several decades, Franz Goller, Roderick Suthers, and their colleagues used bronchial airflow measurements (Suthers, 1990; Goller and Suthers, 1996a,b) and endoscopic examination of the syrinx (Goller and Larsen, 1997; Larsen and Goller, 2002) in singing birds to show that song results from rapid vibrations in the syringeal labia, rather than by vibrations in the MTM or aerodynamic effects (Goller and Cooper, 2004; Suthers and Zollinger, 2004).

3.23.4.2.2 Ventral versus dorsal syringeal muscles

Studies by Suthers and his colleagues also lend considerable insight into the role of different syringeal muscles in birdsong. By using fine wires to record syringeal muscle activity while simultaneously measuring bronchial air flow and subbronchial air pressure in singing birds, Goller and Suthers determined that ventral syringeal muscle activity correlates with the song's fundamental frequency, while dorsal syringeal muscle activity controls air flow through the syrinx and thus sound output (Goller and Suthers, 1996a,b). This suggests that the different syringeal muscles can independently regulate the pitch and fine temporal features of song.

3.23.4.2.3 Independent control of the two sides of the syrinx

Songbirds exploit the bipartite structure of the syrinx to maximum effect. In several species, the two sides of the syrinx have been shown to move independently (Suthers, 1990; Goller and Suthers, 1995), greatly increasing fluency and vocal range (Zollinger and Suthers, 2004). Several species, including the brown thrasher, independently control the two sides of the syrinx to simultaneously sing two harmonically distinct sounds, a vocal effect termed the 'two-voice phenomenon' (Greenwalt, 1968; Suthers et al., 1994).The two sides of the syrinx also differ slightly in diameter, and thus in resonant frequency. The different resonant frequencies of the two sides allow

rapid alternation between notes of greatly contrasting pitch, an effect difficult to achieve with a unipartite vocal organ. The cardinal exploits these different resonances, skillfully and seamlessly switching from one side to the other to sing extremely broad frequency-modulated sweeps, or glissando notes (**Figure 5(c)**) (Hartley and Suthers, 1990; Suthers et al., 2004). Intriguingly, mockingbirds use a similar strategy when imitating the cardinal's glissando notes, suggesting constraints on peripheral song mechanisms (Zollinger and Suthers, 2004).

3.23.4.2.4 Nonlinear oscillatory properties intrinsic to the syrinx

Notably, some of birdsong's acoustical complexity results from nonlinear oscillatory properties intrinsic to the syrinx (Fee et al., 1998), rather than highly elaborate patterns of neuromuscular control. Experiments involving isolated syringes have shown that the syrinx displays nonlinear oscillatory dynamics in response to continuous variations in respiratory drive or syringeal activity (Fee et al., 1998). In terms of neural codes for song, modeling studies show that even simple and continuous changes in neuromuscular activity can trigger nonlinear modes of syringeal vibration, resulting in spectrally and temporally complex sounds (Mindlin et al., 2003; Mindlin, 2005).

3.23.4.3 The Avian Respiratory System and Temporal Control of Song

When songbirds sing, they exploit their specialized respiratory systems, which display impressive adaptations to the metabolic demands of flight (Scheid and Piiper, 1979). Unlike the tidal action of mammalian respiration, in which the lungs fill and empty with each respiratory cycle, avian respiration is unidirectional, with oxygenated air always flowing from the caudal to the rostral margin of the lung. This unidirectional flow is achieved by a series of highly inflatable air sacs that act like bellows to perfuse the relatively inflexible lungs (**Figure 5(a)**). The air sac system and very rapid inspiratory activity (i.e., minibreaths) enable songbirds such as the canary to generate rapidly (5–30 Hz) trilled songs lasting tens of seconds (Suthers et al., 2004).

Measurements of air sac pressure can be used to estimate changes in the pressure head that drives air through the syrinx during singing (Suthers, 1990; Goller and Suthers, 1996a,b; Suthers and Zollinger, 2004). These measurements show that respiratory patterns determine the temporal structure of birdsong. In almost all species studied to date, sounds are produced during expiration, while silent intervals between notes and syllables correspond to inspiration (**Figure 5(c)**). Expiratory pulses may constitute

Figure 5 Anatomy of the songbird respiratory system and the syrinx, and their integrated activity during singing. (a) (left) The avian respiratory system is distinguished by a series of air sacs (gray) that function as bellows to move air through the relatively inflexible lungs. The songbird vocal organ, the syrinx, is a bipartite structure located at the junction between the primary bronchi and the trachea. (a) (right) Ventral view of the songbird syrinx and associated muscles. The syrinx is affected by six bilaterally paired muscles, each innervated by the tracheosyringeal branch of the ipsilateral hypoglossal nerve (XIIts). These muscles control the movement and tension of the medial and lateral labia (ML and LL, respectively), thickenings at the cranial end of each bronchus within the syrinx (see b). (b) A cross section through the syrinx schematizing quiet respiration (left) and sequential lateralized airflow during phonation (middle and right). The trachea and bronchi consist of a series of cartilaginous rings; in the syrinx, the medial parts of the rings are absent and are replaced by the medial tympaniform membrane (MTM). During quiet respiration (left), the syringeal lumen is open on both sides. During singing (middle and right), contraction of the syringeal muscles (m. syringealis dorsalis and m. tracheobronchalis dorsalis) rotates the third bronchial cartilage (B3) into the syringeal lumen, forcing the LL and ML into the airstream and causing them to vibrate, resulting in sound (wavy lines). Phonation can be bilateral (not shown) or unilateral, when contraction of the syringeal muscles on one side of the syrinx is sufficient to completely block airflow. (a, b) Adapted from Suthers RA and Zollinger SA (2004) Producing song: The vocal apparatus. *Ann. N.Y. Acad. Sci.* 1016: 109–129. (c) The song of a northern cardinal illustrates sequential unilateral phonation during singing. The sonogram (top) shows a series of five syllables consisting of long frequency sweeps spanning as much 5 kHz. The lower panels are: airflow through the left (FL) and right (FR) sides of the syrinx (horizontal lines = zero air flow; e, expiration; i, inspiration, shaded grey); P, cranial air sac pressure (horizontal line = ambient pressure); V, oscillogram. The first two syllables, consisting of upward frequency sweeps, were generated largely by the right side of the syrinx. The following three syllables consist of long downward FM sweeps, with the initial high-frequency portion (between first and second vertical lines) produced through the right side of the syrinx and the final lower-frequency portion of the syllable produced by the left side. fundamental motor units of song: Singing birds startled by brief stroboscopic flashes complete the ongoing syllable, only becoming silent at the end of the current expiratory cycle (Franz and Goller, 2002).

Ultimately, the song's temporal pattern is a product of precise control of expiration. Therefore, neural circuitry for song must control and coordinate both syringeal and respiratory motor activity. Indeed, separate neural pathways for respiratory and syringeal control exist in the songbird's brain (Wild, 1997a; Suthers and Margoliash, 2002), a point discussed in greater detail in following sections.

3.23.4.4 Syringeal Dynamic and Upper Vocal Tract Filtering

Songbirds and humans use their upper vocal tracts to filter vocal output. Indeed, simultaneous free field and syringeal recordings show that highly tonal sounds emitted at the beak correspond to harmonic series of tones emanating from the syrinx (Beckers et al., 2003). This discrepancy suggests that the trachea and beak selectively filter out certain harmonics emanating from the syrinx. In essence, the bird's upper vocal tract acts as a filter matched to certain wavelengths of sound produced by the syrinx. One way this filtering effect can be revealed is by placing birds in a helium–oxygen atmosphere (heliox); when notes are sung in heliox (Nowicki, 1987), they sound higher in pitch because the energy of the fundamental decreases while the energy of certain harmonics increases. This effect arises because the speed of sound increases in heliox while the fundamental frequency of syringeal vibration remains unchanged. As a consequence, the sound wavelength associated with syringeal vibration lengthens, no longer matching the filter. Instead, upper harmonics of the syringeal vibration better match the resonant properties of the upper vocal tract, imparting a higher pitch to the note.

The upper vocal tract of birds is a highly dynamic structure that can rapidly match the changing vibratory modes of the syrinx. The beak is part of this variable filter (Goller et al., 2004; Nelson et al., 2005; Fletcher et al., 2006); when the beak is opened wide, the effective length of the upper vocal tract shortens, raising the resonant frequency (Westneat et al., 1993). High-speed X-ray films of singing birds (Riede et al., 2006) show that the oropharyngeal cavity also is actively manipulated to dynamically alter the upper vocal tract resonance. These various observations imply that the bird's brain must actively coordinate respiratory patterning, syringeal tension, and upper vocal tract dynamics to produce song.

3.23.5 Neural Circuits for Singing and Song Learning

3.23.5.1 General Themes

The foundation of songbird neurobiology rests on several major discoveries made over the past three decades. Arguably the most important of these was that the songbird's telencephalon exerts executive control of brainstem vocal-respiratory networks during singing, much as human language cortices command brainstem vocal-respiratory networks during speech (Doupe and Kuhl, 1999). This veritable epiphany stemmed from pioneering neuroanatomical and behavioral studies conducted by Fernando Nottebohm and his colleagues (Nottebohm et al., 1976, 1982; Nottebohm, 2005), who found that the songbird's brain contains a 'song system' – a constellation of interconnected nuclei necessary to singing (**Figure 6**).

Two telencephalic song nuclei, HVC and RA, are essential to singing and form a descending pathway that links the telencephalon to the brainstem vocal-respiratory network (**Figure 6**) (Nottebohm et al., 1976; Wild, 1997b). Intensive studies have yielded much information about the organization of this song motor pathway (SMP) and the nature of song motor 'codes' (Yu and Margoliash, 1996; Fee et al., 2004). Although the SMP has traditionally been viewed as a feedforward circuit, recent findings suggest that recurrent pathways from the brainstem to HVC contribute to song patterning (Ashmore et al., 2005).

A second key discovery was that the song system contains an anterior forebrain pathway (AFP) unnecessary to crystallized song but essential to song plasticity in both juvenile and adult birds (**Figure 6**) (Bottjer et al., 1984; Williams and Mehta, 1999; Brainard and Doupe, 2000; Olveczky et al., 2005). The AFP indirectly links HVC to RA and resembles mammalian cortical–basal ganglia (BG) pathways (Doupe et al., 2005). Experiments have revealed that the AFP helps generate acute song variability (Kao et al., 2005; Olveczky et al., 2005) and also acts over longer timescales to regulate the strength of synaptic connections between HVC and RA (Kittelberger and Mooney, 1999).

A final key discovery was that song nuclei display sensory as well as motor activity (**Figure 6**) (McCasland and Konishi, 1981). Auditory responses

highly selective for the bird's own song can be detected in the song system (Margoliash, 1983; Margoliash and Konish, 1985; Doupe and Konishi, 1991; Margoliash and Fortune, 1992; Mooney, 2000), and behavioral studies show that birds exhibit perceptual as well as vocal motor deficits when HVC or AFP nuclei are damaged (Brenowitz, 1991; Del Negro et al., 1998; Scharff et al., 1998a; Burt et al., 2000). Notably, the sensorimotor nature of HVC and the AFP resembles the expressive and receptive functions performed by language cortices in humans (Doupe and Kuhl, 1999). A major goal of current research is to understand whether auditory activity in the song system relays information about the memorized tutor song and/or auditory feedback.

3.23.5.2 Brainstem Vocal Respiratory Networks

3.23.5.2.1 General themes

Two key determinants of song structure – syringeal tension and respiratory patterning – are mediated by vocal respiratory networks in the brainstem and spinal cord (**Figure 6**). Substantial progress has been made in characterizing the anatomy of this vocal respiratory network. However, we still know relatively little about how these networks function during singing and the neural mechanisms that mediate upper vocal tract filtering (Wild, 2004).

3.23.5.2.2 The tracheosyringeal motor nucleus

The syringeal muscles are innervated by motor neurons in the tracheosyringeal part of the hypoglossal motor nucleus (XIIts) (Nottebohm et al., 1976), a midline medullary nucleus situated caudal to the obex (**Figure 6**). XIIts is myotopically organized: caudal XIIts motor neurons innervate dorsal syringeal muscles, whereas rostral XIIts motor neurons innervate ventral syringeal muscles (Vicario and Nottebohm, 1988). Syringeal motor neurons project ipsilaterally onto the muscles of the syrinx, providing one substrate for lateralized syringeal control. In certain songbird species, unilateral section of the XIIts nerve exerts different effects on song depending on which side is cut (Nottebohm, 1971, 1977; Williams et al., 1992). This observation initially suggested that the central structures controlling song also may be lateralized, as cortical control of speech is lateralized in humans.

Syringeal motor neurons drive highly dynamic syringeal muscle activity during singing. When the XIIts nerve is cut, the spectral and fine temporal features of song are severely disrupted, while the global temporal features of song, which are determined by expiratory musculature, remain largely intact (Williams et al., 1989, 1992; Simpson and Vicario, 1990). The sparing of song temporal structure following XIIts nerve section indicates that central pathways controlling syringeal and respiratory activity are independent. Indeed, these two control systems are partly segregated at the brainstem and at higher levels of the song system (Wild, 1993a,b; Reinke and Wild, 1998b; Suthers and Margoliash, 2002).

3.23.5.2.3 Brainstem and spinal cord respiratory networks

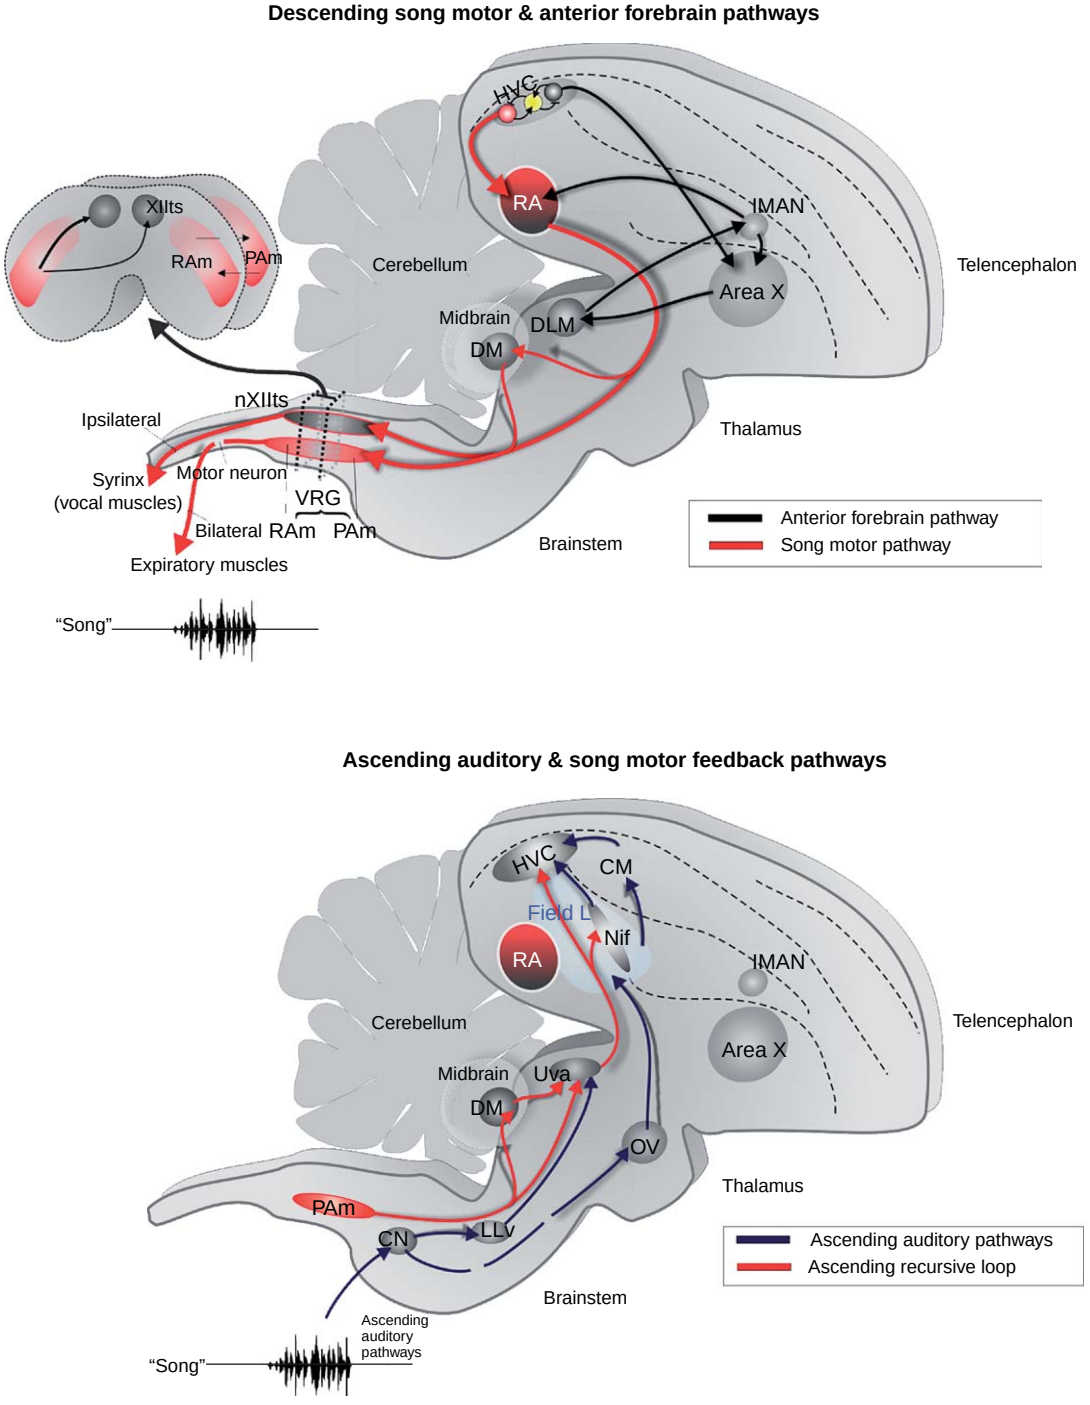
Expiratory and inspiratory motor neurons reside in the thoracolumbar and upper thoracic spinal cord, respectively (Wild, 2004). A cell column in the ventrolateral medulla, known as the ventral respiratory group (VRG), contains premotor neurons that innervate these expiratory and inspiratory motor neurons, thus controlling respiration (**Figure 6**) (Wild, 1994). The caudal VRG (nucleus retroambigualis [RAm]) controls expiration (Wild, 1993a,b), while the rostral VRG (nucleus parambigualis [PAm]) controls inspiration (Reinke and Wild, 1998b). The VRG is bilaterally organized and reciprocally interconnected, with RAm neurons projecting throughout the ipsilateral and contralateral VRG (**Figure 6**). These bilateral projections, as well as the bilateral spinal projections of VRG axons, provide an anatomical substrate for bilateral coordination of respiration during song.

Vocalization requires precise coordination of respiratory and syringeal activity. The bilateral synaptic connections that VRG neurons make onto XIIts motor neurons provide a substrate for this coordination and also are the likely source of the respiratory rhythm that can be recorded from XIIts in nonvocalizing birds (Manogue and Paton, 1982; Williams and Nottebohm, 1985; Vicario, 1991a). Recordings made in brain slices show that XIIts motor neurons receive inhibitory and excitatory inputs from the VRG (Sturdy et al., 2003); the inhibitory input may help establish the observed phase delays between onset of expiratory and syringeal muscle activity (Vicario, 1991a). Although XIIts motor neurons are highly linear in their intrinsic firing properties (Sturdy et al., 2003), the extensive interconnectivity of the brainstem vocal-respiratory network may contribute to pattern generation beyond that provided by inputs from the telencephalic song premotor nucleus RA (Sturdy et al., 2003; Kubke et al., 2005).

3.23.5.3 The Song System: Song Motor and Anterior Forebrain Pathways

3.23.5.3.1 The dawn of songbird neurobiology

Songbird neurobiology took flight in the mid-1970s, when Fernando Nottebohm, Tegner Stokes, and Christiana Leonard discovered that specialized nuclei in the songbird's telencephalon are essential to singing. In a landmark study (Nottebohm et al., 1976), Nottebohm and his coworkers showed that bilateral lesions to one of these nuclei, now referred to simply as 'HVC,' rendered an adult male canary



mute for song, even though it readily assumed a singing posture when presented with a female canary and produced unlearned calls normally. Anterograde tracing revealed two efferents of HVC: the robust nucleus of the arcopallium (RA), in the caudal telencephalon, and area X, in the avian basal ganglia. As its rather mysterious-sounding name might imply, lesions to area X exerted no obvious effect on crystallized song. However, RA lesions profoundly disrupted song, and tracing studies revealed that RA axons terminated in XIIts, suggesting that RA was a song premotor nucleus. This study showed that birdsong, unlike most other animal vocalizations save perhaps human speech, involves direct telencephalic control of vocal motor neurons.

3.23.5.3.2 Current overview of song system anatomy

In the past 30 years, a fully fledged song system has taken wing (Nottebohm, 2005). This system can be divided into two major components: a song motor pathway (SMP) and an anterior forebrain pathway (AFP) (Nottebohm et al., 1976), which both emanate from HVC and converge in RA (**Figure 6**). The SMP and the AFP arise from distinct pools of projection neurons (PNs) located in HVC (Katz and Gurney, 1981; Kirn et al., 1991; Fortune and Margoliash, 1995; Mooney, 2000). One HVC PN type (HVC_{RA}) provides excitatory input onto RA PNs (Mooney, 1992), which innervate syringeal motor neurons and respiratory premotor neurons (Nottebohm et al., 1976; Wild, 1993b). The other PN type (HVC_X) innervates area X, which is part of a serially connected pathway that indirectly links HVC to RA and includes the thalamic nucleus DLM and the anterior telencephalic nucleus LMAN (Nottebohm et al., 1982; Okuhata and Saito, 1987; Foster and Bottjer, 1998). The axons of LMAN PNs bifurcate, with one branch innervating area X (Nixdorf-Bergweiler et al., 1995) and the other forming excitatory synapses on the same RA PNs that receive input from HVC (Mooney, 1992). Targeted photoablation of HVC_{RA} but not HVC_X neurons grossly disrupts song (Scharff et al., 2000), mirroring the differential effects of RA versus area X lesions (Nottebohm et al., 1976) and reinforcing the idea that HVC_{RA} neurons drive song premotor activity in RA. Ultimately, the SMP and AFP arise from different pools of HVC PNs and converge on song premotor neurons in RA that constitute the sole forebrain output of the song system.

The nucleus RA displays anatomical features likely to facilitate selective control of syringeal and respiratory activity. First, neurons located in ventral and medial RA project onto rostral and caudal XIIts (Vicario, 1991b), respectively. Because these different parts of XIIts ultimately innervate different syringeal muscle groups (Vicario and Nottebohm, 1988), activity in different parts of RA could recruit different

Figure 6 Specialized neural circuits in the songbird's brain, collectively referred to as the 'song system,' enable singing and song learning. (a) The song motor pathway (SMP; red) and the anterior forebrain pathway (AFP; black) are schematically illustrated in a parasagittal section through the songbird brain. The SMP arises from neurons in HVC (HVC_{RA} neurons) that project directly to the robust nucleus of the arcopallium (RA). RA in turn provides song motor output from the telencephalon through its projections onto syringeal motor neurons in the tracheosyringeal portion of the hypoglossal motor nucleus (XIIts) and onto respiratory premotor neurons in a column of cells in the ventrolateral medulla known as the ventral respiratory group (VRG). The VRG comprises the nucleus retroambigualis (RAm), which controls expiration, and the nucleus parambigualis (PAm), which controls inspiration. RA also projects onto the dorsomedial intercollicular nucleus (DM) in the midbrain, which also innervates XIIts and the VRG; DM plays a role in call generation in birds. The anterior forebrain pathway (black arrows) arises from a distinct population of HVC neurons (HVC_X neurons) that innervate area X (part of the songbird basal ganglia). Large inhibitory neurons in area X project axons onto the medial nucleus of the dorsolateral thalamus (DLM), which in turn provides excitatory input to the lateral portion of the magnocellular nucleus of the anterior nidopallium (LMAN). Axons from LMAN innervate area X and also innervate the same song premotor neurons in RA that receive input from HVC_{RA} neurons. Thus, the SMP and AFP arise from distinct pools of HVC projections neurons and innervate the same RA song premotor neurons. (b) Pathways that are believed to convey auditory and recurrent song motor information to HVC. Auditory information (blue arrows) originates in the inner ear and passes via the eighth cranial nerve to the cochlear nucleus (CN) in the medulla, where it is relayed indirectly to HVC through two pathways. The first pathway includes the ventral portion of the lateral lemniscus (LLv) and the thalamic nucleus uvaformis (Uva). The second pathway includes an indirect pathway (broken line) through the auditory hindbrain and midbrain (not shown) to the thalamic nucleus ovoidalis (Ov); axons from Ov terminate in the massively interconnected telencephalic area Field L, which is analogous to mammalian primary auditory cortex. From Field L, activity is relayed through an interconnected network comprising the caudal medial nidopallium (NCM) and the caudal mesopallium (CM), which in turn projects directly to HVC and indirectly to HVC through the nucleus interfacialis (NIf). Song motor-related feedback and possibly respiratory-related activity from the brainstem are thought to reach HVC through a recurrent circuit (red lines) that includes PAm, DM, Uva, and NIf. Images courtesy of Todd Roberts.

syringeal muscles. Second, neurons in dorsal RA terminate on regions of the lateral medulla containing respiratory premotor neurons (Wild, 1993b). This segregated organization may enable dorsal and ventral RA neurons to independently modulate respiratory and syringeal activity. Third, RA axons terminate on several structures in the thalamus and midbrain, including the dorsomedial intercollicular nucleus, an area implicated in the generation of innate calls (Wild, 1993b; Wild et al., 1997). Although the function of this latter connection is unknown, one possibility is that RA interacts with DM to suppress call generation during singing. Finally, RA neurons do not directly innervate the glossopharyngeal, facial, and trigeminal motor nuclei that control the upper vocal tract (Wild, 1993b), which suggests that RA influences the upper vocal tract indirectly via the VRG.

The gross structure of HVC and RA correlates with song function. First, these nuclei are absent in birds that do not learn their songs, including flycatchers (Kroodsma and Konishi, 1991), close cousins to the oscines. Second, in those species where only the male sings, HVC and RA are greatly reduced in the female (Nottebohm and Arnold, 1976); such dimorphisms are lacking in duetting species where both sexes sing (Brenowitz et al., 1985). Finally, in seasonal breeders, HVC and RA expand in volume in the spring, when the bird sings a crystallized song, and shrink in the fall, when the bird sings less frequent and more acoustically variable songs (Nottebohm, 1981; Smith et al., 1997b; Brenowitz, 2004).

Despite these gross variations in song system structure, anatomical correlates of song lateralization have remained elusive (DeVoogd and Nottebohm, 1981; Nottebohm et al., 1981). Therefore, peripheral asymmetries in the vocal apparatus and more subtle central specializations underlie the lateralized effects of XIIts nerve section. More generally, the descending projections of the forebrain song nuclei are entirely ipsilateral, and in some species the projections from RA to the brainstem also are ipsilateral (Wild et al., 2000). This arrangement presumably enables distinct motor programs to be sent to the two sides of the syrinx.

3.23.5.3.3 Singing-related neural activity in the SMP

Chronic electrophysiological recordings made in singing birds have illuminated the neural dynamics underlying song. A pioneering effort by McCasland and Konishi showed that bursts of activity in HVC and RA occurred before and during the utterance of individual syllables; premotor activity also could be detected in the nucleus interface (NIf), a telencephalic structure presynaptic to HVC (McCasland and Konishi, 1981). A latency analysis supported the notion of a song motor hierarchy, with a feedforward flow of song motor activity propagating from NIf through HVC, RA, and the brainstem.

Although far ahead of its time, McCasland's study relied on multiunit recording methods, making it difficult to determine how song is encoded at different levels of the SMP. A series of elegant single-unit recording studies overcame this limitation, providing us with a detailed picture of how song motor codes change between HVC and RA (**Figure 7**). A particularly elegant study by Richard Hahnloser, Alex Kozhevnikov, and Michale Fee used a miniature motorized microdrive in the zebra finch to show that single HVC_{RA} neurons fire one brief (~10 ms) burst of action potentials at precisely the same time in each motif, with different HVC_{RA} neurons firing at different times during the motif (**Figures 7(a) and 7(c)**) (Hahnloser et al., 2002). Although only a relatively small number of neurons were sampled from any one bird, this finding implies that sparse activity propagates in a rapid (~100 Hz) clocklike fashion rapidly through the entire HVC_{RA} population, spanning the whole motif. Other groundbreaking studies by Albert Yu and Dan Margoliash, and by Anthony Leonardo and Michale Fee, found that single RA PNs burst at many (~10) precise times during a motif, in contrast to the temporally sparse firing patterns of individual HVC_{RA} neurons (**Figures 7(b) and 7(d)**) (Yu and Margoliash, 1996; Leonardo and Fee, 2005). Intriguingly, recordings made in sleeping birds show that HVC_{RA} and RA neurons generate spontaneous activity patterns similar to those they exhibit during singing (Dave and Margoliash, 2000), suggesting that the SMP 'replays' song motor programs during sleep.

3.23.5.3.4 Models of song patterning networks

The acoustic features of song span many timescales: milliseconds for internote intervals, tens to hundreds of milliseconds for notes and syllables, and one to tens of seconds for an entire song. Several circuit models have been put forth to account for patterning of notes, syllables, and songs. Aspects of all of these models find at least partial support in experimental observations.

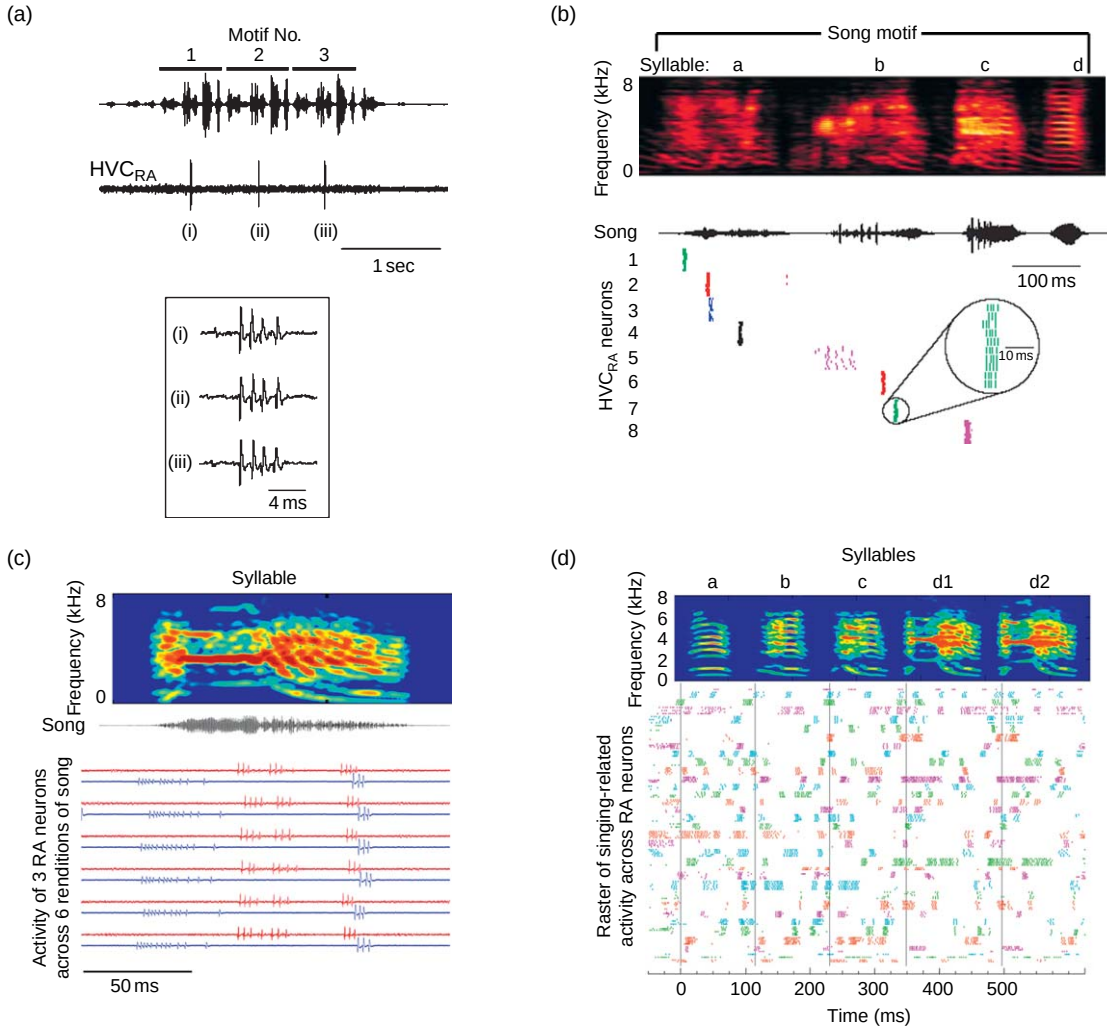


Figure 7 Chronic recordings of single-unit activity in singing zebra finch suggest that neuronal codes for song are transformed from an ultrasparse temporal representation in HVC to a more continuous representation in RA. (a) Individual HVC$_{RA}$ neurons fire a single brief burst of action potentials at one precise time in each motif (top, song oscillogram; bottom, simultaneously recorded neural activity; inset, expanded time base showing structure of the burst). (b) Different HVC$_{RA}$ neurons are active at different points in the motif, suggesting that the entire ensemble of HVC$_{RA}$ neurons provides a fine timescale representation of song (top, sonogram; middle, oscillogram; bottom, raster display of action potential activity for eight different color-coded HVC$_{RA}$ neurons over ten renditions of the motif). (a, b) Reprinted by permission from Macmillan Publishers Ltd: Hahnloser RH, Kozhevnikov AA, and Fee MS (2002) An ultra-sparse code underlies the generation of neural sequences in a songbird. *Nature* 419: 65–70, copyright 2002. (c) Singing-related activity in RA neurons is temporally precise over multiple renditions of the same syllable but is temporally more continuous than in HVC$_{RA}$ neurons (top, sonogram of the syllable; bottom, blue and red records show data aligned to the syllable acquired from different electrodes in RA). (d) Motif-aligned activity of 34 RA neurons recorded from the same bird (top, sonogram of the motif) reveals that each RA neuron exhibited multiple (~10) bursts of activity, the timing of which was similar across different renditions of the motif but generally different from the timing of burst activity in other RA neurons. Different neurons are represented by different colors, with different motif renditions represented by different rows of the raster display. (c, d) Reprinted from Leonardo A and Fee MS (2005) Ensemble coding of vocal control in birdsong. *J. Neurosci.* 25: 652–661.

In the music-box model, the entire HVC$_{RA}$ population can be likened to the programming cylinder in a music box, with the subset of HVC$_{RA}$ neurons active at any instant constituting an individual pin on this cylinder (**Figure 8**) (Fee et al., 2004). A pattern of divergent and convergent feedforward connections transforms temporally sparse activity from these HVC$_{RA}$ 'pins' into more continuous activity in RA,

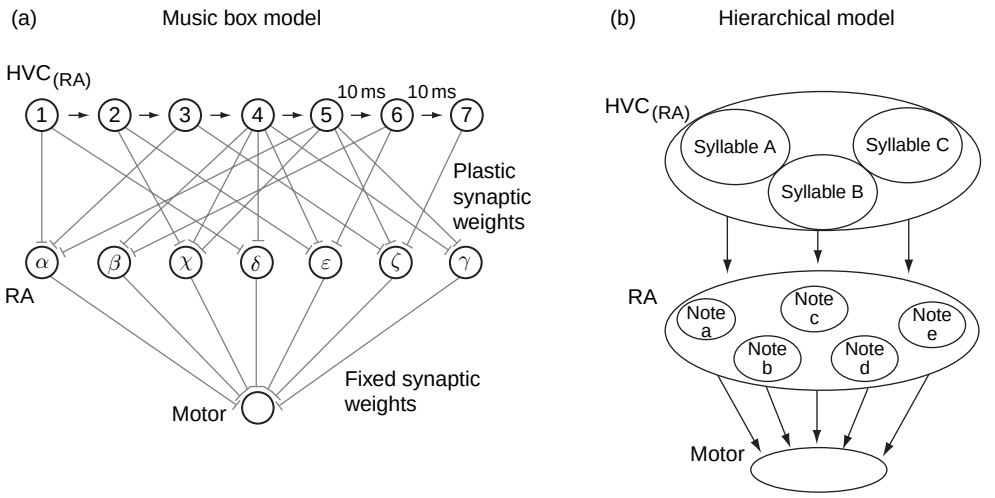

Figure 8 Schematic diagrams illustrating the music box (A) and hierarchical (B) models for song generation. (a) In the music-box model, each HVC_{RA} neuron is active at only one time in the song motif and activity propagates in 10-ms steps through the entire HVC_{RA} ensemble to span the entire motif. A pattern of divergent and convergent HVC / RA synapses translates this temporally sparse activity into a more continuous activity pattern in individual RA neurons, the output from which is transformed by the brainstem motor system into song. A central component of this model is that HVC encodes timing information about song but does not explicitly represent any acoustical features of the song, such as syllables or notes. Reprinted from Leonardo A and Fee MS (2005) Ensemble coding of vocal control in birdsong. *J. Neurosci.* 25: 652–661. (b) In the hierarchical model, HVC encodes large-scale song features, such as syllables. Neurons within RA code for finer-grain song features, such as individual notes.

which then modulates the vocal respiratory system to generate song. In its simplest form, the HVC_{RA} ensemble constitutes a relatively fast (~100 Hz) metronome that, via its synaptic connections with RA, dictates the timing of syllables, notes, and even intersyllable gaps. Interestingly, some HVC_{RA} and RA neurons do burst during silent periods between notes and syllables, suggesting that these song premotor nuclei could encode the timing of silent gaps as well as audible components in the song. Because song output in the music-box model is determined by the specific pattern of synapses HVC_{RA} neurons make in RA, error signals presumably act within RA to alter these connections during sensorimotor learning. In fact, modeling studies show that temporally sparse activity in HVC optimizes learning rates, because error signals that 'correct' the connections of an HVC_{RA} neuron only introduce changes at a single time in the motif (Fiete et al., 2004).

Another feedforward model involves a hierarchical patterning network, with syllables or motifs encoded in 'higher' areas, such as HVC, and lower-level features, such as notes, encoded in RA and the brainstem (**Figure 8**) (Yu and Margoliash, 1996). One early observation supportive of a hierarchy was that HVC microstimulation in the singing zebra finch could reset the entire motif, while RA stimulation only interrupted the ongoing note (Vu et al., 1994). Although consistent with a hierarchical model, electrical stimulation in HVC also activates areas presynaptic to HVC, such as NIf and the thalamic nucleus Uva, and thus any higher-level patterning mechanisms may not be localized to HVC. A recent comprehensive temporal analysis of zebra finch songs shows that, as the song tempo varies, syllables scale much less elastically than do intersyllable gaps (Glaze and Troyer, 2006), implying these features are regulated independently. These behavioral observations are consistent with a hierarchical model and contrast with the music-box model, where syllables and gaps should scale proportionally with variations to the overall song tempo.

In contrast with these two feedforward models, a third idea is that recurrent pathways from the brainstem modulate forebrain song patterning networks, establishing a distributed and possibly circular hierarchy. Indeed, a recent study showed that motif resetting could be triggered by microstimulation in HVC, RA, and even the RVG (Ashmore et al., 2005), a set of observations difficult to reconcile with the strictly feedforward architectures of the music box or hierarchical models. Instead, these results indicate that recurrent pathways from the brainstem to the forebrain likely contribute to song temporal

structure. An anatomical substrate for this recurrent pathway is provided by a subset of RVG axons that project bilaterally to the thalamic nucleus Uva, which in turn innervates HVC and NIf (Reinke and Wild, 1998a; Striedter and Vu, 1998). Because the RVG contains respiratory premotor neurons and receives descending input from RA, it may provide forebrain song nuclei with respiratory information and recurrent song-related motor activity important to setting the song temporal pattern, including the timing of syllable transitions. In addition, because songbirds lack a cerebral commissure, the bilateral projections from RVG to Uva are the most likely substrate for the precise bilateral coordination of song premotor activity seen in HVC. Notably, this recurrent model does not rule out a role for HVC in generating a fine timescale code for song patterning, but such a code would be under the influence of the recurrent loop.

Regardless of which model is most accurate, HVC displays network features that could serve an important role in song patterning. In an isolated HVC preparation, trains of electrical pulses evoke sustained trains of quasi-rhythmic synaptic potentials in HVC neurons (Solis and Perkel, 2005). Additionally, HVC PNs and inhibitory interneurons are reciprocally connected (Mooney and Prather, 2005), a synaptic motif known to sustain oscillatory activity in other pattern-generating networks (Selverston and Moulins, 1985). Whether endogenous pattern generation is unique to HVC is unclear, however, because complex local synaptic networks exist within RA (Spiro et al., 1999) and in the respiratory-vocal brainstem (Sturdy et al., 2003; Kubke et al., 2005) and may be capable of generating rhythmical activity independent of input from HVC.

3.23.5.4 The Role of the Anterior Forebrain Pathway in Song Plasticity

3.23.5.4.1 The AFP is a basal ganglia pathway necessary to song plasticity

The AFP forms intimate links with the SMP: area X is innervated by HVC, and the AFP output, nucleus LMAN, innervates RA (Nottebohm et al., 1976, 1982). Despite direct connections between the AFP and song premotor structures, initial behavioral studies showed that adult crystallized songs were unaffected by lesions to either area X or LMAN (Nottebohm et al., 1976; Bottjer et al., 1984; Sohrabji et al., 1990). A breakthrough came in 1984, when Sarah Bottjer and her coworkers discovered that bilateral LMAN lesions in juvenile zebra finches caused their plastic songs to degrade rapidly and become much less variable, assuming a highly repetitive and simplified form (Bottjer et al., 1984). A subsequent analysis of area X lesions made in juvenile birds showed that songs in these birds remained highly variable into adulthood, never achieving the stereotypy typical of crystallized song (Sohrabji et al., 1990; Scharff and Nottebohm, 1991).

These age-dependent effects of AFP lesions lent support to the idea that the AFP plays a developmentally restricted role in song learning. However, more recent findings show that the AFP also is necessary to adult forms of song plasticity. Rather remarkably, LMAN lesions block the song deterioration (i.e., decrystallization) normally triggered in adult zebra finches by deafening (**Figure 9**) (Brainard and Doupe, 2000) or by exposure to chronically distorted auditory feedback (Williams and Mehta, 1999). An important implication is that decrystallization is an active process requiring the AFP and not simply a degenerative process. The AFP also plays an ongoing role in adult song recrystallization; adult white-crowned sparrows subjected to LMAN lesions during the winter, prior to the annual reexpression of plastic song, failed to successfully recrystallize their songs (Benton et al., 1998). Finally, song learning in adult isolates also has been shown to be blocked by LMAN lesions (Morrison and Nottebohm, 1993), further underscoring that the AFP's role in song plasticity is not age limited.

The specific means by which the AFP contributes to song plasticity is of great interest. One way the AFP could enable song plasticity is by generating acute song variations that serve as 'stepping stones' for larger and more gradual changes to song. Over longer timescales, the AFP also might enable song plasticity by exerting trophic effects on synapses in the SMP. In either case, the AFP could play either a permissive or instructive role to enable song learning.

3.23.5.4.2 LMAN plays an acute role in generating song variability

Understanding the synaptic connections that LMAN makes with RA can inform how the AFP could influence song plasticity. Morphological and electrophysiological studies reveal that RA song premotor neurons receive convergent excitation from both HVC and LMAN axon terminals (Canady et al., 1988; Mooney and Konishi, 1991; Mooney, 1992). Both inputs excite ionotropic glutamate receptors on RA PN dendrites, but near the resting membrane potential, those from LMAN predominantly activate

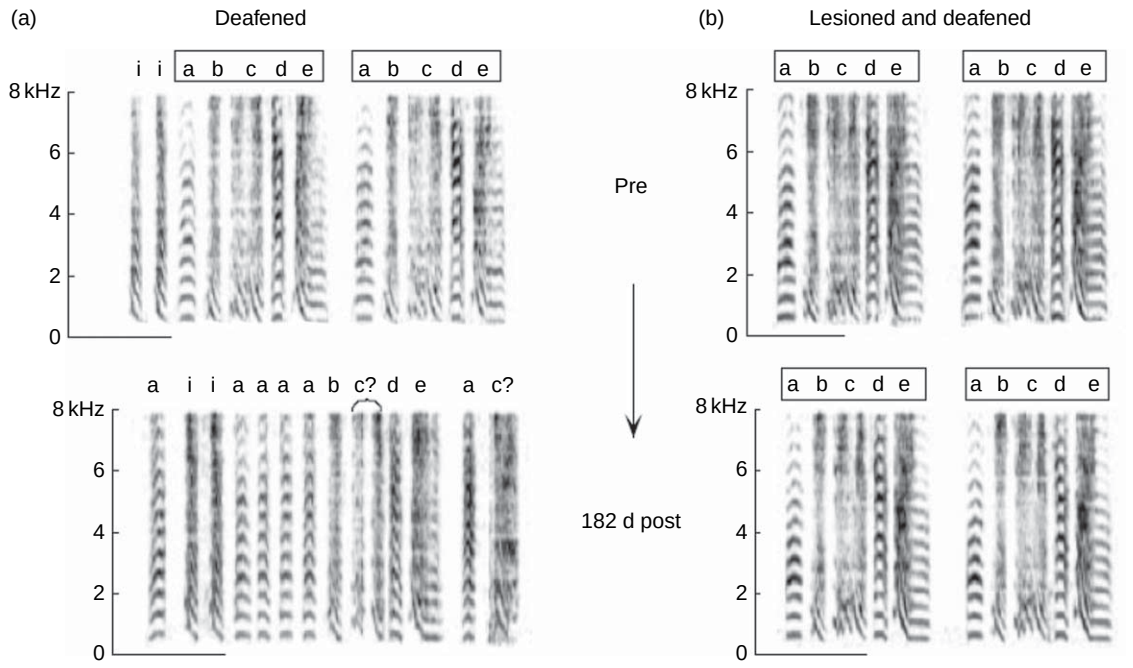

Figure 9 An intact AFP is necessary for deafening-induced song decrystallization in adult zebra finches. (a) Sonograms of an adult zebra finch before and 182 days after deafening reveal changes in the structure of the bird's song, including stuttered syllables ('a'), altered syllable morphology ('?'), and changes to the syllable sequences ('a–c –?'). (b) Bilateral lesions in LMAN made prior to adult deafening prevent changes to song structure. Reprinted by permission from Macmillan Publishers Ltd: Brainard M and Doupe A (2000) Interruption of a forebrain-basal ganglia circuit prevents plasticity of learned vocalizations. *Nature* 404: 762–766, copyright 2000.

postsynaptic *N*-methyl-D-aspartate (NMDA) receptors, while those from HVC predominantly activate alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors (Kubota and Saito, 1991; Mooney and Konishi, 1991; Mooney, 1992). Differential activation of NMDA and AMPA receptors in other pattern-generating networks leads to different output patterns (Dale and Roberts, 1984; Dye et al., 1989), suggesting that differential activation of LMAN and HVC inputs onto RA neurons could lead to song variability.

Indeed, several observations show that LMAN drives acute song variability. First, pharmacologically inactivating LMAN in juvenile zebra finches rapidly and reversibly reduces note and sequence variability in their plastic songs (Olveczky et al., 2005). Blocking NMDA receptors in RA exerts similar effects, underscoring that LMAN drives song variability via its synaptic connections with song premotor neurons (Olveczky et al., 2005). Second, microstimulation in LMAN can drive slight variations in song of adult zebra finches (Kao et al., 2005). Third, LMAN neurons are active during both directed and undirected singing in adult zebra finches, but during the more variable undirected singing, they burst at higher frequencies and in more variable patterns (Kao and Brainard, 2006). Finally, the acoustic variability of undirected songs is abolished by LMAN lesions (Kao and Brainard, 2006). Ultimately, these various findings indicate that in both the juvenile and the adult, LMAN operates over a short timescale (tens to hundreds of milliseconds) to drive song variability.

The details of AFP connectivity provide a useful context in which to interpret the effects of AFP lesions on song variability. The AFP bears strong similarities to mammalian cortical–basal ganglia pathways (Doupe et al., 2005), with HVC and LMAN providing the 'cortical' input and output and area X and the medial part of the dorsolateral thalamus (DLM) the interposed basal ganglia and thalamic 'relays.' The basal ganglia homologue area X comprises many different cell types, including a smaller GABAergic cell type (SN) that resembles mammalian striatal medium spiny neurons and a larger pallidal-like GABAergic cell type (AF) that makes massive inhibitory synapses onto DLM neurons (Luo and Perkel, 1999; Ding and Perkel, 2002; Farries and Perkel, 2002). These thalamic neurons make excitatory synapses onto LMAN neurons

(Livingston and Mooney, 1997; Boettiger and Doupe, 1998), which in turn form excitatory synapses on RA neurons (Mooney and Konishi, 1991). Because AF neurons fire spontaneously at high rates (Farries and Perkel, 2002), a reasonable assumption is that, at 'resting' levels, DLM neurons are tonically inhibited and LMAN activity remains low. Conversely, factors that suppress AF neuron firing would release DLM neurons from inhibition, ultimately rendering LMAN neurons more active (Person and Perkel, 2005). Indeed, this connectivity provides a useful context in which to understand the contrasting behavioral effects of LMAN and area X lesions: LMAN lesions abolish activity necessary to driving acute song variability, whereas lesions to area X remove tonic inhibition on DLM, increasing LMAN activity and generating higher levels of song variability. If this model is correct, then a key to understanding endogenous regulation of song variability will rest on determining how afferents to area X, which include HVC and midbrain dopamine neurons, influence AF neuron activity.

3.23.5.4.3 Trophic regulation of HVC–RA connectivity by LMAN

In addition to driving bout-to-bout variability, LMAN also could affect song plasticity by exerting trophic effects on RA. As seen more widely in the developing vertebrate central nervous system (CNS), synaptic density in RA describes an inverted 'U' over development, with numbers of HVC axon terminals and RA dendritic spines reaching a peak during the height of sensorimotor learning (Herrmann and Arnold, 1991; Kittelberger and Mooney, 1999). Both of these parameters decline markedly by crystallization, indicative of synapse elimination, while the remaining HVC > RA synapses increase in strength, suggestive of synapse consolidation (Herrmann and Arnold, 1991; Kittelberger and Mooney, 1999).

One idea is that, in the juvenile, LMAN actively maintains RA microcircuitry in a state permissive for song plasticity. Consistent with this idea, LMAN lesions trigger a rapid consolidation of HVC > RA synapses like the consolidation that occurs gradually over normal development (Kittelberger and Mooney, 1999). These experiments show that HVC > RA synapses in juvenile songbirds are highly plastic, and that LMAN plays a role in regulating this synaptic plasticity. These studies also suggest that a normal developmental decline in the number or efficacy of LMAN synapses in RA could consolidate HVC > RA synapses, leading to persistent changes in song. Candidates for mediating this trophic effect include the brain-derived neuronotrophic factor (BDNF), which is expressed in both LMAN and HVC_{RA} neurons (Johnson et al., 1997; Akutagawa and Konishi, 1998; Li et al., 2000), and which at earlier stages of development has been shown to rescue RA neurons from cell death triggered by LMAN lesions (Johnson et al., 1997). Consistent with the idea that BDNF acts as a permissive signal for song plasticity, BDNF injections into the RA of the adult zebra finch simultaneously elevate song variability and augment the density of HVC terminals in RA (Kittelberger and Mooney, 2005).

3.23.5.4.4 The AFP and critical periods for song plasticity

The means by which LMAN enables song plasticity also suggest mechanisms of song crystallization. One possibility is that crystallization arises as a result of decreased variability in LMAN firing patterns during singing. In support of this idea, the acoustic variability of undirected song and the variability of LMAN activity decline in parallel as adult zebra finches grow older (Kao and Brainard, 2006). Crystallization also could arise because the 'gain' of LMAN synaptic currents decreases in adults. In fact, LMAN > RA synaptic currents shorten in duration between juvenile and adult life (Stark and Perkel, 1999; White et al., 1999; Livingston et al., 2000), likely because of an elevation in the NR2A:NR2B subunit ratio of postsynaptic NMDA receptors (Scott et al., 2004). A shortening of LMAN > RA synaptic timecourse also can be precipitated rapidly in juvenile zebra finches by testosterone implants (White et al., 1999), a treatment that also impairs sensorimotor learning (Korsia and Bottjer, 1991). Moreover, the NR2A:NR2B subunit ratio in the RA of the adult canary waxes and wanes in parallel with changes in day length, testosterone titers, and song stereotypy (Singh et al., 2003). Thus, changes to the firing patterns of LMAN neurons and the efficacy of their synapses in RA could underlie the decline in song variability that occurs with song crystallization.

3.23.5.5 Auditory Roles of the Song System: Templates, Feedback, and Error Signals

3.23.5.5.1 General themes

The neural components underlying a template model of song learning include a motor pathway for song production, an auditory memory of the tutor song (i.e., a template), and a mechanism for comparing singing-related auditory feedback to the template (Konishi, 1965, 2004). When this 'comparator' detects

mismatches between the feedback signal and the template, it generates an error signal that modifies motor activity in the song production pathway, with the eventual result that the bird's song comes to resemble the tutor song. In addition to a song motor role, several lines of evidence suggest that the song system also may serve one or more auditory roles, including song recognition, template storage, conveying auditory feedback, or processing the resulting error signal. One piece of evidence is that auditory responses can be detected throughout the song system (Katz and Gurney, 1981; Margoliash, 1983; Williams and Nottebohm, 1985; Williams, 1989; Doupe and Konishi, 1991). Second, some song system neurons respond selectively to the bird's own song (BOS) and to the tutor song, indicating that they encode aspects of the bird's auditory experience (Margoliash, 1986; Solis and Doupe, 1999). Third, lesions to HVC or the AFP impair song recognition, suggesting auditory activity in the song system serves a perceptual role (Brenowitz, 1991; Scharff et al., 1998b; Burt et al., 2000). Finally, the presence of auditory activity in the AFP, a pathway necessary to song learning, raises the possibility that it conveys either feedback or the resulting error signal to the SMP (Doupe and Konishi, 1991; Brainard and Doupe, 2000).

3.23.5.5.2 *Auditory responses in the song system*

Intriguingly, the earliest chronic recordings of singing-related neural activity conducted in HVC also detected robust responses to auditory presentation (i.e., playback) of the BOS (McCasland and Konishi, 1981). Subsequent playback studies, mostly in anesthetized zebra finches, detected auditory responses throughout the AFP and the SMP, even in the hypoglossal nerve (Margoliash, 1983, 1986; Williams and Nottebohm, 1985; Doupe and Konishi, 1991). The source of this widespread auditory activity is HVC, which transmits auditory activity to the SMP and the AFP via its two populations of projection neurons (Doupe and Konishi, 1991; Vicario and Yohay, 1993; Mooney, 2000).

Song system neurons exhibit some of the most selective sensory responses yet described. Many HVC neurons are 'BOS selective,' firing vigorously to BOS playback but not to playback of conspecific songs or time-reversed BOS (**Figure 10**) (Margoliash,

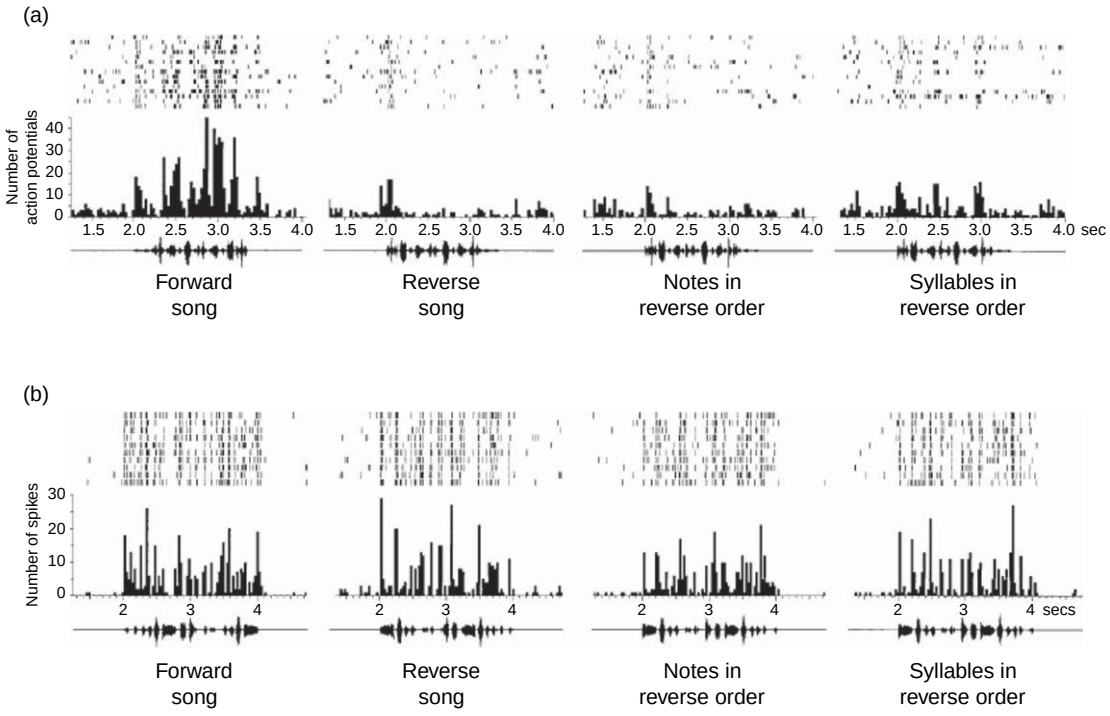

Figure 10 Auditory selectivity for the bird's own song (BOS) emerges between Field L and HVC. Each panel contains the raster of a single neuron's action potential response to the given auditory stimulus (top), the cumulative histogram of those responses (middle), and an oscillogram of the stimulus (bottom). (a) An HVC neuron responds strongly to playback of the BOS but weakly or not at all to temporally manipulated versions of the BOS. (b) In contrast, a Field L neuron responds strongly to playback of the BOS and to temporally manipulated versions of the BOS. Reprinted from Lewicki MS and Arthur BJ (1996) Hierarchical organization of auditory temporal context sensitivity. *J. Neurosci.* 16: 6987–6998.

1983, 1986; Doupe and Konishi, 1991; Volman, 1996). BOS-selective neurons are sensitive to temporal cues, as revealed by their selectivity for forward over reverse BOS, two stimuli with equivalent spectral content but contrasting temporal features. Some BOS-selective neurons also are sensitive to harmonic features of song (Margoliash and Fortune, 1992). Studies using synthetic songs have found that HVC neurons typically are more sensitive to degradation of temporal rather than spectral features, and that their temporal acuity is remarkable given HVC's distance from the auditory periphery (Theunissen and Doupe, 1998). Furthermore, a subset of HVC neurons responds exclusively to note-combinations in the BOS; studies where internote intervals were artificially manipulated show that these combination-sensitive neurons can integrate auditory information over hundreds of milliseconds (Margoliash, 1983; Lewicki and Konishi, 1995). Finally, in the swamp sparrow, a bird with multiple song types, different HVC neurons respond in an all-or-none fashion to different song types in the bird's repertoire (Mooney et al., 2001). From a functional standpoint, BOS-selective neurons are well suited for a feedback role, because they can respond differentially to slight variations in local (i.e., within-note) and global (i.e., note or syllable sequence) temporal structure of the BOS. BOS-selective neurons also could play an important communicative role by facilitating discrimination of the fine syntax variations that distinguish songs produced by conspecific birds from different breeding populations.

One clue that auditory activity in the song system actually plays a perceptual role is that lesions made either in HVC or in the AFP impair song recognition (Brenowitz, 1991; Scharff et al., 1998b; Burt et al., 2000). This perceptual deficit is perhaps most striking in female songbirds, which typically do not respond to playback of other species' (i.e., heterospecific) songs. However, following bilateral HVC lesions, females generate 'promiscuous' CSDs in response to heterospecific song playback (Brenowitz, 1991). In male songbirds, deficits in discrimination following lesions to the AFP are most pronounced for songs resembling the BOS, implicating BOS-selective neurons in perceptual processes (Scharff et al., 1998b). More generally, the mixed sensorimotor roles of HVC are strongly reminiscent of the mixed expressive and receptive roles in human speech served by language cortices in humans.

Another clue that auditory activity in the song system serves an important function is that it can be gated in a state-dependent fashion (Dave et al., 1998; Schmidt and Konishi, 1998). In the adult zebra finch, playback-evoked auditory responses in NIf, HVC, and RA are most robust when the bird is asleep or anesthetized and diminished and more variable (but not altogether absent) during wakefulness (Dave et al., 1998; Schmidt and Konishi, 1998; Cardin and Schmidt, 2003, 2004). One idea is that sleep–wake changes in auditory activity in the song system reflect the presence of an auditory 'gate' that operates more dynamically in the waking bird as a function of arousal or changes in attention or saliency. Although the function of auditory gating in the song system is unknown, one idea is that it prevents auditory signals from altering vocal activity in sensorimotor neurons (Williams, 1989; Konishi, 2004). Additionally, auditory gating in HVC also may vary in a species-dependent manner; in notable contrast to the zebra finch, robust auditory activity is present in the HVC of both canaries and swamp sparrows during periods of wakefulness (McCasland and Konishi, 1981; Prather et al., in revision). In contrast to male zebra finches, which are colonial animals that sing unidirectionally to females, male canaries and sparrows are solitary animals that rely on song to identify neighboring males and defend territory, behaviors that may necessitate a more active role for the song system in auditory perception.

3.23.5.5.3 Sources of auditory input to the song system

The mechanisms that generate BOS electivity must to some extent be influenced by auditory experience, because the BOS is a learned behavior. Thus, locating where BOS selectivity arises in the brain can point to sites that encode aspects of auditory experience, particularly singing-related auditory feedback. Notably, BOS selectivity is largely absent from Field L, the avian equivalent of the mammalian primary auditory cortex, and the indirect source of auditory input to HVC (**Figure 10**) (Lewicki and Arthur, 1996; Amin et al., 2004; Theunissen et al., 2004). Current evidence indicates that BOS selectivity arises in areas interposed between Field L and HVC (Theunissen et al., 2004; Theunissen and Shaevitz, 2006) and that HVC integrates both selective and nonselective inputs from a variety of sources in the forebrain (Cardin and Schmidt, 2004; Coleman and Mooney, 2004; Rosen and Mooney, 2006; R. Mooney, unpublished observations).

Anatomical and functional studies indicate that HVC receives auditory inputs from three other song nuclei – NIf, Uva, and mMAN – and from the secondary auditory telencephalic region CM (Vates et al., 1997; Cardin and Schmidt, 2004; Coleman and

Mooney, 2004; R. Mooney, unpublished observations). At the population level, NIf and mMAN neurons are BOS selective, whereas Uva neurons are nonselective (Vates et al., 1997; Coleman and Mooney, 2004; M. Coleman personal communication). Similar to HVC, these three song nuclei are sensorimotor structures, and thus selectivity in these areas may reflect aspects of motor as well as auditory experience. In contrast, CM is embedded in the auditory telencephalon and thus may constitute a 'pure' source of auditory information to the song system. CM is densely interconnected with primary and secondary regions of the auditory telencephalon, including Field L and NCM (Vates et al., 1996). At the population level, CM neurons are not BOS selective, although they respond more to conspecific songs than to synthetic sounds, and their sensitivity to conspecific songs is enhanced relative to Field L neurons (Grace et al., 2003; Theunissen et al., 2004; Theunissen and Shaevitz, 2006). An especially fascinating study in starlings showed that the response properties of CM neurons can be altered during auditory learning tasks (Gentner and Margoliash, 2003). Furthermore, some CM neurons are BOS selective, and robust auditory activity can be detected in CM during quiet wakefulness and singing (R. Mooney, unpublished observations). Thus, CM may convey auditory feedback to the song system and could weight this information as a function of the bird's auditory experience of its own song and the songs of other birds.

Although a response bias to the BOS is established at least as early as NIf and in some CM neurons, cells in both areas show elevated firing rate responses to a wide range of non-BOS stimuli (Coleman and Mooney, 2004; R. Mooney, unpublished observations). In contrast, note combination–sensitive HVC neurons appear to fire only to the BOS and to the songs of conspecific birds with similar note sequences (Margoliash, 1983; Lewicki and Konishi, 1995). This all-or-none selectivity arises in HVC through synaptic interactions between HVC's BOS-selective excitatory afferents (i.e., NIf and possibly CM) and BOS-selective inhibitory interneurons in HVC (Mooney, 2000; Rosen and Mooney, 2003, 2006). Specifically, excitatory and inhibitory inputs onto HVC_X neurons generate highly nonlinear responses to the BOS through both thresholding effects and priming mechanisms (Rosen and Mooney, 2003). Thus, auditory representations of the BOS are enhanced locally in HVC, and both HVC and areas immediately presynaptic to HVC are likely to encode aspects of auditory experience.

3.23.5.5.4 Does auditory activity in the song system encode the template?

In the context of a template model, one idea is that auditory activity in the song system encodes experience of the tutor song. In fact, studies in juvenile zebra finches found that blocking NMDA receptors in LMAN during tutoring sessions subsequently impaired copying (Basham et al., 1996). One potential confound is the close overlap between sensory acquisition and sensorimotor learning in zebra finches, which makes it difficult to rule out an effect of drug treatment on motor aspects of song learning. Another potential confound is a nonspecific impairment of attention or arousal, due perhaps to diffusion of the drug into brain regions surrounding LMAN.

A related idea is that auditory selectivity in the song system reflects experience of the tutor song. Nonetheless, several findings suggest that BOS selectivity reflects the bird's experience of its own song, rather than of its tutor. First, most HVC and AFP neurons in adult birds respond best to the BOS (Margoliash, 1986; Doupe and Konishi, 1991; Volman, 1996), whereas template neurons presumably would respond best to the tutor song. Second, juvenile zebra finches sequentially tutored by two different birds develop transient responses in LMAN to the first tutor's song and the bird's own imitation of this model, but these responses are lost or overwritten as the bird copies the second tutor (Yazaki-Sugiyama and Mooney, 2004). Thus, even when young birds demonstrate they have learned from a tutor, LMAN neurons do not permanently encode memories of these songs. Third, recordings made in HVC and the AFP of anesthetized juvenile songbirds reveal that song selectivity emerges only after the bird begins to sing; before this time, auditory responses in HVC and LMAN are typically weak and nonselective, despite experience of the tutor song sufficient to enable subsequent copying (Volman, 1993; Doupe, 1997). Moreover, in juvenile birds singing plastic song, most HVC and AFP neurons are BOS selective (Volman, 1993; Solis and Doupe, 1997), although many BOS-selective neurons also respond more strongly to the tutor song than to the songs of other conspecific birds (Solis and Doupe, 1997).

Neurons with 'dual selectivity' for the BOS and the tutor song could potentially encode tutor song experience, with the qualification that, when learning is successful, these two songs share acoustic features.

Thus, a potential caveat is that neurons in which selectivity was specified solely by the BOS might respond to these shared features, rather than encoding features unique to the tutor song. To investigate this possibility, Solis and Doupe unilaterally cut the syringeal nerve in juvenile zebra finches, spectrally distorting their songs and rendering them dissimilar from their tutors' songs based on several criteria (Solis and Doupe, 1999). Notably, most LMAN neurons in such 'dysphonic' juvenile birds developed strong selectivity for the distorted BOS, reinforcing the idea that the bird's experience of its own song is the primary factor influencing selectivity. Nonetheless, some neurons responded equally well to the distorted BOS and to the tutor song, raising the possibility that they encoded different BOS and tutor song features. However, the features in the distorted BOS and the tutor song that evoked responses were not characterized and were not necessarily those judged to be dissimilar in the two songs. Thus, it remains plausible that selectivity in LMAN is shaped by the bird's experience of its own song, and dual-selective neurons in 'dysphonic' birds respond to features common to the BOS and tutor song.

An important concern is that most studies of auditory selectivity in the song system have been conducted in anesthetized animals. Indeed, a recent study using chronic multiunit recordings in the awake juvenile zebra finch found evidence of mild selectivity for the tutor song in HVC (Nick and Konishi, 2005). Further studies are needed in freely behaving birds to confirm that auditory selectivity, as well as auditory responsiveness, may change in a state-dependent fashion. However, the present weight of evidence points away from the song system and the AFP in particular as sites where tutor song memories are stored.

These largely negative findings advance regions outside the song system as candidates for storing the song template (Bolhuis and Gahr, 2006). Foremost amongst these is NCM, which is reciprocally connected to CM and thus provides an indirect source of auditory input to the song system (Vates et al., 1996). Both IEG and electrophysiological studies show that auditory responses of NCM neurons habituate to repeated playback of the same song (Chew et al., 1995; Mello et al., 1995), consistent with NCM being a site of experience-dependent plasticity. A specific role for NCM in template storage is hinted at by the finding that tutor song playback can induce IEG expression in the adult zebra finch NCM, with expression levels correlating with how well the bird copied the tutor song (Bolhuis et al., 2000, 2001; Terpstra et al., 2004). Similarly, NCM neuronal firing rates in adult finches habituate more slowly to playback of tutor song than to novel songs, with the slowest habituation rates for those tutor songs copied most accurately (Phan et al., 2006). As with studies of auditory selectivity in the song system, one necessary caveat is that these closely copied tutor songs are acoustically similar to the BOS. Thus, more definitive experiments, perhaps using vocal nerve section to increase the acoustical 'distance' between the BOS and the tutor song, are needed to determine to what extent NCM neurons encode tutor song memories as opposed to self-experience.

3.23.5.5.5 Does the song system process auditory feedback and/or error signals?

Singing-related auditory feedback is essential to sensorimotor learning and, in certain songbirds, to adult song maintenance. One idea is that feedback is evaluated by a neural comparator, which generates an error signal when it detects mismatches between the feedback signal and the template. The error signal could either provide 'simple' reinforcement, acting in an all-or-none fashion to 'punish' vocal errors (or to 'reward' correct performances), or provide information about the direction and magnitude of the vocal error. In either case, the error signal would adaptively modify song during sensorimotor learning, but it also could drive maladaptive changes, as when deafening or delayed feedback triggers song decrystallization. Although feedback must be integrated by the brain in real time as the bird sings, questions remain as to the timescale over which the resultant error signal operates. In an online model, auditory feedback acts over a short timescale (perhaps within a single song or song bout) to generate the error signal. In an offline model, the error signal arises more slowly, driving changes in song only after a substantial delay of hours, days, or even weeks.

The AFP is an attractive site to look for both auditory feedback and error signals because it conveys BOS-selective auditory information and because it is necessary to song plasticity. Anthony Leonardo directly tested whether the AFP in adult zebra finches encoded feedback or error signals by measuring the singing-related activity of individual LMAN neurons in the presence and absence of delayed auditory feedback (DAF), a treatment that decrystallizes song gradually over several weeks (Leonardo and Konishi, 1999; Leonardo, 2004). Notably, the singing-related activity patterns of

individual LMAN neurons were unchanged by DAF, at least over the relatively short timescales at which single-unit isolation could be maintained (tens of minutes) (Leonardo, 2004). This finding reinforced an earlier study, also performed in adult zebra finches, which found that singing-related multiunit activity patterns in LMAN were unaltered immediately after deafening (Hessler and Doupe, 1999a). These results are difficult to reconcile with a feedback function for the AFP, and instead show that most or all of the singing-related activity in the AFP is song motor corollary discharge. Indeed, the local HVC circuit contains direct and indirect synaptic pathways from HVC_{RA} to HVC_X neurons, providing a robust substrate for relaying song premotor activity to the AFP (Mooney and Prather, 2005). These findings also suggest that LMAN does not transmit an acute error signal but, instead, either conveys an offline error signal or plays a permissive rather than instructive role in song learning.

One technical limitation to these studies is that neural activity was monitored over only short timescales, whereas DAF and deafening induce song plasticity in adults only after many weeks (Nordeen and Nordeen, 1992; Leonardo and Konishi, 1999). The slow onset of adult plasticity raises the possibility that the 'gain' of feedback and/or error signals decreases markedly in the adult. One hint that feedback may act slowly in the adult AFP comes from the finding that, following syringeal nerve section in adult zebra finches, selectivity in LMAN can shift to the spectrally distorted song over a 1- to 2-week period, prior to the onset of decrystallization (Roy and Mooney, in press). Another hint that the AFP may convey an error signal over longer times is that auditory responses of LMAN neurons were absent in adult zebra finches that sustained syringeal nerve section as juveniles (Solis and Doupe, 2000); such depression of sensory-evoked activity could be caused by the actions of an error signal arising from the chronic mismatch between auditory feedback and the memorized model.

Another potential concern is that most attempts to detect feedback or error signals have been undertaken in the adult, because the crystallized song provides a stable motor 'background' on which to detect these signals. Nevertheless, feedback and error signals are likely to be most robust in juveniles singing plastic songs. Especially relevant in this regard are chronic recording studies in juvenile zebra finches, which report that short-term exposure to DAF failed to perturb singing-related activity of HVC_X neurons (Kozhevnikov et al., 2006). Here an important consideration is that even in auditory-vocal specialists such as humans and bats, vocal modulation by auditory feedback is in some sense offline, arising only after a delay of 150 ms to several seconds following feedback perturbations (Schuller et al., 1975; Donath et al., 2002; Konishi, 2004). Thus examining activity patterns just during the motif may set too narrow a time window to detect feedback- or error signal–related signals.

Behavioral studies may highlight the best times during sensorimotor learning to search for error signals. In juvenile zebra finches, the most dynamic changes in song structure occur during the first few hours of the morning and overnight (Tchernichovski et al., 2001; Deregnaucourt et al., 2005). The rapid improvement in syllable matching seen each morning hints that online or fast offline processes adaptively modify song. Conversely, the nightly deterioration of the match between the BOS and the tutor song suggests that an offline error signal drives song deconsolidation during sleep. One plausible idea is that song deconsolidation is actively driven by a comparator that interprets bursting activity in HVC and RA during sleep as song motor activity lacking any sensory feedback (Dave and Margoliash, 2000; Deregnaucourt et al., 2005). The contrasting processes of daily improvement followed by nightly deconsolidation also underscore that song learning could involve multiple error signals, acting online as well as offline, rather than a single reinforcement or directional error signal acting entirely on- or offline.

3.23.6 Future Directions and Conclusions

Important insights into birdsong have been gleaned at many different levels, ranging from behavioral aspects of song learning to biomechanical and neural mechanisms of singing and song learning. Despite these important advances, some of the most basic and exciting questions remain to be answered, and comparative approaches remain vastly underexploited.

To date, the search for neural correlates of song has largely been a top-down affair. Consequently, we know much more about singing-related activity of neurons in HVC, RA, and LMAN than in the brainstem. It is unlikely that song motor codes can be fully deciphered without analyzing brainstem and

neuromuscular components of the song system in singing birds. Moreover, we still know remarkably little about coding strategies in the HVC and RA of species with larger and syntactically more variable repertoires than displayed by the zebra finch. To what extent is the sparse singing-related activity seen in the zebra finch HVC_{RA} neurons a general song-coding strategy, especially in species with large song repertoires? What are the mechanisms that generate variations in syntax that characterize songs of species other than the zebra finch? What are the mechanisms contributing to the remarkably sparse singing-related activity seen in HVC_{RA} neurons?

An especially important line of future research pertains to the synaptic basis of song learning. Notably, acute forms of synaptic plasticity have been detected in the AFP, and consolidation has been observed at HVC > RA synapses over development (Kittelberger and Mooney, 1999; Boettiger and Doupe, 2001; Ding and Perkel, 2004). Moreover, the architecture of the AFP suggests that RA is a major site of synaptic modification underlying song learning. However, whether classical forms of synaptic plasticity, such as LTP, contribute to song learning remains unknown, and the field is still in its infancy as far as relating synaptic and cellular mechanisms to the song behavior.

Arguably the most exciting questions in songbird research – the nature of the template, auditory feedback, and error signals – are still largely unanswered. The current body of largely negative evidence indicates that feedback or error signals arise in the song system of the adult only over a slow timescale or are mediated largely outside the song system. Nevertheless, concerns remain that we have not focused on the most appropriate species, employed the best methods for triggering an error signal, or concentrated on the right time during development. First, it may be useful to focus on those species, such as the Bengalese finch, that in adulthood depend acutely on auditory feedback to maintain their songs. Second, though DAF ultimately triggers song plasticity, initial exposure may not be detected by the bird as vocal error. Thus it may be useful to induce actual vocal errors, perhaps by stimulating the syringeal nerve during singing. Although technically challenging, more chronic recording studies are needed in juvenile birds learning to sing. The search for singing-related auditory feedback signals should be expanded to include those regions of auditory forebrain that ultimately provide auditory drive to the song system. Such a bottom-up approach may reveal the degree to which vocalization gates auditory activity in the auditory system, as has been seen in other vocalizing animals, and help establish the degree to which these auditory areas can register changes in feedback in an online fashion. Finally, the nightly process of song deconsolidation seen during sensorimotor learning and the evidence of song motor replay seen in sleeping birds have lent support to the idea that these sleep-related patterns of activity are necessary to song learning. Therefore, a future goal should be to directly test whether spontaneous bursting activity in the sleeping bird plays a role in song learning.

3.24 Emotional Learning: Animals

S. Maren, University of Michigan, Ann Arbor, MI, USA

3.24.1 Introduction

The capacity to learn and retain information, whether it is the sequence and rhythm of muscle movements required for a motor skill or the details of a traumatic emotional experience, imbues organisms with an enormous advantage for coping with an ever-changing world. How the brain forges memory from experience has been a question of considerable interest to psychologists and neuroscientists for decades. What has become clear in the last several decades is that memory representations are not monolithic and are therefore not wrought by a singular core of specialized brain tissue. Rather, multiple brain systems and regions participate in the encoding and storage of many different types of memories for skills, emotions, facts, and episodes, and so on.

The parsing of memory into different domains is probably best illustrated by the dissociation in memory systems apparent after brain lesions in people. In the 1960s, Milner described the most instructive and well-studied case of dissociable brain systems for memory in a man known by his initials as H.M. (Milner, 1962). Patient H.M. came to Milner's attention when he presented with severe amnesia, both for past events and newly experienced events, after he received a bilateral medial temporal lobe resection for intractable epilepsy. Despite his profound amnesia for episodes in his daily life, he exhibited apparently normal learning and memory for a variety of motor tasks, including mirror-tracing and rotary pursuit. The critical observation made by Milner was that H.M.'s memory deficit was selective for certain types of information. She necessarily concluded that there must be multiple memory systems in the brain. In particular, the medial temporal lobe the hippocampus, which was the major site of brain damage in H.M., was clearly critical for episodic memory, but not motor memory. Years of research have now confirmed this view and revealed dissociable neural systems underlying memory for emotional events, pleasurable rewards, skeletal motor responses, sensory percepts, and facts and episodes, to name but a few.

This implies that any single experience is always a hybrid of memorable events traced in different neural circuits in the brain. Consider the memory of a traumatic experience, such as an armed robbery by a masked man in a convenience store. The victim of
