To investigate this issue, Clayton and Dickinson (1999a) then gave the jays a second test trial (i.e., with no food actually present at recovery to test for memory), using an interleaved trial procedure shown in **Figure 2**. The jays were allowed to cache one food type on one side of a tray, while the other side of the tray was made inaccessible for caching by attaching a transparent strip of Plexiglas to cover all the caches sites on that side of the tray. The birds then got their trays back in the morning of the fifth day, prepared so that the birds

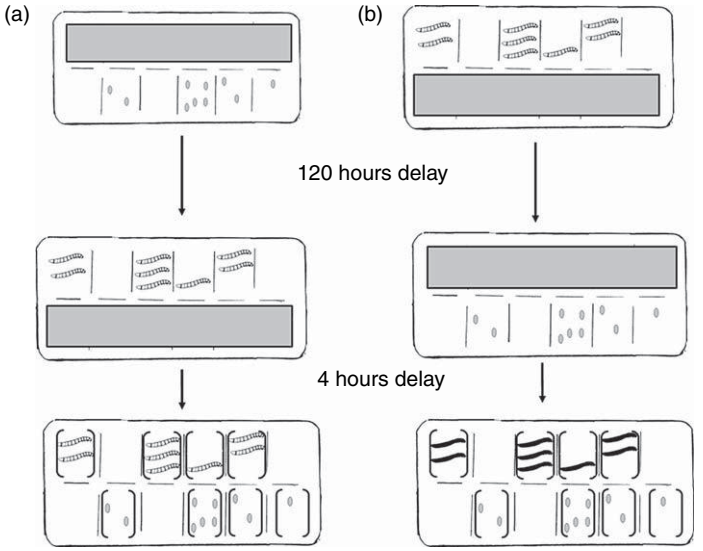

Figure 2 The food caching what-where-when memory paradigm used to test the content criterion of episodic-like memory by Western scrub-jays. Having received a series of training trials in which the birds could cache and recover peanuts and wax worms, the birds received an interleaved trials procedure in which they cached peanuts in one side of a caching tray and then wax worms in the other side of the tray 120 h later (a) or vice versa (b). On test, 4 h later, they then were given the opportunity to search in both sides of the tray. The brackets indicate the fact that the food caches were not present at recovery in order to test for memory. The open symbols represent fresh wax worms, the black symbols illustrate rotten wax worms, and the grey filled circles denote peanuts. The grey bar indicates the side of the tray that was blocked by a Plexiglas strip (the unavailable cache site) during each of the two caching events.

could cache the second food type in the previously inaccessible side of the very same tray, and they were prevented from recovering the previous caches by our attaching the Plexiglas strip to the other side of the caching tray. In the afternoon of this day 5, the jays were allowed to search in both sides of the tray. What is important here is that the interleaved procedure removes the differential relative familiarity of the tray because the temporal pattern of exposures to the tray was the same irrespective of whether or not the worms had been cached first, 124 h ago, or second, just 4 h ago. And since the caches were not present at recovery, the birds would have to rely on their memory of the previous caching episodes in order to search appropriately.

This they did: the jays spontaneously searched for the worms they had cached 4 h earlier, whereas on the trial in which they had cached the worms 5 days ago they ignored searching in the worm sites and instead searched for peanuts. This pattern of recovery searches suggests that the birds were not using tray familiarity as a cue but, rather, that they were remembering specific past caching episodes in terms of where they had hidden the peanuts and worms, and how long ago. Subsequent work established that the jays could also keep track of two perishable foods that decayed at different rates (Clayton et al., 2001b).

Several authors have argued that, as the jays had received a number of training trials in which they could cache and recover the various food items, they may have learned to solve the task by learning semantic factual rules about when to recover the particular foods rather than episodically recalling which foods had been cached where and how long ago (e.g., Zentall et al., 2001; Dere et al., 2005; Hampton et al., 2005). However, such claims misunderstand the theoretical interpretations of the role of semantic and episodic-like memory in the control of caching. Clayton and colleagues have argued that, to search in a particular tray for the perishable caches only when fresh and not when degraded, the birds must integrate a semantic-like rule about how long each food type remains fresh with a specific episodic-like memory of which caches they hid where in a given tray on a specific day (Clayton et al., 2003b).

1.23.3.1.2 Evidence of what-where-and-when memories in other animals

There have been a number of attempts to assess the content criterion of episodic-like memory in other animals (*See* Chapter 1.22). For example, Hampton and colleagues (Hampton et al., 2005) adopted our scrub-jay paradigm to test what rhesus monkeys

remember about specific foraging events. The test room contained three foraging sites, two baited and one unbaited, and what the monkeys had to learn was that all food was fresh after 1 h, but their preferred food was rotten after 25 h, while the less-preferred food remained fresh. The monkeys rapidly learned to search first for their preferred food, and to avoid the empty foraging location. However, although rhesus monkeys rejected the rotten food much like the jays did, they did not reverse their search patterns after the long delay, but instead they revisited those locations that contained their preferred food irrespective of the length of the delay. Like the jays, the monkeys remembered the what-and-where of trial-unique events; however, unlike the jays, there was no evidence that they encoded temporal information.

Perhaps the foraging paradigm might be less suitable for testing episodic-like memory in rhesus monkeys, given that they do not naturally cache perishable and nonperishable foods, although they do have specialized cheek-pouches that allow them to hoard food and eat it later in safe surroundings. But certainly their survival does not depend on them caching food for later, and their feeding ecology does not require them to keep track of decay rates, as they are primarily herbivorous (Hampton et al., 2005). Given the complexity of their social lives (e.g., Humphrey, 1976; Tomasello and Call, 1997; Whiten and Byrne, 1997), however, tests of episodic-like memory in primates that involve a social component, such as who was present in a particular social setting, may be more salient.

Roberts and colleagues found no evidence that rats could remember when they had cached various food types (Bird et al., 2003; McKenzie et al., 2005). However, most species of rat do not store much food in the wild (Vander Wall, 1990), and like primates, but unlike the jays, they do not rely on their caches for survival (Vander Wall, 1990). When viewed in this light, perhaps it is not so surprising that the rats behaved like the monkeys rather than like the jays, preferentially searching at recovery in those locations in which they had hidden food more often than other locations that had not been associated with food. Yet there was no evidence that they encoded the 'when,' because they did so even when items repeatedly degraded or were pilfered before recovery (Bird et al., 2003; McKenzie et al., 2005).

By contrast, recent work by Babb and Crystal (2005) did provide some evidence that rats could remember the what-where-and-when of specific past events. Instead of hoarding the food items themselves, the rats were trained to remember where they had previously encountered food that they could subsequently recover after either 1 h (the short RI) or after 25 h (the long RI). As shown in **Figure 3**, using a

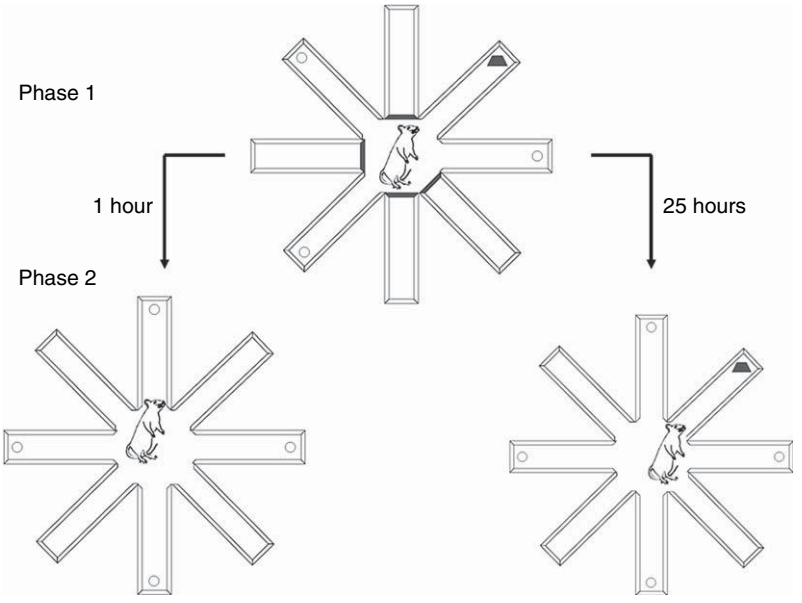

Figure 3 The what-where-when memory paradigm used to test rodents in a radial arm maze. In phase 1 the rats were given the opportunity to explore four of eight arms, three of which contain rat pellets, and one of which contains chocolate. During phase 2, the rats were allowed to explore all eight arms. The delay between phase 1 and phase 2 was either 1 h or 25 h, and rats received training with both the short and the long delay. The black bars show entrances that were inaccessible during phase 1; open circles represent rat pellets, and solid symbols denote chocolate pieces.

standard eight-arm radial maze, the rats were allowed to search during phase 1 for food located at the ends of four arms of the maze (the other four arms were blocked): three of them with regular pellets and one with highly preferred chocolate pellets. During phase 2, the rats were returned to the maze with all eight arms accessible, and the four previously inaccessible arms were baited with regular pellets. In addition the chocolate pellets were replenished if the rats were returned to the maze after a long delay, but not after a short RI. If the rats remembered which arms they had visited and eaten food from in phase 1, then they should selectively search in the previously inaccessible arms, because these are the ones that still contain food. If they also remembered which foods were available where and how long ago they had visited the maze in phase 1 then they should prefer to visit the arm containing the chocolate pellets after the long RI, but avoid that arm after the short RI.

Babb and Crystal found that the rats did learn to avoid the previously baited arms and to revisit the chocolate arm after a long RI only, demonstrating that rats could use the length of the retention interval as a cue to guide their choice of where to search, a finding that has also been replicated by Roberts' group (Naqshbandi et al., 2007). In both studies, however, the issue is whether the rats also remembered the specific contents of the encountered food. Although the rats may have remembered that a particular arm they had visited during phase 1 specifically contained chocolate, it is also possible that they simply encoded that the arm contained something more preferred than rat chow as opposed to encoding the precise type of food. Actually Clayton and Dickinson (1999b) already made a similar argument in the case of the jays' memories for what they had cached where. To establish that the jays did remember the content of their caches, the jays were given the opportunity to cache two equally preferred foods, and then just prior to recovery they were fed one of the two foods until sated. The jays searched preferentially for the non-prefed food at recovery, even on test trials in which no food items were present during recovery, thereby demonstrating that the jays did remember which particular foods they had cached where.

Babb and Crystal (2006b) addressed this question in an elegant satiation study. In phase 1, rats found three arms baited with regular food, and two of the other arms were each baited with a particular flavored food (grape, raspberry), both of which were equally preferred over regular pellets and both replenished after the long, but not short, RI. The rats were more likely to revisit the flavored arms and avoid the other previously baited arms after the long delay, just as they had done in the previous study. However, when the rats were sated on one flavor shortly before phase 2, the rats avoided that arm but revisited the arm containing the other flavored food, suggesting that they remembered not only which arms contained preferred food but that they also recalled the specific food contents of these arms. A transfer experiment using banana chips and chocolate, the latter devaluated by pairing it with a lithium chloride injection after phase 1, produced the same results.

Crystal (2006) argued that these experiments provide evidence of episodic-like memory in rats. Only by remembering what happened where and when could the rats return reliably to the replenishing chocolate arm after the long interval, but avoid this arm when the chocolate was devalued. However, this experiment does not control for relative familiarity. It is not clear whether the rats really remembered when to visit the chocolate arm or whether the rats could have solved the task by learning a rule that it is only when the arm appears to be relatively unfamiliar that the rats should search for the chocolate, or grape, or raspberry. As the lithium chloride treatment may have caused a general aversion to chocolate, the rats had to return only to the previously blocked arm, and since that arm had not been visited during phase 1, it may have been less familiar to the rat than the arms that had been visited in phase 1.

The results of the satiation study, although more convincing, can still be explained in terms of familiarity. Although rats do not use time of day or state of hunger as cues guiding their behavior (Babb and Crystal, 2006a), the relative familiarity of the maze itself could function as a cue to avoid or to revisit arms with preferred food in just the same way as we argued for the jays and their trays in the first experiment, namely that when the maze cues are highly familiar, then avoid all familiar arms, and when the maze cues are much less familiar, then revisit the arm containing the preferred food. Clearly what is needed to discriminate between these two possibilities is an interleaved trial procedure of the kind described for the jays in **Figure 2**.

Eichenbaum and colleagues used a different approach when developing their rodent model of episodic-like memory, with a focus on resolving the recollection versus familiarity dispute (*See* Chapter 1.21 for detailed discussion). Their sequence learning paradigm is based on the assumption that humans

may infer the sequence of events by their relative times of occurrence (Roberts, 2002), because "one event precedes, co-occurs, or succeeds another in time" (Tulving, 1983: 38). For example, Ergorul and Eichenbaum (2004) trained their rats to learn unique sequences of four odors in terms of which odors the rats encountered where and in what order ('when'). On test, two of the four odors were presented, and the rats were reinforced for choosing the location of the cup containing the odor that had occurred earlier in the sequence. This they did. However, when the rats were given a probe test, in which the cups that had previously contained the odors were placed in the correct locations but the odors had been removed so that they did not provide scent cues, then the rats failed to make the correct choice. Consequently, the rats may have solved this task by remembering which odors they had encountered earliest in the sequence without any recourse to remembering where.

A similar rational was adopted by Schwartz and Evans (2001), who tested the 31-year-old gorilla, King, for his ability to remember a temporal sequence of specific past feeding events. Specifically, they argued that "the animal's response should provide information about its past rather than about the current state of knowledge" (Schwartz et al., 2005: 231). King received three types of food in succession, each 5 min after finishing eating the former one. On test, a few minutes later, the experimenter asked King what he had eaten and in what order. Although King was able to answer correctly, he itemized the food in reversed order only, from the most familiar to the least familiar item. Consequently, his performance could be explained in terms of relative familiarity rather than episodic-like recall.

To summarize this section, attempts to establish models of episodic-like memory in nonhuman animals other than Western scrub-jays suggest that the 'when' component is by far the most challenging feature. In some studies, the animals failed to show any sensitivity to the temporal relationships between events (Bird et al., 2003; Hampton et al., 2005). Of course, the absence of evidence is not evidence of absence, and the fact that rats do appear to remember what happened where and how long ago when tested for the memory of food they have seen previously (Babb and Crystal, 2005, 2006b; Naqushbandi et al., 2007), but have not cached previously (Bird et al., 2003), suggests that the ecological salience of the task may be critical. One advantage of the caching paradigm when employed with Western scrub-jays is that it taps into this particular species' natural propensity – if not obsession – to cache and efficiently recover perishable as well as nonperishable food. That said, an outstanding issue in the rodent memory models is whether the animals may have solved these tasks using relative familiarity or rule learning after intensive training instead of episodic recall (Schwartz and Evans, 2001; Babb and Crystal, 2005, 2006a), and the extent to which an animal's ability to remember and discriminate between sequences (e.g., Schwartz and Evans, 2001; Agster et al., 2002; Ergorul and Eichenbaum, 2004; *see also* Chapter 1.21) depends on episodic-like recall.

1.23.3.1.3 Challenging the "when" component

Other researchers have questioned whether the encoding of the 'when' component is central to the concept of episodic-like memory, or whether in fact it is the context in which the event occurred that is critical. Although human memories are usually rich and detailed in some aspects, the quality of the temporal information may be rather poor (e.g., Friedman, 1993, 2001; Simpson et al., 1998; Eacott and Norman, 2004). This does not remove our own sense of the pastness of a memory, however, just as Proust was fully aware of the concurrence of his present and the mentally relived past. Furthermore, most humans have seemingly little difficulty in discriminating between memories that have the same 'what' and 'where' contents but different 'when' components. For example, most of us find it easy to differentiate between memories of two different meals with the same friend. In this case the 'when' component may simply be a temporal form of the occasion setting 'which,' and we distinguish between our memories of the two events by binding each episode to the different contexts provided by the two restaurants. Eacott and Norman (2004) therefore suggested that the behavioral criteria for episodic-like memory should not be restricted to what-where-and-when but should also include what-where-and-which, with the 'which' component functioning as the occasion-specific context (see also Kart-Teke et al., 2006).

The what-where-and-which concept of episodic memory has been exploited by capitalizing on the rodent's propensity to seek out novelty (e.g., Eacott and Norman, 2004; Dere et al., 2005; Norman and Eacott, 2005; Kart-Teke et al., 2006). The most convincing example is that conducted by Eacott and her colleagues (2005), because they were able to control for relative familiarity. To do so, they built a maze in the shape of an E so that they could place two different novel objects at the two outside ends of

the E-maze, out of sight of the rats at their starting point, as shown in **Figure 4**. The rats were given the opportunity to explore the two different objects in one specific context before being allowed to investigate them again in a different configuration in a second context that was texturally different from the first (plain grey and smooth to the touch versus wire mesh). Following this episode, the rats were exposed to one of the objects outside the two contexts until they had become habituated to it, an experience that enhanced their propensity to explore the other object when returned to one of the two E-maze contexts. A rat could only do so, however, if it had remembered where the objects were located in the E-maze in a particular context during the initial episode. Their rats' success at this task led Eacott and colleagues to argue that the rats recollected the object (what) and its location (where) in a particular context (which) on the basis of unique what-where-and-which memories. Note that, because the objects were out of sight at the starting point, the rat's choice to turn right or left could not have been based on relative familiarity of the object.

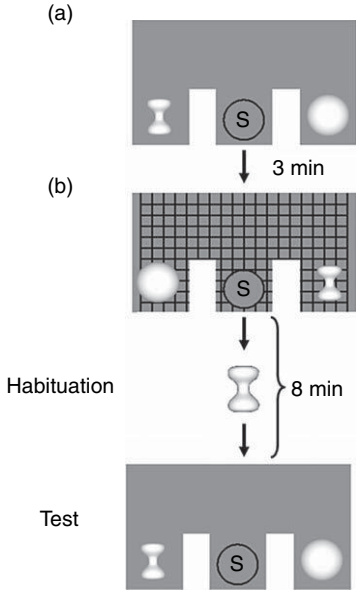

Figure 4 The what-where-which paradigm used to test rodents in the E-maze. The rats explored two different objects placed in a certain spatial configuration in a particular context (a), before investigating them again in a different configuration in a second context (b). Following this episode, the rats were exposed to one of the objects in a different place until they were habituated. On test they were placed back in either context (a) or (b), but the objects were not visible from the starting point (S) in order to test for memory.

1.23.3.1.4 Differential forgetting or remembrance of times past?

Although we have argued strongly for the importance of the 'when' component of an episodic-like memory, several researchers have suggested that demonstrations of an animal's ability to remember the what-where-and-when of a specific past event may not be sufficient to claim that the animal is capable of episodic recall. In the case of our jays, it is argued that, instead of traveling back in time, the birds might have used the strengths or ages of memory traces in order to know when to search for the food items at particular locations.

There are two ways in which a jay could use the strength or vividness of the memory trace to date its memory of a particular caching event: spontaneous forgetting and directed forgetting (for detailed discussion see de Kort et al., 2005). Consider the case of the jays that learned that if there was a short delay between caching and recovery then their worms would still be fresh at the time of recovery, whereas if a long interval had elapsed between caching and recovery then the worms would have degraded. In terms of spontaneous forgetting, the bird might simply forget the location of degraded worms because the event happened a relatively long time ago. Alternatively, rather than having an all-or-none response (remember–forget), the bird might use forgetting, just like familiarity, as a conditional cue to control its pattern of searches at recovery. The birds learn to search for the worms when they recall a vivid memory of the caching episode, whereas they learn to avoid attempting to recover the worms when they recall a less vivid or partially forgotten memory. Staddon and Higa (1999) have recently proposed an account of interval timing based upon conditional control by the strength of the memory for a time marker.

If the jays use vividness to date the caching episode, we should expect the birds to show some evidence of forgetting for other aspects of the content of the memory, specifically the location and types of caches, at longer delays. Even if the worms did not degrade with time since caching, the time-dependent forgetting of the memory representation should be accompanied by a loss in accuracy for locating the different caches of food. To assess this possibility, Clayton and colleagues (Clayton and Dickinson, 1998, 1999a; Clayton et al., 2001b) tested the cache recovery behavior of a second group of jays, whose potentially perishable caches did not in fact degrade. These birds showed no loss in accuracy of locating the food caches at the retention

intervals for which the putative forgetting should have been controlling the recovery choice of the birds whose caches did degrade. Furthermore, the jays were just as accurate at locating caches after 5 days as they were after 4 h (Clayton and Dickinson, 1999b), even though we should have to assume that the strength of the cache memory after 5 days was significantly weaker than after 4 h if this strength difference is to control a complete reversal in recovery patterns. Consequently we think that it is unlikely that the jays' temporal control of caching was mediated by memory decay.

Although spontaneous forgetting is unlikely to account for the behavior of the jays, perhaps directed forgetting (Roper and Zentall, 1993) may be more plausible. Consider, once again, the case in which jays cache and recover worms and peanuts after a short and a long delay. As the peanuts never perish, the jays always recover fresh peanuts. However, this is not the case for their worm caches, which are found to be degraded at recovery on half of the trials (i.e., those in which recovery occurs after a long delay). According to the directed forgetting account, experience with unpalatable worms on half of the recovery trials causes the jays to forget the location of these caches more rapidly. For example, perhaps having experienced degraded, unpalatable worms at recovery, the jays subsequently devote less processing of the location of these caches on subsequent caching episodes, which in turn leads to more rapid forgetting of those caches.

A test of this hypothesis would be to establish whether the jays could learn the opposite profile for when worms are edible, namely one in which worms ripen rather than degrade over time (de Kort et al., 2005). To do so the jays received a series of trials in which they could cache peanuts and worms as before, but this time the worms were degraded after the short delay but were fresh after the long delay. de Kort and colleagues found that the jays rapidly learned to avoid searching for worms after the short retention interval, while preferentially searching for them after the long one. The fact that jays' performance could not be explained by either spontaneous or directed forgetting strongly suggests that jays encode time specifically within their episodic-like memory of events (de Kort et al., 2005).

As explained in the first section, we can never ascertain whether or not an animal is aware of the past while retrieving a memory. All we know is that animals can discriminate among events which occurred at different times in the past. One way to tackle this issue would be to devise an experiment in which the animal is given the opportunity to report that it knows whether or not it has remembered using an uncertainty monitoring paradigm (Smith, 2005), just as Hampton (2001) did when testing whether his rhesus monkeys knew what they had and had not remembered.

1.23.3.2 The Structural Criterion of Episodic-Like Memories: An Integrated Representation

In humans, the content of an episodic memory is usually a rich representation of what happened, where, and when. Imagine the moment when handing over a carefully chosen present to a special person. We not only remember where and when we bought this present, and of course what we have chosen, but we may spontaneously remember a number of other details about the event, such as whether it was a rainy or a sunny day, and whether the shop was overcrowded or completely empty, and some of us might remember other seemingly trivial details such as what shoes we were wearing.

One of the cardinal features of human episodic memory is that, when we come to recall the event to mind, we retrieve all these components together as a gestalt image. This reflects the structure of episodic memory, namely that the 'what,' 'where,' and 'when' components are not encoded separately but are bound together in an integrated representation, and consequently the retrieval of one component elicits the retrieval of the others. Contrast this integrated representation with a linear one in which the components are not directly linked. If we were to remember the episode as a series of separate components, then we would not be able to distinguish between episodes that have similar contents and locations but different temporal contexts, such as family Christmas dinners that occurred in different years. It is this feature that led Clayton et al. (2003a) to argue that the criterion of remembering what-where-and-when is not, by itself, sufficient to characterize a memory as episodic-like if, by this term, we mean that the memory has the behavioral properties of human episodic memory.

To illustrate this point, let us consider another food-caching scrub-jay scenario in which the birds cache the same foods in two trays at different times. The design is illustrated in **Figure 5**. Briefly, the trained jays were allowed to cache peanuts and worms in one tray on one day, and then at a later time they cache the same food types in a second tray, after which the jays are allowed to recover from both

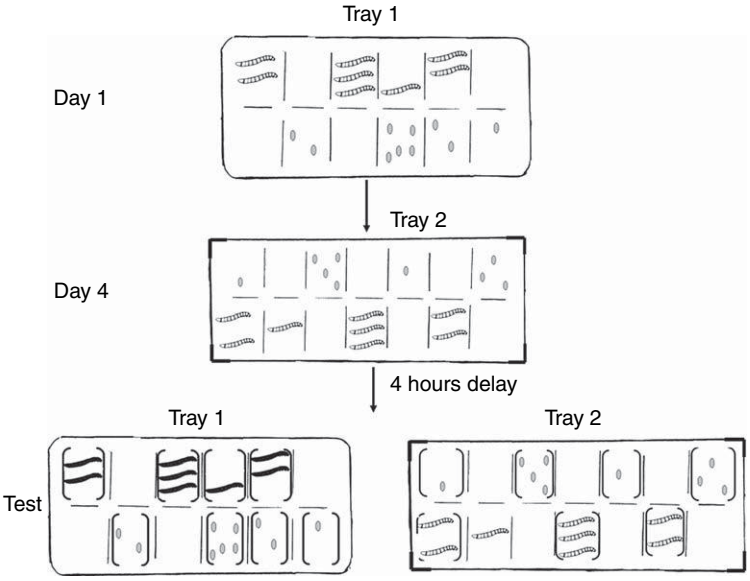

Figure 5 The food caching what-where-when memory paradigm used to test the structure criterion of episodic-like memory by Western scrub-jays. The jays cached peanuts and wax worms in one caching tray on day 1, and then again in a second tray on day 4. On test, 4 h later, the jays were given the opportunity to search in both trays. The brackets indicate the fact that the food caches were not present at recovery in order to test for memory. The open worms represent fresh wax worm caches, the black worm symbols denote rotten wax worm caches, and the grey filled circles illustrate peanut caches.

trays. The retention intervals are such that the worms will be decayed in the first tray while still being fresh in the second tray, and the critical question is whether the jays show the appropriate search pattern for each of the two trays.

If the birds retrieved the 'when' component separately, they could not have distinguished between the caching episodes because, by that account, the jays would simply associate caching the worms with a temporal tag, and the memory of caching worms at recovery would retrieve temporal tags for both the long and short RIs. In short, a linear mnemonic structure does not support the appropriate recovery pattern, namely searching for peanuts in the first tray and worms in the second tray. However, the jays do in fact search appropriately (Clayton et al., 2001b), a result that suggests that they do form integrated memories, because they can distinguish in memory between the two caching episodes in terms of their time and location, even though they involved the same food items.

Clayton and colleagues interpreted this finding as evidence that the jays' behavior met what they called the *structural* criterion for episodic-like memory (Clayton et al., 2003a,b). Not only must a memory have the what-where-when representational *content* to be episodic-like, but that content must be bound in a form that yields a unique memory for each caching episode. It is this representational binding that allows the jays, like humans, to discriminate between similar episodes that occurred at different times and possibly different places.

What of other animals? So far, the only other study to test the structural criterion of episodic-like memory is that by Shettleworth and colleagues (Skov-Rackett et al., 2006). In a series of delayed matching to sample tasks on a touch screen, they tested their pigeons' memory of all three features independently: on some trials they had to select the correct 'what' in terms of an object's identity, on other trials they had to select the correct 'where' in terms of an item's location on the screen, and on yet other trials they were tested for their memory of 'when' in terms of the time intervals passed since presentation of items. The pigeons performed well above chance on all three types of trials, which suggests that the pigeons could encode all three features during a single presentation. However, further tests established that the pigeons' memories were stored independently in a linear rather than in an integrated structure. It remains to be seen whether the rodent what-where-when and even what-where-which memories possess an integrated structure like those of jays and humans, or whether they are linear, like those of pigeons.

Further evidence for the integrated structure of scrub-jay episodic-like memories comes from studies of the social context of caching (reviewed by Clayton et al., 2007). These birds readily steal one another's caches (e.g., Clayton and Emery, 2004) and go to great lengths to protect their own caches from being stolen by another bird, hiding them behind barriers (e.g., Dally et al., 2005) and moving those caches another individual has seen them make once that other individual has left the scene (Emery and Clayton, 2001). Of particular relevance to the issue of integrated memories is the finding that these jays recognize particular individuals and remember which particular individual was watching them cache during specific past caching episodes and take protective action accordingly (Dally et al., 2006). It is this integrated structure of their episodic-like memories that allows them to discriminate between caching episodes that differed only in terms of who was watching when.

The only other published study that tested an animal's episodic-like memory with a 'who' component was conducted on the gorilla King (Schwartz et al., 2002), who was trained to associate five food types and their respective English words with five wooden cards carrying a picture of each food in question. In addition, he was trained to associate each of two human trainers who were present during the trials with a card carrying the name of that person. To test King's episodic-like social memory, the "to-be-remembered trainer" handed the gorilla one piece of food through the bars of the cage, while the second trainer was present but did not do anything. On test, either about 10 min later or on the next day, King received five cards for the various food types plus the two cards for the two trainers. In response to the questions "What did you eat?" and "Who gave you the food?" King was expected to hand over the card that corresponded to the food he had eaten and the card with the name of the trainer who had given him the food, which he did for the most part accurately (see also Schwartz et al., 2004). However, the issue remains as to whether King episodically recalled the specific past event or whether King's performance could have been based on relative familiarity, given that he simply needed to select the cards that matched the stimuli he had encountered most recently (for detailed discussion see Schwartz, 2005; Schwartz et al., 2005).

To summarize this section, we have argued in order to demonstrate episodic-like memory in an animal requires not only evidence that the animal remember the what-where-and-when of a specific past event, and in a way that cannot be explained by relative familiarity, but that the structure of this memory requires an integrated representation. To our knowledge, so far only the jay studies provide evidence for all features. Even less well studied than the structural criterion is the third key feature of episodic-like memory – its flexibility.

1.23.3.3 The Flexibility Criterion

As we argued at the end of the section titled 'Animal studies,' there is a third defining feature of episodic-like memory, namely that it should be capable of flexible deployment (Clayton et al., 2003a). This term refers to the fact that the use of the information encoded in a memory can vary depending on the context. Because episodic memories are embedded within a larger declarative memory system that also encodes factual knowledge (e.g., Tulving and Markowitsch, 1998), the information can not only be generalized across situations but also updated when new information is acquired after the encoding of the original memory.

Evidence for the updating of episodic-like memories comes from a study by Clayton and Dickinson (1999b) in which the jays cached two types of food, peanuts and dog kibble, in both of two trays. They then allowed the jays to recover the peanuts from tray A and the dog kibble from tray B. If the birds could update their original cache memories in light of these recoveries, they should have represented tray A as containing only kibble and tray B only peanuts following the recovery episodes. To test whether this was so, one of the foods was then devalued by allowing the jays to consume it to satiety before they once again searched for their caches. Evidence for mnemonic updating came from the observation that the jays searched the kibble sites when prefed peanuts and peanut sites when prefed kibble, thereby demonstrating that they integrated the memories of the caching and recovery episodes in a way that enabled them to know the identity of the food items remaining in the trays.

This study also illustrated a second form of flexibility. The fact that the jays searched preferentially for the nondevalued food types shows that the deployment of cache memories is sensitive to changes in the incentive values of the caches. There is now good evidence that rats are also capable of this form of mnemonic flexibility. Eacott and colleagues have argued that their rats do show flexibility

because the demonstration of the what-where-and-which depended upon devaluing one of the objects as a target of exploration by habituation. A similar claim was made by Babb and Crystal (2006a) on the basis of the fact that, when their rats acquired taste aversion to chocolate after the memorization phase, they subsequently avoided the chocolate arm.

A final form of flexibility illustrates the fact that episodic memory is embedded with a general declarative system and that episodic information interacts with semantic knowledge in the control of behavior. Again this point can be illustrated with the scrub-jay food-caching paradigm. Across a series of training trials, the jays learned that different types of perishable food decayed at different rates – mealworms were rotten just 1 day later, whereas crickets, like wax worms, took longer to degrade (Clayton et al., 2001b). Clayton and colleagues argued that, in order to adopt the appropriate recovery strategy of recovering perishable caches while they are still fresh but avoiding them once they have perished, the jays would need to acquire a semantic-like knowledge about the rates at which various cached foods decay and to combine this with an episodic-like memory for each particular caching event (Clayton et al., 2001b, 2003b). The basic idea is that degrade rates of the different foods are extracted across a number of caching-and-recovery bouts and stored in a semantic-like representation, but that this information needs to be coupled with a particular episodic-like memory of the caching event if the jay is to know what to search for and where. The flexibility of this declarative memory system arises from the fact that the same episodic-like memory can support different recovery strategies depending upon the jay's semantic-like knowledge of when the caches degrade.

A strong test of this declarative flexibility asks whether the deployment of a cache memory is sensitive to new information about perishability, even though this information is not available until after the caching has occurred. Clayton et al. (2003b) assessed this form of flexibility. To do so, the jays first received a series of training trials in which they learned that crickets remain fresh for 1 day but have degraded after 4 days. On the basis of a temporal generalization test, it was then established that the birds behaved as though they expected the crickets to remain fresh for up to 3 days after caching, even though they had not been trained with these retention intervals and had no direct information upon which to base these expectations, merely an interpolation from the differential training at the 1- and 4-day intervals. At issue was whether the birds would change their strategy of where to search at recovery if they obtained subsequent information after they had already cached the food that their expectation about the durability of the cricket caches was, in fact, false.

In order to provide this information, the jays were given the opportunity to cache crickets in three different trays on three successive days. The critical design of this test is illustrated in **Figure 6**. On the fourth and fifth days the jays recovered the crickets from each of the first two trays, one per day, so that the jays had experienced a 3-day retention interval between each caching and recovery episode. During these two recovery episodes, the jays discovered to their surprise that the crickets were degraded. Note that this information was acquired a long time after the birds had formed the episodic-like memory of caching crickets in a particular tray on a given day.

At issue was whether the birds in this group would integrate this new, semantic-like information with the episodic-like memory of caching in the third tray on day 3. On the sixth day the birds received the final tray back, but no caches were present in order to test for memory. All the birds avoided searching in the cricket sites on test, a result which demonstrates that such integration occurred and attests to the declarative nature of the jay's memory for caching in particular trays. By contrast, a control group whose caches perished at the expected rate showed the same recovery pattern as before, preferentially searching for crickets.

1.23.3.4 Incidental and Automatic Encoding

So far we have argued that there are three key features of the behavioral components of episodic memory. The first – in terms of content – is that the subject recalls a specific event that happened in the past and in a way that cannot be explained in terms of discrimination by relative familiarity. Second, the representation of that past event should contain multiple features (e.g., where, what, who) in addition to 'when,' which are bound in an integrated structure. The third pertains to the flexible deployment of information acquired after encoding of the original memory, which allows memories to be embedded within a broader declarative memory structure and allows the subject to keep track and update information accordingly. However, several

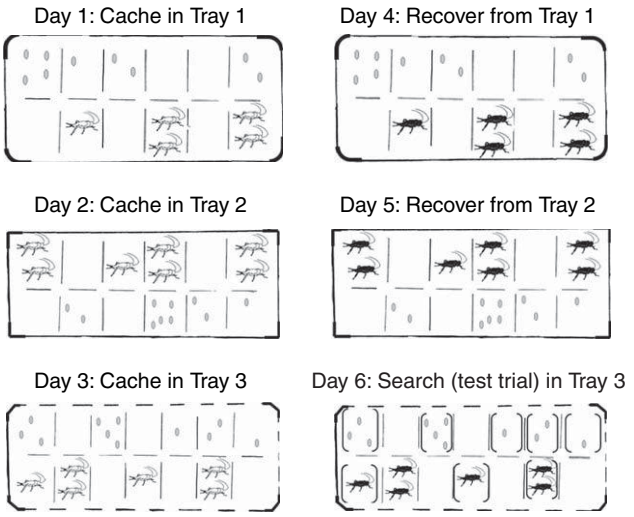

Figure 6 The food caching what-where-when memory paradigm used to test the flexibility criterion of episodic-like memory by Western scrub-jays. The jays cached peanuts and crickets in one caching tray on day 1, and then again in a second tray on day 2, and in a third tray on day 3. The birds were given the opportunity to recover the caches they had hidden in tray 1 on day 4, and in tray 2 on day 5. On test, on day 6, the jays were allowed to search in tray 3. The brackets indicate the fact that the food caches were not present at recovery on day 6 in order to test for memory. The open symbols represent fresh cricket caches, the black symbols represent rotten cricket caches, and the grey filled circles represent peanut caches.

other facts of human episodic memory remain to be explored.

When addressing the issue of an integrated representation, for example, we noted the richness of many episodic representations, of how we typically encode many seemingly incidental features of an event, without any deliberate intent to do so. So what is the origin that causes the flood of memories during episodic recall? In their "automatic recording of attended experience" hypothesis, which they invoked to explain the function of synaptic plasticity in the hippocampus, Morris and Frey (1997) emphasized this feature of episodic memory.

Zentall and colleagues (Zentall et al., 2001) have made a similar point by noting that, when animals receive a number of training trials, they may come to expect a test of their memory even though the event may be novel. For example, in the case of the jays, the birds may come to expect that their caches will be available for recovery, and that the expectation of this recovery test may lead to a semantic memory rather episodically encoding the unique features of that particular caching event. He argues that it is only when asked an unexpected question that one has to travel mentally back in time to reexperience the event in question and find the correct answer. We remain to be convinced, however, that incidental encoding is a defining feature of episodic memory. While many features of an event may indeed be encoded automatically, it does not follow that a prior request to remember specific aspects of an event preclude it from being encoded as an episodic memory. Consider a special event, a wedding, for example. Knowing that one may be asked to describe the event to others later does not prevent one from reexperiencing that episode each time one is asked to do so.

Perhaps some of the most convincing work on spontaneous episodic recall comes from C. Menzel's (1999, 2005) studies of Panzee, an 11-year-old female chimpanzee, who was trained to use a lexigram as well as gestures in her daily encounters with her human caretakers (**Figure 7**). Panzee could regularly watch from indoors how a human caretaker in the outdoor area kept a particular object in his hand and then hid it under a natural cover before leaving the outdoor area. Later, Panzee would spontaneously initiate contact with the caretaker, showing that person the lexigram of the hidden food type, and subsequently guiding the trainer outdoors, giving the gesture for 'hide,' and eventually pointing in the direction where she had observed the object being hidden. Of course Panzee's own initiative in catching the caretaker's attention and communicating is not without nonepisodic explanations (for discussion, see Menzel, 2005), but it may provide a promising avenue for future studies on this issue.

1.23.4 The Distribution and Evolution of Episodic Memory

Many people share Nietzsche's view that animals are stuck in the present and thus cannot episodically recall specific events that happened in their past because they have no sense of possessing a personalized past:

> they do not know what is meant by yesterday or today, they leap about, eat, rest, digest, leap about again, and so from morn till night and from day to day, fettered to the moment and its pleasure or displeasure, and thus neither melancholy nor bored. (Nietzsche, 1983: 60)

Such an ability to acquire and retrieve information about the world in a seemingly depersonalized timeless zone may have its advantages, for as Nietzsche pointed out:

> This is a hard sight for man to see; for, though he thinks himself better than the animals because he is human, he cannot help envying them in their happiness – what they have, a life neither bored nor painful, is precisely what he wants. (Nietzsche, 1983: 60)

The problem with such an account is that it is essentially untestable. As we pointed out at the start of the introduction, we can probably never know whether any nonhuman animal is capable of episodic recall, at least in the form that we humans experience, with the associated conscious experiences of chronesthesia and autonoesis.

By turning our focus to the behavioral criteria for episodic memory, we can at least assess which animals possess these elements of episodic memory that, in the absence of any assessment of phenomenological criteria, we call episodic-like memory. This perspective may in turn provide clues as to how and why episodic memory evolved. After all, it seems unlikely that episodic memory evolved in humans *de novo,* without any precursors in the rest of the animal kingdom.

What does an understanding of the distribution of episodic-like memory among animals tell us about the evolution of episodic memory? If we accept that episodic-like memory is present in at least one species of corvid (i.e., the Western scrub-jay) and at least one species of ape (i.e., humans), then it follows that this ability might have arisen through convergent evolution (similarities that arise as a result of adaptation to similar selection pressures in distantly related species) rather than through a shared common ancestor (homology). However, if we were to show that all birds and mammals possess episodic-like memory, then the parsimonious explanation would be that they share a common ancestor who also possessed the same traits. The answer to this question will only be known when studies have been conducted on a wider sample of species.

So far the attempts to establish models of episodic-like memory in nonhuman animals are still in their relative infancy, and perhaps this is not too surprising given that the initial paper on episodic-like memory in jays was published about 10 years ago (Clayton and Dickinson, 1998). Our review of the available evidence to date suggests that a strong case can be made for the scrub-jays, and a promising case for the chimpanzees, yet there is no evidence that rhesus monkeys remember when as well as what and where, and for rats the results are mixed. Rats do appear to remember what happened where and how long ago when tested for the memory of food they have seen previously (Babb and Crystal, 2005, 2006b;

Naqshbandi et al., 2006), but not that they have cached previously (Bird et al., 2003), suggesting that ecological salience may be critical in designing and developing the appropriate tasks.

As we noted earlier in this chapter, an outstanding issue in the rodent memory models is whether the animals may have solved these tasks using relative familiarity or rule learning after intensive training instead of episodic recall (Schwartz and Evans, 2001; Babb and Crystal, 2005, 2006a), and the extent to which an animals' ability to remember and discriminate between sequences (e.g., Schwartz and Evans, 2001; Agster et al., 2002; Ergorul and Eichenbaum, 2004; *See also* Chapter 1.21) depends on episodic-like recall. Furthermore, with the exception of the scrub-jay studies, most of the experiments have focused on the content criterion for episodic-like memory, rather than on its structure or flexibility of deployment. So clearly there is much more work to be done. A key question for future research will be to make sense of these apparently conflicting results, perhaps by using similar paradigms with different species. But this pattern of mixed results provides a cautionary note that even species that can remember the what, where, and when of a specific past experience may not necessarily express this ability under all conditions (Clayton, 2007).

The other point worthy of mention, and one we alluded to earlier, is that of ecological salience. Perhaps it is no coincidence that the evidence for episodic-like memory in the jays comes from studies of their natural propensity to cache and form rich representations of previous caching events in order to recover their food efficiently in the future. There are a number of features of the food-caching behavior of scrub-jays that might be rather special. The first is that there is no need to train the animals to perform a caching and recovery task, as these are behaviors that the animals do for a living. Moreover, Western scrub-jays are highly motivated to do so and will go to great lengths to protect their caches from being stolen by conspecifics (see review by Clayton et al., 2007), and so presumably there was intense selection pressure on mnemonic processing by jays. McKenzie et al. came to a similar conclusion when arguing that the observed differences in chronesthesia between rats and scrub-jays

> favor greater fitness for birds through sooner and greater acquisition of food. . . . Food hoarding and retrieval behaviors inherited by rats from rodent ancestors may not have been fine-tuned by the same demands placed on food-storing birds. (McKenzie et al., 2005: 24)

Perhaps it is not surprising that the scrub-jays show such rapid learning about the fate of their caches over just two or three trials.

Indeed, the jays cache perishable foods in an environment where the rate at which foods decay changes across the year, and from day to day, depending on the weather conditions between caching and recovery, so fast that flexible learning may be essential to their survival. For jays that live in the Central Valley (California, USA), the ambient temperatures rarely fall below 10 °C but may rise to over 40 °C between July and September. At such temperatures, caches that consist of various invertebrates, for example, will degrade rapidly in the heat and more slowly in cold. So the problem for a scrub-jay is not only to learn how quickly a particular food type degrades but also to be capable of updating information in a flexible manner, based on the ecological conditions that occur in the interim between caching the item and recovering it (de Kort et al., 2005).

Not all animals cache food, but there are a number of others that forage for food that degrades, ripens, or replenishes, providing another potential candidate for studying episodic memory that could be investigated experimentally (for suggestions of other candidates, see Clayton et al., 2001a; Griffiths and Clayton, 2001; Clayton and Griffiths, 2002). Nectar-feeding hummingbirds and bats, for example, could increase their food intake by taking into account a given flower's secretion rate to guide an individual's revisiting schedule. Henderson et al. (2006) tested whether free-living, territorial Rufous hummingbirds (*Selasphorus rufus*) could keep track of when the flowers refilled with nectar. The animals quickly learned the different refilling rates of the two types of flowers and roughly adjusted their revisiting schedules accordingly. Furthermore, the birds appeared to remember which particular flower they had emptied recently (Jones and Healy, 2006). Similarly, Gonzalez-Gomez and Vasquez (2006) found that green-backed firecrown hummingbirds (*Sephanoides sephaniodes*) remembered not only the location of a particular flower but also the locations of the most rewarding nectar sources among less-rewarding flowers. The flower bats (Phyllostomidae, Glossophaginae), for example, *Glossophaga soricina,* may also be a promising candidate for testing episodic-like memory, especially given that these bats can hold more than 40 feeder visits in working memory without indication of memory decay (Winter and Stich, 2005), and would allow a second test of convergence of episodic-like memory in birds and mammals.

If convergent evolution is the most likely process, then what are the common selective pressures shared between the ape and corvid species (see Emery and Clayton, 2004), or between the hummingbirds and bats? One direction for future research will be to characterize what advantages the possession of episodic memory might have, and this is where comparisons of different behavioral systems may be particularly informative. It is important to note at this point that similarity arising as a result of convergence need not lead to identical solutions (e.g., Salwiczek and Wickler, 2004), and therefore episodic-like memory in different groups may have similar functional properties without necessarily having similar neurobiological structures (de Kort and Clayton, 2006). A second direction for future research will be to ask questions about the brain systems necessary to support the various kinds of memory and the extent to which convergently evolved brain systems are similar in their details. For example, although there is good evidence that the hippocampus plays an important role in spatial memory processing in both birds and mammals, the two types of hippocampi differ in structure, with the avian one being nuclear and the mammalian one being laminar (see Emery and Clayton, 2005).

1.24 Reconsolidation: Historical Perspective and Theoretical Aspects

S. J. Sara, Collège de France, Paris, France

> *Everything flows and nothing abides; everything gives way and nothing stays fixed.* (Heraclitus 535–475 BC)

1.24.1 Historical Background: Thinking About Memory

Memory is dynamic, in that it is constantly being updated as it is retrieved. Heraclitus was the first writer to insist on this dynamic nature of memory with his metaphor cited above or with the more familiar,

> You can never step twice into the same river as other waters are ever flowing on you. (Heraclitus 535–475 BC).

William James (1892) updated this view, arguing that memory was a dynamic property of the nervous system, in constant flux as a result of being retrieved within current cognitive environments. These speculations were largely supported by the seminal experiments of Bartlett (1932), showing that information was gradually biased toward the subjects' cultural expectations as it was repeatedly recalled. Extensive evidence for this comes from laboratory studies of human memory processes over the past three decades, where old memories have been shown to be profoundly influenced by information in the retrieval environment, particularly if this information is in contradiction of the old memory (see Loftus, 2005a,b for reviews; *See also* Chapters 1.02, 1.04).

1.24.1.1 Reconsolidation: A Hypothetical Construct

Postretrieval retrograde amnesia was demonstrated experimentally in rats several decades ago, but the term 'reconsolidation' was introduced more recently, as a hypothetical construct to account for amnesia after cued recall (Pryzbyslawsky and Sara, 1997). Reconsolidation has attracted wide interest among contemporary neurobiologists for a number of reasons, including broad therapeutic applications (Pryzbyslawsky and Sara, 1997; Debiec and Ledoux, 2006). There has been a proliferation of papers appearing in the literature in the past decade, mostly addressed at understanding the molecular and cellular mechanisms underlying this still-hypothetical process. As with any area of scientific inquiry, as the number of investigators addressing the question increases, so do discrepancies in results, alternative explanations of the data, and definitions of constraints. Several reviews of this recent literature are available (Nader, 2003; Dudai, 2004, 2006; Alberini, 2005; Alberini et al., 2006; *See* Chapters 1.27, 4.14). The purpose of this chapter is to provide a deeper historical perspective from which to understand and evaluate current issues.

1.24.2 The Consolidation Hypothesis

1.24.2.1 Origins and Fate of the Consolidation Hypothesis

To understand the significance of the growing literature and issues being raised around the reconsolidation construct requires a brief reminder concerning the origins and fate of the consolidation hypothesis (for recent, more extensive, reviews see Dudai, 2004; Sara and Hars, 2006). Scientific investigation of memory processes was initiated at the end of the nineteenth century by German psychologists, first Ebbinghaus (1885) and then Mueller and Pilzecker (1900). Their studies of verbal learning and retention in human subjects led them to suggest that a memory trace was formed gradually over time after acquisition, and they introduced the term 'consolidation.' Contemporary with this were the very influential clinical observations and theoretical elaborations of the French psychiatrist, Ribot (1882). From his studies of amnesic patients, he formulated 'La loi de regression' that simply notes that as memories age, they become more resistant to trauma-induced amnesia. The origins of the neurobiological studies of memory processes can be found in early animal models of experimental amnesia (Duncan, 1945, 1948, 1949). Based on a clear temporal gradient of efficacy of the amnestic treatment, these early investigators concluded that retrograde amnesia experiments provided direct evidence for Mueller and Pilzecker's hypothesis stating that postlearning neural perseveration was necessary for consolidating memory. Electroconvulsive shock treatments (ECS) disrupted this activity, thereby preventing postacquisition memory consolidation. In the same year, and quite independently of Duncan's results, Hebb (1949) formalized the idea that propagating or recurrent impulses of a specific spatiotemporal pattern underlie initial memory. This provided the rationale for the use of ECS as an amnesic agent to study the temporal dynamics of consolidation, since such a specific spatiotemporal pattern of neural activity could hardly survive the electrical storm induced by ECS.

Thus the study of memory became, for the most part, a study of function through dysfunction. Investigators overwhelmingly relied on amnesia – either clinical studies of amnesic patients or animal models of experimental amnesia. The protocol of retrograde amnesia, indeed, opened a door on a neurobiological approach to the study of memory, evaluating the efficacy and temporal dynamics of diverse physiological treatments to disrupt memory without interfering with acquisition. The common feature of these experiments is that amnesic agents lose their ability to respectively impair memory as the interval between memory acquisition and treatment is increased, defining a temporal gradient. This large body of data supported the consolidation hypothesis, which stipulates that (1) memories are fixated or consolidated over time; (2) once consolidated, memories are then stable; and (3) acquisition of a new memory and its consolidation together form a unique event. Consolidation happens only once (McGaugh, 1966, 2000).

1.24.2.2 Challenges to the Consolidation Hypothesis

Embedded in the extensive literature on memory consolidation generated during the 1970s, however, were a myriad of studies challenging the interpretation of these retrograde amnesia experiments (*See also* Chapters 1.04, 1.05, 1.14). These include scores of demonstrations of recovery from retrograde amnesia

over time or after a reminder. Spontaneous recovery at various times after ECS-induced amnesia was reported by Cooper and Koppenaal (1964), Kohlenberg and Trabasso (1968), Young and Galluscio, (1971), and D'andrea and Kesner (1973). There were similar reports of spontaneous recovery after protein-synthesis-induced amnesia as well (Quartermain et al., 1970; Serota, 1971; Squire and Barondes, 1972). Moreover, reminders before the retention test in the form of exposure to the conditioned stimulus (CS) or the unconditioned stimulus (US) (Koppenaal et al., 1967; Galluscio, 1971; Miller and Springer, 1972; Quartermain et al., 1972) or to the training context (Quartermain et al., 1970; Sara, 1973; Sara and David-Remacle, 1974) could effectively promote expression of memory in rats that had been submitted to an amnestic treatment after learning. Later, pharmacological studies added particularly strong arguments for the contention that the amnesic agent did not prevent formation of a memory trace. Drug treatment given before the retention test could attenuate or reverse amnesia (Gordon and Spear, 1973; Sara and Remacle, 1977; Rigter and VanRiezen, 1979; Quartermain et al., 1988). If the animal could express memory after a drug treatment, with no further exposures to the elements of the learning situation, then the recovery could not be attributed to new learning.

This large and growing body of literature benefited from a thorough and thoughtful review by Donald Lewis as early as 1976, in a paper titled "A cognitive approach to experimental amnesia." His conclusion at that time was that memory 'fixation' was very rapid – a matter of seconds, and that the extended retrograde amnesia gradient was due to the effect of the treatments on retrieval (Lewis, 1976). Indeed, if memory disruption after ECS, hypothermia, or protein synthesis inhibition is alleviated by reminders or drugs given before the test, then the sparing of the original memory trace would be a logical imperative, requiring an alternative explanation for the behavioral deficit. Reconsolidation has awakened new interest in this literature, generated more than 30 years ago, and several reviews by those very investigators who contributed the initial studies 30 years ago have been published recently (Gold, 2006; Riccio, 2006; Sara and Hars, 2006).

Many clinical investigators dealing with human amnesic patients also argued convincingly that amnestic syndromes were, for the most part, due to retrieval dysfunction (*See* Chapters 1.14, 1.15). This was based on experiments showing that profoundly amnesic patients were able to benefit as much as healthy volunteers from partial cuing in a memory test of previously acquired word lists. This retrieval facilitation by cuing occurred even though the patients did not remember ever having learned the list. Such a phenomenon led to the conclusion that the memory deficit was due to a retrieval dysfunction rather than a failure to consolidate the new memory (Warrington and Weiskrantz, 1970). This naturally led to a call for consideration of retrieval, itself, as an intricate part of the memory process. Warrington and Weiskrantz went on to warn against any interpretation of behavioral deficits after amnestic treatments in animals as failure to consolidate, because it was impossible to demonstrate experimentally the absence of a memory trace. On the other hand, their studies clearly demonstrated that memory traces could be revealed by appropriate retrieval cues.

1.24.2.3 Amnesia and Forgetting As Retrieval Failure

Norman Spear took the position, with Weiskrantz, that all memory deficits, including forgetting, should be considered as retrieval failure, since it was impossible to prove the absence of a memory trace (Spear, 1971). He argued in several monographs published in the 1970s that memory studies should focus on retrieval. Remote memory is always apprehended through its retrieval and, especially in animal studies, through its expression as adaptive behavior. Thus the context in which the retention test is administered can play a determinant role in the behavioral expression of memory (or amnesia). The retrieval context includes the learning-associated environmental cues, and also the internal state of the animal, including motivational and attentional factors (Spear, 1971, 1973, 1976, 1981; Spear and Mueller, 1984). Indeed, many studies were later to confirm this hypothesis: Spontaneous forgetting of a complex maze task could be reversed by exposure to contextual cues just before the retention test (Deweer et al., 1980; Deweer and Sara, 1984; Gisquet-Verrier and Alexinsky, 1986). Furthermore, electrical stimulation of the mesencephalic reticular formation (MRF) (Sara et al., 1980; Dekeyne et al., 1987) or the noradrenergic nucleus locus coeruleus (Sara and Devauges, 1988; Devauges and Sara, 1991) also facilitated the retrieval of the a 'forgotten' maze task when administered before the retention test. All of these experiments used the same

appetitively reinforced maze task adapted from that described by Donald Lewis in his earlier 'cue-dependent amnesia' studies (see below).

While emphasizing the 'lability' of the retrieval process and its dependence on the information in the retrieval environment, Spear's main thesis was that "consolidation occurs when memory is retrieved, as well as when it was stored originally" (Spear and Mueller, 1984, p. 116; see also Spear, 1981). Nevertheless, it is nowhere specified in Spear's writings that retrieval processes trigger time-dependent neurobiological processes identical to that occurring after learning, nor does he suggest experimental protocols that would test this thesis. The experiments cited above, demonstrating a facilitation of retrieval by pretest manipulations, do not directly address the issue of consolidation occurring at retrieval, because the retention test occurs within a time frame when one would expect residual effects of the memory-modulating treatment on behavior. The adequate protocol to test treatment effects on a putative post-retrieval consolidation would be to reactivate the memory by means of a retrieval cue, administer the treatment, and then test for retention at some later time, when the effects of the treatment would have dissipated. A change in memory expression, compared with a nontreated control group, could then be attributed to reinforcement or disruption of a postretrieval consolidation process.

1.24.3 Cue-Dependent Amnesia

1.24.3.1 Seminal Studies by Donald Lewis

Such experiments, carried out independently by Donald Lewis and his colleagues, demonstrated 'cue-dependent amnesia' in the rat. These studies showed that a temporally graded retrograde amnesia could be obtained when the memory trace was activated by a reminder of the original learning event, just before the amnestic treatment. While the 'recovery' studies, discussed above, challenged the consolidation hypothesis' claim that experimental amnesia procedures block the time-dependent formation of the memory trace, the 'cue-dependent amnesia' studies challenged the corollary that consolidation occurs only once, that is, that consolidated trace is fixed and impervious to further disruption (McGaugh, 1966, 2000; Dudai, 2004).

These studies of Lewis are really at the origin of today's 'reconsolidation' hypothesis, so it is appropriate to examine these experiments in detail to determine to what extent they already addressed some of the current issues being raised. In the first series of experiments from the Lewis laboratory, rats were trained in conditioned lick-suppression protocol. Thirsty rats learned to lick a drinking spout; when this behavior was well established, a tone (conditioned stimulus, CS), followed by a footshock (unconditioned stimulus, US), was presented during the ongoing licking behavior. Subsequent presentations of the tone alone elicited suppression of licking. A day after training, when memory expression was robust and reliable in control rats, the CS was presented alone, followed by electroconvulsive shock, a treatment that produces amnesia when administered after learning. Those rats that were 'reminded' by the CS, before ECS, showed a significant behavioral deficit when tested the following day. ECS in absence of the cue had no effect on subsequent behavior. These investigators referred to the phenomenon as 'cue-dependent amnesia.' Their interpretation was that the cue reinstated the memory, putting it in an active state and making it labile, as it was immediately after acquisition (Lewis and Maher, 1965, 1966; Misanin et al., 1968; Lewis, 1969, for Review). Cue-dependent amnesia was replicated by Mactutus et al. (1979), see Lewis 1969 for review using hypothermia as the amnesic agent.

Cue-dependent amnesia could likewise be induced by protein synthesis inhibition in much the same way that newly acquired memories are. Judge and Quartermain (1982) trained mice on the conditioned lick suppression task used by Lewis. The protein synthesis inhibitor anisomycin was injected systemically at different time intervals after a single memory reactivation, consisting of a brief exposure to the training context. There was a clear renewed efficacy of the treatment after reactivation, although the temporal gradient was steeper than for that generated after initial learning. (It can be noted that the conditioned lick suppression is a Pavlovian conditioning protocol based on the tone-shock association and, as such, is perfectly analogous to the 'conditioned fear' protocol that is now almost universally used in reconsolidation studies. In both cases the response to presentation of the CS alone is behavioral inhibition; i.e., lick suppression or freezing.)

Later experiments from the Lewis laboratory showed that the phenomenon of cue-dependent amnesia was not limited to aversive Pavlovian conditioning protocols. In a series of experiments, rats were trained in a complex maze consisting of four consecutive left–right choices, using food reward as the incentive (see **Figure 1**). The training procedure

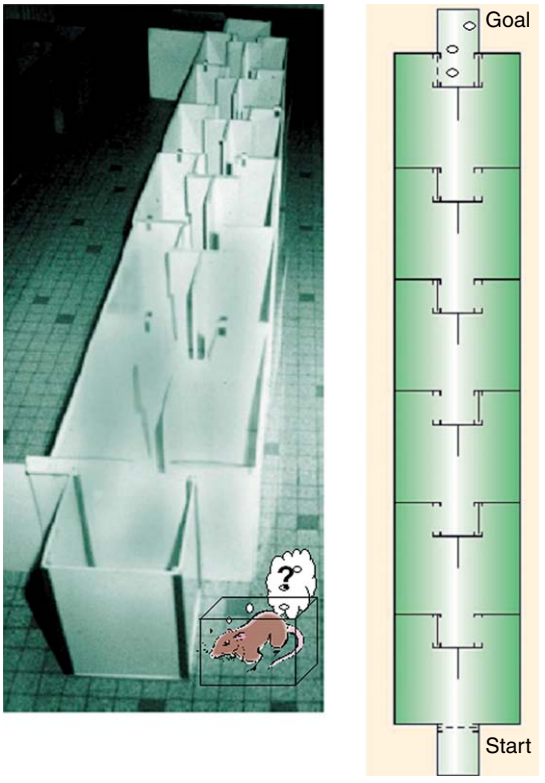

Figure 1 Krechevsky maze consisting of a series of left–right choices to reach a goal box containing palatable food. In the six-unit version, shown here, exposure to contextual cues in the experimental room, combined with stimulation of the reticular formation or the locus coeruleus just before the retention test, alleviated forgetting. A four-unit version of the task was used by Lewis to show cue-dependent amnesia. Adapted from Sara SJ (2000b) Strengthening the shaky trace through retrieval. *Nat. Rev. Neurosci.* 1: 212–213.

involved 10 days of elaborate pretraining, and then rats were trained for ten trials/day over several days until they reached the stringent behavioral criterion of 11/12 correct choices on three successive trials. During a 7-day rest period, rats were handled several times daily in order to extinguish handling-associated arousal. The following day, rats were exposed to the start box of the maze and the click of the door opening to provide reinstatement cues for the memory of the maze. This procedure was followed by electroconvulsive shock treatment. Retention was assessed 24 h later by counting the number of errors made before attaining the initial training criterion. Rats subjected to the reactivation procedure followed by ECS expressed profound amnesia compared with those subjected to ECS alone in the absence of the reactivation. A series of careful control experiments eliminated motivational and arousal confounds and explored the nature of the relevant cues in the start box. It was determined in this case that the click of the door opening in the start box was the salient feature in reinstating the memory (Lewis et al., 1972; Lewis and Bregman, 1973).

1.24.3.2 Behavioral Studies

Purely behavioral studies, in animals and humans, further confirmed that retrieval induces memory lability. Gordon and Spear (1973), in a series of experiments in rats, showed that reactivation of memory by various reminders makes it vulnerable to interference by another task, or to distortion by nonrelevant cues present at the moment of reactivation. This approach has been used recently with human subjects, showing that the memory for a list of junk objects can be distorted by intrusions from a second list presented right after the memory of the first list was reactivated by a reminder cue. An important observation in the latter series was that the disruption of memory was only expressed after a delay of 1 day; subjects tested right after learning the second list showed good retention (Hupbach et al., 2007). This experiment not only illustrates that memory can be distorted by intrusions but, on a more positive note, also shows how new information is integrated into an existing functional memory system when it is in an active state. This is the kind of analysis and approach advocated by Lewis several decades ago in his monograph entitled "A cognitive approach to experimental amnesia" (Lewis, 1976).

These studies are compatible with a long line of human studies suggesting that memory is substantially modified by the incorporation of new information during retrieval (Loftus, 1979, 1981). In the view of all these authors, the modulation of long-term memory is not an ongoing continuous process but occurs at transient windows of opportunity when the trace is in an active state. Reactivation can be spontaneous or triggered by external or internal events and, as discussed below, may even occur during sleep (see Sara and Hars, 2006, for review).

1.24.4 Cue-Dependent Amnesia: Neurobiological Hypotheses

Thus it was clearly established, by broad experimental evidence, as early as the late 1960–1970s, that well-consolidated memories are vulnerable to interference in a time-dependent manner when they were

in an active state. Unfortunately, little attempt was made at the time to integrate this phenomenon of 'cue-dependent amnesia' into the rapidly developing neurobiological hypotheses of memory formation.

1.24.4.1 NMDA Receptors in Cue-Dependent Amnesia

In 1997, our interest in cue-dependent amnesia was rekindled by some unexpected results that would provide the opportunity for such integration. The initial purpose of our experiments had been to study the effect of *N*-methyl-D-aspartate (NMDA) receptor blockade on various stages of acquisition of a spatial reference memory task to fix a critical time point during the multisession acquisition when these receptors might play a specific role. The surprising result of the initial experiment was that not only did the NMDA receptor antagonist, MK-801, disrupt performance of a well-trained spatial task but the rats continued to show a decrement on the subsequent trial, 24 h later. Follow-up experiments showed that posttrial injections of the antagonist up to 2 h after the training trial likewise induced the performance decrement the following day. Given our long-standing interest in the dynamics of memory retrieval and recovery from amnesia, we interpreted these unexpected results within Lewis' conceptual framework of 'cue-dependent amnesia.' Since there were no previous reports of long-lasting effects of MK-801, we performed a series of experiments to confirm that a well-consolidated spatial memory, acquired over many days, reactivated by a single errorless trial, was somehow dependent upon intact NMDA receptors to maintain stability. The memory deficit was robust, in that there was no spontaneous recovery 48 h later (Przybyskawski and Sara, 1997, Exp4). Amnesia was, however, only partial, in that drug-treated rats could relearn the task and attain asymptotic levels of performance in only a few massed trials (Przybyskawski and Sara, 1997, Exp3). Extrapolating from these data, we suggested that

> memory is reconsolidated, so to speak, each time it is retrieved and these reconsolidation processes are dependent on the NMDA receptor for at least 2 h after the reactivation. (Przybyskawski and Sara, 1997, p. 245)

To our knowledge, this is the first use of the term 'reconsolidation' in the literature in relation to the well-established phenomenon of cue-dependent amnesia.

1.24.4.2 Role of the Noradrenergic System

We went on to investigate the role of beta-adrenergic receptors in this putative reconsolidation process and showed that postreactivation, a systemically injected beta antagonist, propranolol, induced amnesia in the spatial memory task protocol. Memory had to be reactivated by a single reminder trial for the drug to induce amnesia, expressed 24 h later.

As the spatial discrimination task is acquired over many trials, it does not lend itself to comparison of the temporal dynamics of postretrieval reconsolidation with that of postacquisition consolidation. This is an essential step in establishing that reconsolidation involves cellular processes similar to those occurring during the initial consolidation. Injection of propranolol after reactivation of a single-trial passive avoidance task also induced amnesia. In this case the effect of the beta receptor antagonist was even more robust after reactivation than after original training (Przybyskawski et al., 1999, Figs. 4 and 5).

Both the spatial memory task and passive avoidance memory formation depend upon hippocampal activity. To investigate the temporal dynamics of NMDA and beta receptors in reconsolidation in a task that does not involve the hippocampus, we used a simple, rapidly learned odor-reward association task (Tronel and Sara, 2002). Rats were extensively handled, mildly food deprived, and familiarized with the palatable reinforcement. Three sponges, each impregnated with a different odor, are arranged symmetrically within a wooden box; the spatial configuration of the sponges within the box are changed from trial to trial. Chocokrispies are hidden in the hole of the sponge with the target odor. The response is measured as a nose poke into the correct hole. Rats are very proficient at this task, learning the three-way discrimination in only three trials (for further details see Tronel and Sara, 2002). Intracerebroventricular (ICV) injections of an NMDA receptor antagonist induce amnesia not only when the injections are made immediately after learning (Tronel and Sara, 2003) but also when drug treatment is administered after a reminder cue consisting of the target odor presented in the experimental context (Torras-Garcia et al., 2005). In this task, ICV injection of beta receptor antagonists induces amnesia when the injection is made within a narrow time window around 2 h after learning, and the rat is tested 48 h later (**Figure 2**, top). Quite strikingly, the same temporal dynamic of involvement of beta receptors is seen after memory reactivation (**Figure 2**, bottom);

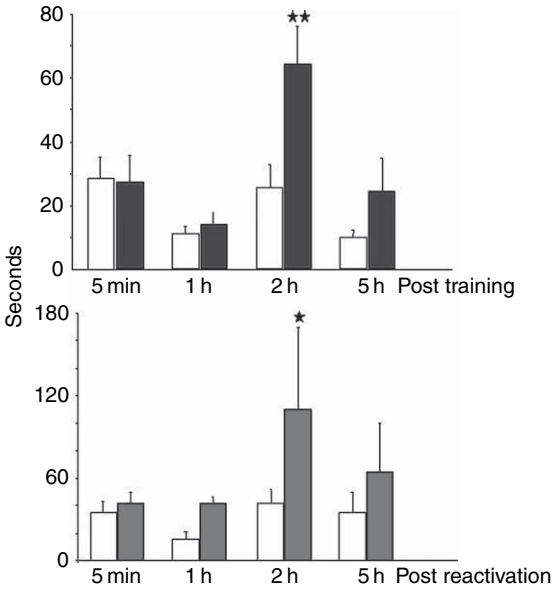

Figure 2 Retention performance in terms of latency to find the reward in an odor-reward association task 24 h after learning (top) or 24 h after memory reactivation by a brief exposure to the CS in the experimental context (bottom). Rats were injected with saline (white bars) or a beta receptor antagonist (red bars) at times indicated after training. There was a narrow time window at 2 h after training when the initial memory required beta receptors and a strikingly similar time window after reactivation when the drug treatment was effective in producing amnesia. Adapted from Tronel S, Feenstra MG, and Sara SJ (2004) Noradrenergic action in prefrontal cortex in the late stage of memory consolidation. *Learn. Mem.* 11: 453–458.

thus, the noradrenergic system appears to be involved in a late phase of memory consolidation, and again in reconsolidation (Tronel et al., 2004).

Based on the data from these studies, we proposed that treatment with propranolol in conjunction with psychotherapeutic memory reactivation could serve to attenuate the compulsive traumatic memories associated with posttraumatic stress disorder (Przybyskawski et al., 1999).

1.24.5 Rebirth of Reconsolidation

These pharmacological data, showing cue-dependent amnesia effects of NMDA and beta antagonists, merely confirmed and extended results obtained by many others nearly three decades earlier. Donald Lewis had proposed, in light of the large amount of data already available at this early date, to replace the consolidation paradigm by a conceptual framework of active and inactive memory in labile and stable states and to open the way for a more cognitive interpretation of amnestic syndromes (Lewis, 1979). It is truly ironic that the Lewis cue-dependent amnesia studies are at the origin of the current 'reconsolidation' hypothesis, as it is clear that the phenomenon of postreactivation lability cannot be understood by a simple extension of the consolidation concept. The problem is that cue-dependent amnesia is not predicted by the consolidation hypothesis and is, in fact, in direct contradiction of it. Neither Lewis nor his contemporaries used the term reconsolidation, and they were generally not interested in such questions as "does reconsolidation recapitulate consolidation?" Their aim had been merely to show that the amnesia gradient did not reflect the duration of a consolidation process and that consolidation was not a unique event. Memory was labile when in an active state, and lability was not time bound to acquisition. Indeed, the initial series of experiments was explicitly designed by Lewis and colleagues to challenge the interpretation of retrograde amnesia as consolidation failure and to inspire a more cognitive interpretation of memory function and dysfunction.

Nevertheless, there has been a surge of interest in 'reconsolidation' initiated by elegant experiments from the Ledoux laboratory. These investigators found that amnesia could be obtained after reactivation of conditioned fear by injecting, directly into the amygdala, the protein synthesis inhibitor anisomycin (Nader et al., 2000). The results obtained were similar to those of Judge and Quartermain (1982), except that now the protein synthesis inhibition was limited to a structure that is part of the neural circuit underlying the fear conditioning.

1.24.6 Neurobiological Substrates and Boundaries of Reconsolidation

The decade since this report has seen a proliferation of studies of cue-dependent amnesia that fall into two categories. One approach has been to study the cellular and molecular processes implicated in putative reconsolidation and to investigate to what extent they recapitulate consolidation processes occurring after initial learning. The second, and by far the more controversial, approach lies in an attempt to firmly establish (or repudiate) reconsolidation as a real phenomenon in memory processing by delineating the 'boundaries' within which cue-dependent amnesia can be obtained and sustained.

1.24.6.1 Neurobiological Substrates

The search for cellular and molecular substrates of reconsolidation has produced a myriad of results delineating neuromodulatory systems, neurotransmitters, intracellular signaling pathways, transcription factors, and brain regions that are necessary for both posttraining and postretrieval memory stabilization. Others seem to be specific to one or the other stage of memory processing. For example, NMDA receptors are necessary for both consolidation and reconsolidation across tasks and species (Pryzbyslawski and Sara, 1997; Perdreia et al., 2002; Torras-Garcia, 2005; Akirav and Maroun, 2006; Lee et al., 2006). The role of beta noradrenergic receptors, on the other hand, seems to be restricted to postretrieval memory processing (Debiec and LeDoux, 2006; Pryzbyslawski et al., 1999; Roullet and Sara, 1998; Diergaarde et al., 2006). Early implication of the transcription factor cAMP response element binding protein (CREB) in the stabilization of both new and reactivated fear memory was established by experiments using transgenic mice with inducible and reversible CREB repressor (Kida et al., 2002). This burgeoning literature concerning neurobiological substrates of postretrieval memory processes, focusing, for the most part, on intracellular cascades and immediate early gene expression, has been subject to several recent comprehensive reviews (Alberini, 2005; Alberini et al., 2006; Dudai and Eisenberg, 2004) and has been updated in the present volume (*See* Chapter 4.14).

1.24.6.2 Boundaries of Reconsolidation

It is becoming increasingly evident, as the literature grows, that the same old questions raised during the consolidation era, concerning the nature of the memory deficit after an amnestic treatment, persist, although the discussion lacks the strong polemics of the past generation. Does the amnestic agent block consolidation, or now reconsolidation, or does it impair retrieval (*See* Chapters 1.04, 1.05, 1.14)? The single-trial inhibitory avoidance protocol that was used almost exclusively in earlier consolidation studies has been replaced by a simplified version of conditioned fear, in which a CS is associated with footshock to produce a conditioned emotional response measured as freezing behavior. The protein synthesis inhibitor, anisomycin, has largely replaced ECS as the generic amnestic agent in these reconsolidation boundary studies.

1.24.6.2.1 A note on the action of anisomycin

The increasing use of anisomycin as a generic amnestic agent to study boundaries and temporal dynamics of postretrieval memory processing is based on the widely held assumption that *de novo* protein synthesis is the final step of the intracellular cascade triggered by a learning or retrieval event and necessary for the consolidation or reconsolidation of long-term memory. This recent literature largely ignores the fact that caution was urged by the early users of protein synthesis inhibitors as amnestic agents in behavioral experiments, because of toxicity and ability to induce behavioral aversion. Thus, special care must be taken, especially in avoidance experiments, to dissociate aversive and amnestic effects of the drugs on behavior (Squire et al., 1975; Davis et al., 1980). Furthermore, several early investigators provided evidence that memory impairment attributed to protein synthesis inhibitors could be accounted for, at least in part, by specific effects on brain catecholamine systems (Flexner and Goodman, 1975; Quartermain et al., 1977; Flood et al., 1980; Altman and Quartermain, 1983; Davis and Squire, 1984, for review). These data take on particular importance in the light of several recent studies reporting the amnestic effects of the beta adrenergic antagonist propranolol after memory retrieval (see preceding paragraph).

More recent literature has underlined the fact that anisomycin activates the MAPkinase intracellular signaling pathway and causes apoptosis at doses lower that those that inhibit protein synthesis (Routtenberg and Rekart, 2005; Rudy et al., 2006). So, while the behavioral deficits associated with administration of anisomycin after memory reactivation are quite reliable, they may be caused by effects other than the inhibition of protein synthesis. This underlines the caveats inherent in elaborating a theory of memory function relying exclusively on a single paradigm that includes fear conditioning and anisomycin-induced amnesia.

1.24.6.2.2 Permanence of cue-dependent amnesia?

Is the memory deficit permanent, or is there spontaneous recovery or the possibility of recovering the memory by further treatments or reminders? Quartermain showed early on that postretrieval anisomycin-induced memory deficits in mice were less persistent than the deficits obtained by the same dose administered after training (Judge and Quartermain, 1982). They found

spontaneous recovery of memory in mice 4 days after the reactivation-drug treatment, while behavioral expression of amnesia was still present in those mice receiving the anisomycin after training. In more recent studies, in mice submitted to context fear conditioning and systemic injection of anisomycin, amnesia is durable after acquisition, but after reactivation it is necessary to use repeated injections, and the amnesia is transitory (seen at 1 day but not at 21 days; Lattal and Abel, 2004; Prado-Alcala et al., 2006). Spontaneous recovery from cue-dependent amnesia has been confirmed by others using either systemic or locally injected anisomycin in rats, mice, chicks, or fish (Anokhin et al., 2002; Eisenberg and Dudai, 2004; Power et al., 2006). On the other hand, at least one group reports persistent amnesia even several weeks after retrieval and treatment by anisomycin (Duvarci and Nader, 2004). These discrepancies are similar to those reported decades ago concerning the nature and permanence of the memory dysfunction in experimental amnesia studies, as discussed above. Moreover, the same logical objection voiced by Warrington and Weiskrantz (1970) years ago can be raised here. Experimental amnesia studies are fatally flawed from the outset, since it is not possible to prove the null hypothesis (i.e., the absence of a memory trace).

1.24.6.2.3 Age and strength of the memory

The ease with which cue-dependent amnesia can be obtained may depend upon the age and the strength of the memory. Newer memories appear to be more susceptible to disruption after their retrieval than are older memories (Milekic and Alberini, 2002; Eisenberg and Dudai, 2004; Suzuki et al., 2004). Moreover, the strength of the memory, as revealed by the probability of its behavioral expression, also determines its vulnerability at retrieval. This has been shown by manipulating the number of unreinforced reminder trials to yield either reactivation or extinction (Eisenberg et al., 2003; Stollhoff et al., 2005; *See* Chapter 1.27). With a weak memory, resulting from a single training trial, in a conditioned taste aversion task, unreinforced presentation of the CS results in extinction. If this is followed by an amnestic treatment, extinction is blocked, and retention for initial learning is expressed at retention test. If the initial memory is strong, presentation of the CS reactivates the memory, rendering it labile, and amnesia is expressed at retention test (Eisenberg et al., 2003).

Another way to shift from retrieval to extinction in behavioral control is to modify the duration or the repetition of the cuing episode: a brief retrieval will reactivate the memory, making it labile. A long or repeated retrieval will lead to extinction (i.e., new learning, with its requirement for consolidation). Using a fear conditioning to context protocol, Suzuki et al. (2004) show that there is no amnesia with brief exposure to the CS (1 min), amnesia with a moderate exposure (3 min), or retention with a long CS exposure (30 min). This retention is interpreted as an amnesia for the extinction induced by the 30-min unreinforced CS exposure. Interestingly, they observe that the effective duration of cuing to induce lability increases with either the strength or the age of the memory.

1.24.6.2.4 Task- and species-related boundaries

Although most of the studies of cue-dependent amnesia use fear conditioning, the phenomenon can readily be obtained after different forms of appetitive and aversive learning in many species: rodents (Lewis et al., 1972; Lewis and Bregman, 1973; Pryzbyslawski and Sara, 1997; Pryzbyslawski et al., 1999; Torras-Garcia et al., 2005; Wang et al., 2005; *See* Chapter 1.09), and even in the honeybee (Stollhof et al., 2005), crab (Frenkel et al., 2005), slug (Sangha et al., 2003), and snail (Gainutdinova et al., 2005; Kemenes et al., 2006) (*See* Chapter 1.27). Behavioral tasks used in these studies have included conditioned taste aversion (Eisenberg et al., 2003; Gruest et al., 2004a,b), object recognition (Kelly et al., 2003), inhibitory avoidance (Milekic and Alberini, 2002), instrumental incentive learning (Wang et al., 2005), odor reward association (Torras-Garcia et al., 2005), and eyelid conditioning (Inda et al., 2005). Moreover, at least in the case of rodents, this aspect of memorization is already present at the beginning of life, showing that it is a fundamental aspect of memory (Gruest et al., 2004a,b).

Despite generality of the cue-dependent amnesia phenomenon across species and tasks, some important constraints have recently been reported. Biedenkapp and Rudy (2004) attempted to induce amnesia by injecting anisomycin after reactivating a memory for a context. Rats received six massed exposures to a specific context in which they would be later receive tone–shock fear conditioning. In this particular protocol, the context preexposure is necessary for the rat to subsequently learn the tone–shock

association. The authors clearly showed that intrahippocampal anisomycin induces amnesia for the context when injections are made immediately after the preexposure. However, they failed to obtain cue-dependent amnesia if the injections were made after a 5-s or a 1-min reactivation of the context memory. One explanation that they offer to account for their negative findings is the 'significant event hypothesis.' A significant event is one that has been associated with a reinforcement, giving it predictive value. This hypothesis is quite appealing in light of the strong evidence for a major role for the locus-coeruleus noradrenergic system in memory retrieval and putative reconsolidation processes, as discussed above. It would take a 'significant event' to elicit the attention or arousal response associated with the activation of neuromodulatory systems (Sara, 1985, 1991; Bouret and Sara, 2004, 2006).

A related determinant of the lability of a reactivated memory is the extent to which a new encoding mode is solicited at the time of retrieval (Morris et al., 2006). These authors show that a reactivated spatial reference memory, learned in the water maze over several days, is not susceptible to amnesia induced by injection of a protein synthesis inhibitor into the hippocampus. It is only when new information must be integrated into the existing memory that amnesia follows such injections. These data fit nicely with the 'significant event' hypothesis. New information requiring behavioral adaptation should elicit attention and activate neuromodulatory systems necessary for stabilization of the reorganized memory.

1.24.6.2.5 A note on the problem with negative results

Cue-dependent amnesia studies lead to the conclusion that memory in an active state is labile and can be disrupted by a wide range of treatments, many of which are effective in producing amnesia when applied after new learning, as well. If an animal expresses amnesia after training and amnestic treatment, one concludes that memory consolidation was blocked by the treatment. If the memory is subsequently expressed after a reminder or a pharmacological treatment, one must conclude that the trace was there, but for some reason the animal could not express it behaviorally. What about possible outcomes of experiments evaluating the putative reconsolidation processes? There the amnestic agent is applied after a reminder that is supposed to reactivate the memory. If the rat expresses amnesia on a retention test, can it be taken as proof that the treatment erased or weakened the reactivated, labile trace by preventing reconsolidation? Suppose the memory is expressed at some later test? Or after a reminder? So, as Weiskrantz warned, we are faced with the impossible challenge of proving that the memory trace does not exist. When no cue-dependent amnesia is expressed on the retention test, there are several possible conclusions: (1) the amnestic agent was not effective in blocking reconsolidation because of, for example, inappropriate dose), (2) the reactivation treatment was not sufficient to elicit the memory to put it into an active labile state, or (3) postreactivation reconsolidation processes are not necessary.

1.24.7 Beyond Cue-Dependent Amnesia: Retrieval Strengthens Memory

This large body of literature concerned with cue-dependent amnesia confirms the *lability* of a memory trace after its reactivation, but it should not lead to the counterintuitive conclusion that retrieval weakens memory. Memory lability has always been easier to document behaviorally through amnesic rather than through promnesic treatments, which is why most investigators have chosen this research strategy. We know, however, that retrieval of memory does not usually result in wiping it out or even weakening it. On the contrary, a high level of attention or arousal during retrieval, a more likely real-life scenario, should *reinforce* the labile active memory. Remembering, especially when it involves effortful retrieval, usually occurs in an attentive, motivated behavioral state. During such states, neuromodulatory systems are activated (Bouret and Sara, 2004), releasing noradrenaline, dopamine, and other neuromodulators in the forebrain structures involved in the ongoing sensory processing and retrieval. These neuromodulators act to promote synaptic plasticity and trigger intracellular processes leading to new protein synthesis, upon which stable long-term memory is dependent (Sara, 2000a,b) (*See* Chapter 1.27 for a discussion of the internal reinforcement theory).

1.24.7.1 Cue-Dependent Enhancement

1.24.7.1.1 Enhancement by MRF stimulation

Although the strengthening of a memory trace by repeated remembering seems intuitively valid, experimental documentation of retrieval-associated memory improvement is rather sparse. There are a few reports

of marked improvement of memory in the rat when retrieval is accompanied by arousal. Experiments by DeVietti et al. (1977) demonstrated that electrical stimulation of the mesencephalic reticular formation (MRF), which improves memory consolidation when administered within a short time after acquisition, improved memory for a well-consolidated conditioned fear response when it was applied after memory reactivation. The reactivation treatment consisted of a 15-s exposure to the tone in the training chamber; the rat was tested 24 h later. The shorter the interval between the reactivation and the MRF stimulation, the better the memory enhancement, the temporal gradient of efficacy being strikingly similar to the postacquisition gradient (**Figure 3**).

1.24.7.1.2 Enhancement by activation of the noradrenergic system

It has been shown repeatedly that stimulation of the noradrenergic system will enhance memory retrieval when given before the retention test (reviewed above), but it is only recently that the effects of pharmacologically increasing noradrenergic tonus on putative reconsolidation processes have been investigated. The alpha 2 receptor antagonist, idazoxan, increases firing of noradrenergic neurons of the locus coeruleus twofold at a dose that has no detectable effect on overt behavior such as locomotor activity (Sara, 1991). Rats were trained in the odor-reward association task used in the timolol studies described above. Forty-eight hours later, they were exposed to the odor in a neutral cage, located in the experimental room. This was followed by an injection of idazoxan; control rats were handled in the colony room before injection. Idazoxan enhanced performance when the rat was tested 48 h later, but only when the injection was given after memory reactivation (**Figure 4**). These data complement studies showing cue-dependent amnesia induced by beta adrenergic antagonists, discussed earlier. Together they lend support to the notion that the locus-coeruleus-noradrenergic system is activated by cues associated with target memories and contributes to the postreactivation stabilization or reinforcement of the memory (Sara, 2000b; see also Sara, 1985).

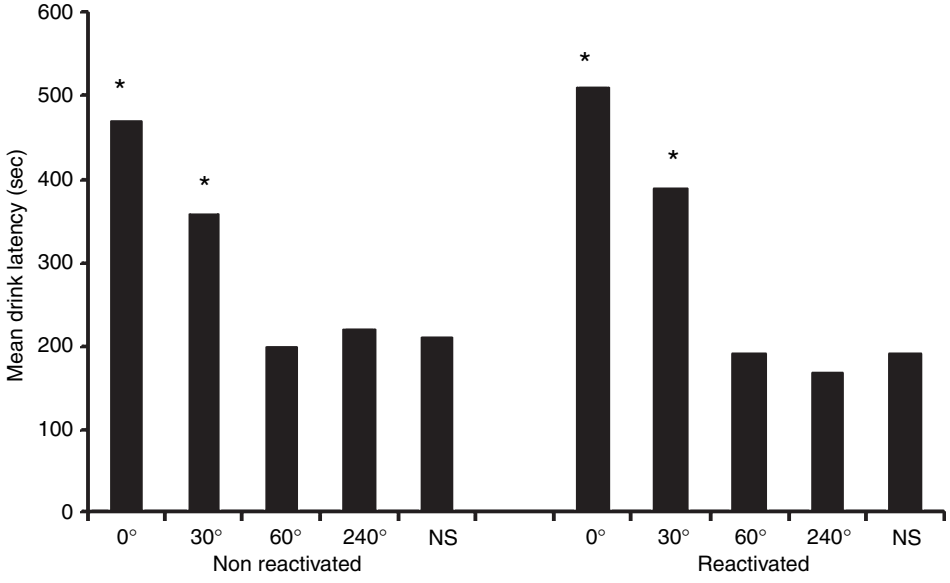

Figure 3 Retention performance in a lick suppression task after training and electrical stimulation of the mesencephalic reticular formation (MRF) (left) or after memory reactivation by the tone conditioned stimulus and (MRF) stimulation (right). In each condition one group of rats received no stimulation, to provide a baseline performance (NS). Histograms from left to right represent data from rats stimulated immediately after training or exposure to the tone or progressively longer delays. The treatment was effective in improving retention when applied up to 30 min after training; behavioral performance of rats stimulated after that was indistinguishable from that of NS rats. Note the striking similarity between the temporal gradient of efficacy after training and after reactivation. Figure adapted from Devietti TL, Conger GL, and Kirkpatrick BR (1977). Comparison of the enhancement gradients of retention obtained with stimulation of the mesencephalic reticular formation after training or memory reactivation. *Physiol. Behav.* 19: 549–554, with permission from Elsevier.

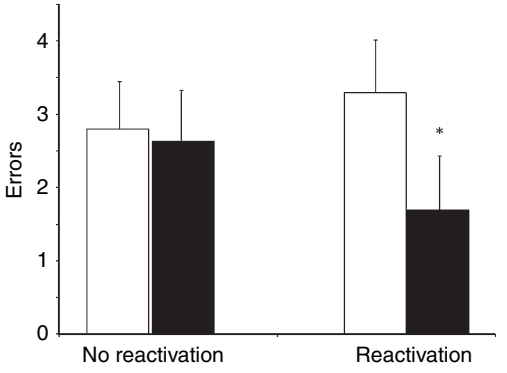

Figure 4 Retention performance in terms of errors before finding the reward in a retention test, 3 weeks after learning the odor-reward association test. Left: data from rats receiving no reactivation on the day before the test. Right: data from rats exposed for a few minutes to the target odor in the experimental room, 24 h before the retention test. White bars: saline injections after reactivation or no reactivation. Black bars: rats injected with idazoxan (an alpha 2 receptor antagonist that increases release of NE), 2 mg kg^{-1} ip, after no reactivation or reactivation.

1.24.7.1.3 Enhancement by activation of PKA

The beta adrenergic receptor is one of a family of receptors positively linked to G proteins that serve to activate the cyclic AMP intracellular signaling cascade, leading to gene induction by the transcription factor CREB. The resulting *de novo* protein synthesis is thought to be essential for the stabilization of long-term memory. Activation of protein kinase A (PKA) is an important step in this cyclic AMP intracellular signaling cascade. A recent study by Tronson et al. (2006) has shown that pharmacologically activating PKA within the rat amygdala can facilitate fear memory if and only if the memory has been reactivated by a reminder. These results, taken together with the studies showing enhancement of reactivated memory by beta adrenergic agonists, lend support to the notion that the noradrenergic system, activated at retrieval, serves to reinforce memories rendered labile by reactivation.

1.24.7.2 Clinical Significance of Cue-Dependent Enhancement

Clinical syndromes such as posttraumatic stress disorder (PTSD), phobias, obsessive compulsion, and craving in addiction share the common feature of underlying compelling, persistent memories. The possibility that memory may be rendered labile under controlled conditions has broad therapeutic applications for these disorders, accounting for the increasing number of investigators interested in this aspect of memory.

In particular, the susceptibility of reactivated memories to noradrenergic manipulation sheds some light on the underlying mechanisms of pathological persistence of memory. In the case of PTSD, it has already been established that there is greater noradrenergic (NE) activity under baseline conditions in patients with chronic PTSD than in healthy subjects, with a direct relationship of NE activity to the severity of the clinical syndrome (Geracioti et al., 2001). Further activation of this system during stress could recreate the internal state induced by the original trauma and thereby reinstate the memory (Grillon et al., 1996). The demonstrated role of the intracellular pathway activated by this system in reinforcing reactivated memories (Tronson et al., 2006) suggests that the memory recalled in the presence of a high level of NE will be reinforced each time (see also **Figure 3**).

The potential usefulness of noradrenergic receptor–blocking agents in PTSD has already been pointed out by Cahill (1997), who suggested that treatment with beta blockers as soon as possible after the traumatic event might prevent the development of PTSD. The recent 'rediscovery' of the phenomenon of lability of memory in its active state adds a new dimension to this potential use. Treatment with beta receptor antagonists, at the time of spontaneous or clinically elicited reinstatement of the traumatic memory, should serve to attenuate the active memory by blocking reconsolidation processes (Przybyskawski et al., 1999).

1.24.8 New Look at Retrieval and 'Reconsolidation'

Memory only lends itself to study through its retrieval; as William James underlined more than a century ago, "the only proof of there being retention is that recall actually takes place" (James, 1892). Although some memory retrieval is likely to occur spontaneously as a result of random fluctuations of network activity in the brain, retrieval is usually brought about with effort, as a result of integration of incoming environmental information with the 'memory network' driven by that information (Tulving and Thomson, 1973). It follows from this that the formation of new memories will always be made on the background of retrieved information. Recent functional imaging studies in humans are, indeed, confirming these earlier theoretical

speculations (e.g., Cabeza et al., 2002; Nyberg et al., 1996a,b). They are providing clear evidence that it is memory of the past that organizes and provides meaning to the present perceptual experience. Borrowing Tulving's terminology, new episodic memory, to be remembered in a meaningful way, must be consolidated within a preexisting semantic memory (Tulving, 2002).

This analysis does not allow a clear demarcation between consolidation and retrieval processes, and in this view, it can be assumed that every retrieval operation should trigger a reconsolidation process. This is a view similar to that of Spear, although he never used the term 'reconsolidation' (Spear and Mueller, 1984). It follows from this that retrieval will change the information content of the 'trace' such that memory can be viewed as an emergent, dynamic, adaptive property of the nervous system. It is in that sense that

> Everything flows and nothing abides; everything gives way and nothing stays fixed.

1.25 Learning and Memory in Communication and Navigation in Insects

R. J. De Marco and R. Menzel, Freie Universität Berlin, Berlin, Germany

1.25.1 Introduction

The distinction between instinctive and learned behavior is a fundamental issue in behavioral research. A major difficulty in addressing it relies on the fact that labeling behaviors as either instinctive or learned is in most cases a merely analytical approach to the problem. Behavior develops on the basis of the interplay between an animal's phylogenetic boundaries and the sources of external signals that belong to its specific sensory world (Tinbergen, 1963; Lorenz, 1981; Shettleworth, 1998; Macphail and Bolhuis, 2001). It follows that when an animal computes the differences between stimuli activating the same or different sensory modalities, its subsequent behavior will be the outcome of an unbroken succession of possible responses, whose particular boundaries have been modified by selection in the course of evolution. Learning is embedded into this continuousness, and its effects on the animal's instantaneous performance will be superimposed onto those of its specific phylogenetic boundaries. This is why it is so fundamental to focus on salient responses invariably linked to the animal's previous experience when distinguishing between instinctive and learned behaviors. From a behavioral point of view, this leads to the search for the mechanisms underlying the animal's decision, a notion that denotes the process of parsing complexes of stimuli into equivalent options and the control of the subsequent responses that arise from the corresponding choices.

A central argument advanced in this chapter is that some invertebrate taxa constitute powerful model systems for the study of the teamwork between these two modes of behaviors, instinctive and learned, and for the analysis of basic principles of learning and memory, particularly within the context of communication and spatial cognition, where the possibility of revealing decisions might be within reach. Our focus is on social insects, animals that form societies and appear to have been exposed to higher cognitive demands during the course of evolution, perhaps due to their long lifetime, the diversity and complexity of the signals involved in their social interactions, and the development of counterresponses. In fact, "if Earth's social organisms are scored by complexity of communication, division of labor and intensity of group integration, three

pinnacles of evolution stand out: humanity, the jellyfish-like siphonophores, and a select assemblage of social insect species" (Wilson, 2006). Within this insect group, emphasis is on the honeybee, *Apis mellifera*, simply because its communication and navigation skills are impressive (e.g., von Frisch, 1967; Seeley, 1995; Menzel et al., 2005). Furthermore, because their brains are small, bees appear to be suitable subjects for studying system-level neural correlates of learning and memory through robust behavioral approaches, both at the level of single neurons and neural networks.

1.25.2 Communication

Since its early days, ethology has nurtured the study of learning and memory phenomena, and a great deal of its classical ideas "emerged or crystallized from the study of animal communication" (Konishi, 1999). It follows, therefore, that communication in nonlinguistic animals has been at the center of many of the current behavioral approaches to learning and memory. The study of animal communication is concerned with the production of and the responses to signals, including adaptive advantages and mechanisms of central processing, motor coordination, and peripheral detection and filtering. In invertebrates, it is in the context of communication and navigation that learning transcends elementary forms of association in particularly clear ways (Menzel et al., 2006). The evaluating signal for storing experience must come from internal nervous system conditions at the time of learning, depends considerably on the motivational level, requires attention to a subset of stimuli, and is adjusted to the animal's own behavior in an intricate way. The signals learned are usually composed of multimodal inputs, which cannot be isolated from each other, and the motor performances involve sophisticated sequences of programs. Insects make use of all sensory channels for communication and evolved sophisticated sender–receiver systems serving mate recognition and sexual selection, predator–prey relationships, and complex social interactions. Although the sensory, ecological, and evolutionary aspects of these communication systems have long been studied in detail (see the following discussion), little is known about the cognitive dimensions of these communication systems (e.g., how innate mechanisms interact with experience-dependent developmental processes, how these mechanisms depend on internal and external conditions, and how learning actually shapes a communication process). In the present context the neural mechanisms of insect communication will henceforth be eschewed altogether. We shall describe a few examples from several taxa illustrating the dominance of innate behaviors with regard to communication with conspecifics; these examples will be listed according to the sensory modalities involved in the processing of communicating signals. We will then focus on a few examples illustrating simple forms of learning in a selected group of insects, and finally, we will focus on the study case of the honeybee dance communication system, with special emphasis on the structure and content of the spatial memory underlying such complex phenomenon.

1.25.2.1 The Dominance of Innately Programmed Responses in Communication

1.25.2.1.1 Chemical

In highly eusocial species, the interplay between innate and learned behaviors becomes evident through group recognition, which greatly depends on smell and genetically programmed responses to information gathered in specific, innately recognized behavioral contexts (Lindauer, 1961; Wilson, 1971; Michener, 1974; Barrows et al., 1975; Oster and Wilson, 1978; Fletcher and Ross, 1985; Hölldobler and Wilson, 1990). Within an insect society, conspecific individuals respond differently to age, sex, and physiological groups, and the task of recognizing queens, males, workers (both egg-layers and infertile individuals), as well as intruders, strongly relies on volatile pheromones, variations in hydrocarbon cuticular profiles, and environmental odors (e.g., Eberhard, 1969; Bell, 1974; Franks and Scovell, 1983; Wagner et al., 1998; Liebig et al., 2000).

Individually distinctive or colony odors are frequent across highly eusocial insects and constitute the basis of colony integration and social organization (Hölldobler and Michener, 1980). Foragers from many ant species, for example, resume their field excursions by following trails chemically marked with colony-specific components (Hölldobler and Wilson, 1990; Billen and Morgan, 1998). Research on the harvesting ant *Pogonomyrmex*, for example, shows how context-dependent innate responses to olfactory stimuli lead to adaptive behavioral flexibility during foraging (Greene and Gordon, 2003). A colony of these ants consists of a single queen and

several thousand workers, including foragers and patrollers. Patrollers scout the foraging area before foragers leave the nest; if they do not return from their early excursions, the foragers will not begin to work. Recently, Greene and Gordon (2003) first blocked a *Pogonomyrmex* colony's foraging activity by removing its patrollers and then presented the foragers with glass beads at the nest's entrance. These beads had previously been coated with cuticular lipids from patrollers, hydrocarbon profiles from either patrollers or within-the-nest ants, and plain solvent; they also used live patrollers as a positive control. The authors thus found that task-specific cuticular hydrocarbons from patrollers were sufficient to rescue the colony's foraging activity, and that the foragers' responses depended not only on the patrollers' hydrocarbon profiles, but also on whether or not they were presented at the nest's entrance and at the right time of day (Greene and Gordon, 2003). The question remains of to what degree simple forms of learning, such as habituation (Barrows et al., 1975), underlie these responses to colony and individually distinctive odors.

1.25.2.1.2 Visual

Visual stimuli also control innate responses in communicating insects. Fireflies use luminescent signals for attracting mates (Lloyd, 1983). Butterflies use bright colors, iridescence, and polarized light in the context of long-range mate recognition and sexual selection (e.g., Vane-Wright and Boppre, 1993; Sweeney et al., 2003). Males of the hoverfly *Syritta pipiens* closely track the movements of conspecifics (Collett and Land, 1975), a skill that seemingly serves copulatory functions. Male flies of the genus *Lispe* perform a dancelike motion pattern during courtship that is seemingly perceived through vision (Frantsevich and Gorb, 2006). Visual cues enhance recruitment orientation to food sources in stingless bees (Nieh, 2004), that is, several species of these highly social insects exhibit local enhancement and orient toward the visual presence of foraging conspecifics (Slaa et al., 2003), a phenomenon also found in honeybees (Tautz and Sandeman, 2002) and wasps (D'Adamo and Lozada, 2005). Furthermore, stingless bees also appear to visually track the piloting flights of experienced conspecifics, and these movements can guide them for at least part of the distance to a food source (Esch et al., 1965; Esch, 1967; Kerr, 1969), although the role of learning in this intriguing form of recruitment has yet to be analyzed.

1.25.2.1.3 Mechanosensory

The use of air pressure waves, substrate-born vibrations, and touching is widespread in sexual selection, alarm and defensive behavior, and complex social interactions in insects (e.g., Webster et al., 1992; Fullard and Yack, 1993; Michelsen, 1999; Hölldobler and Roces, 2001; Virant-Doberlet and Cokl, 2004). Complex behaviors involving these types of signals vary considerably across species. Female crickets, for example, orient toward males by recognizing and localizing the sound signals they produce. Their auditory orientation emerges from mechanisms detecting species-specific temporal structures of the males' sound signals, as well as reactive motor responses to individual sound pulses (Webster et al., 1992; Stumpner and von Helversen, 2001; Hedwig and Poulet, 2004). Leaf-cutting ants are highly sensitive to substrate-borne vibrations (Markl, 1965) and possess stridulatory organs that produce such vibrations when the animals are engaged in leaf-cutting (Tautz et al., 1995; Hölldobler and Roces, 2001). It has been shown that these substrate-born stridulatory vibrations operate as short-range recruitment signals that enhance the effect of recruitment pheromones (Hölldobler and Roces, 2001).

Moreover, the exchange of liquid food by mouth is widespread among highly eusocial species of insects (Wilson, 1971), and these social interactions depend strongly on intense antennal contacts that occur between donor and food-receivers (Free, 1956; Montagner and Galliot, 1982). In the honeybee, antennal interactions are also important in the transmission of waggle dance information (Rohrseitz and Tautz, 1999). Ants recruit nest-mates to newly discovered food sources as well as possible nest sites by means of tandem running (Hingston, 1928), a behavioral mechanism that strongly relies on mechanosensory cues (e.g., Wilson, 1959; Hölldobler et al., 1974; Möglich et al., 1974; Traniello and Hölldobler, 1984). Camponotus ants returning from successful field excursions stimulate nest-mates through fast directed movements of their front legs or even their entire bodies, as well as food samples; they then present the nest-mates with their gasters, and tandem running begins between pairs of leaders and followers (Hingston, 1928; Hölldobler et al., 1974; Hölldobler and Wilson, 1990). Hölldobler (1974) and colleagues demonstrated that tactile signals from the follower's antennae are sufficient to trigger an ant's leadership behavior, and that the subsequent following behavior relies on mechanical stimulation based on contact with a leader's gaster. Tandem running is especially

interesting in the context of genetically programmed mechanosensory communication because it clearly exposes the bidirectionality of the communication process. It has recently been shown through the behaviors of both the leader and the follower in a pair of tandemly running *Temnothorax* ants how they depend on each other (Franks and Richardson, 2006), that is, there is an evident feedback between both ants that relies on mechanical stimuli and helps in maximizing the speed at which the two of them can travel their path. It remains open whether and how the follower gathers path-related information during tandem running that might subsequently be used in solitary excursions.

1.25.2.2 Learning in Communication

1.25.2.2.1 Chemical

Some animals imprint on salient aspects of their sensory world pre- and postnatally. Slave-making ants provide an interesting example of imprinting. These ants invade colonies of other ant species and transport the pupae back to their own nest. Adults emerging from these pupae behave and work for the slave-making species as if it were its own species (Isingrini et al., 1985; Carlin and Schwartz, 1989). Evidence indicates that this phenomenon depends on a process of imprinting, by which the slave ants learn to recognize the slave-makers as members of their own species. This process involves learning about the slave-makers' hydrocarbon cuticular profiles, a distinctive olfactory mark of the species. Apparently, imprinting is successfully accomplished when the hydrocarbon cuticular profiles of both ant species, the slave-makers and the slaves, do not differ markedly (Lenoir et al., 2001; D'Ettorre et al., 2002).

Communicating insects also benefit from anticipatory behavior based on simple associative principles. In the honeybee, for example, and probably also in many other social species, the exchange of liquid food by mouth, called trophallaxis, allows individuals to assign nectar odors with predictive values. Animals associate the odor (as the conditioned stimulus or CS) and the sucrose (as the unconditioned stimulus or US) present in the nectar they receive through these social interactions. This form of learning leads to long-term olfactory memories after a single learning trial – even when trophallaxis is brief – and the strength of association depends on CS and US intensity, as well as on the animals' past foraging experience (Gil and De Marco, 2005). Olfactory memories established in this manner may have important implications in the organization of foraging (Gil and De Marco, 2006): First, foragers and food-receivers may benefit from learned odors in searching for a transfer partner, eliciting trophallaxis, or even avoiding it; second, currently unemployed foragers as well as nonexperienced foragers may benefit from a highly prevalent CS available within the colony to resume their subsequent foraging flights (e.g., the higher the rate of encounter with a rewarding olfactory CS the higher the probability of flying out to search for the prospective nectar source).

1.25.2.2.2 Visual

Polistes wasps provide an example of selective learning, which develops around innate responsiveness to simple sign stimuli: the yellow-black patterns of the wasps' faces and abdomens (Tibbetts, 2002). These patterns vary across individuals and correlate well with a wasp's ranking in a colony's hierarchy based on body size and dominance. Manipulating them induces aggressive responses in staged contests between pairs of unfamiliar individuals, and subordinate wasps with experimentally altered facial color patterns are targets of considerably more aggression from the dominant individuals than sham controls (Tibbetts and Dale, 2004). The question of whether these observations reveal individual recognition in insects remains open, but the wasps' behavior in the staged contests indicates that these animals learn about visual signals of quality that convey information on conspecifics on the basis of a colony's inherent hierarchy. Another interesting example of visual learning involved in communication may arise from the dance behavior of the Asian honeybee, *Apis florea*. In contrast to *Apis mellifera* bees, these animals do not dance on a vertical plane, but on the flattened tops of their open combs, which are directly exposed to a view of the sky (Lindauer, 1956; Koeniger et al., 1982; Dyer, 1985). These bees orient their dances on the horizontal plane according to both celestial cues and landmarks (Dyer, 1985), and the bees that closely follow these communicating dances might use their vision to collect information from them.

1.25.2.2.3 Mechanosensory and combined modalities

The seemingly ritualized movements or dances that honeybees use to recruit nest-mates from the colony – or the swarm – to the location of a desirable resource involve multiple signals, including mechanosensory stimuli (von Frisch, 1967). The role of learning in the context of dance communication was initially

dismissed (Lindauer, 1952), but we shall see that this system's functioning may depend strongly on the structure and content of the honeybees' spatial memory.

Karl von Frisch (1946) revealed that a highly stereotyped, still variable motion pattern that honeybees perform on the comb surface conveys to the human observer the position of a well-defined target at the endpoint of an average vector in a two-dimensional egocentric system of coordinates. Since its early days, von Frisch's (1946) discovery was recognized as one of the most impressive achievements of twentieth-century behavioral biology. This motion pattern involves finely controlled repetitive movements and can therefore be described on the basis of its inherent, well-defined features: orientation in space and tempo. The term waggle dance denotes a form of this pattern that conveys information about targets located fairly far from the hive, whereas the term round dance refers to a slightly different form that the animals perform after returning from nearby locations (von Frisch, 1967). Honeybees also use other stereotyped motion patterns when engaged in cooperative work that have also been called dances (von Frisch, 1967; Seeley, 1998). For example, a honeybee may shake its body back and forth, also rotating its body axis every second or so, and walk slowly in all directions across the comb (Seeley 1992). This type of motion pattern has been called tremble dance (von Frisch, 1923), and it helps the colony members to coordinate their activities while handling the collected nectar, both outside and inside the nest (Seeley, 1992). When a forager returns from a highly desirable nectar source and has problems searching for a food receiver (a younger bee that receives its load and eventually stores it in the honeycombs) (Doolittle, 1907; Lindauer, 1952), it usually performs a tremble dance, which may last several tens of minutes. These dances are followed by a rise in the number of available food-receivers and a drop in recruitment of additional foragers to nectar sources, thereby helping the colony to maintain its rate of nectar processing matched with its rate of nectar gathering (Seeley, 1992). In another intriguing example of these dances, a honeybee remains stationary and briefly vibrates its body laterally at a frequency of 4–9 Hz, sometimes alternating brief periods of self-grooming. This pattern has been called the grooming invitation dance (Haydak, 1945) and increases the workers' chances of being rapidly groomed by a nest-mate (Bozic and Valentincic, 1995; Land and Seeley, 2004). These two later forms of dances, however, do not convey spatial information. Our focus is therefore on the waggle dance, which does convey spatial information and is perhaps the most intriguing form of these complex, iterative movements.

The homeostasis of a honeybee colony greatly depends on cooperative work and efficient communication (e.g., Lindauer, 1961). Compelling evidence indicates that the waggle dance is embedded in a series of communication systems that enables the colony to coordinate the activity of its members during foraging and nest-site selection (e.g., Seeley, 1995). Hence dancing honeybees have their own spectators. The colony members that keep close contact with a dancing bee, usually called dance followers or recruits, appear to detect a variety of signals emitted by the dancer and process them in such a way that their ensuing behaviors may greatly vary due to the content of these signals (von Frisch, 1967). Nevertheless, the way in which the followers detect the dance signals is not yet well understood, but the diversity of these signals indicates that multiple sensory modalities are involved in dance communication (Michelsen, 1999). Mechanical stimuli derived from the body contacts between dancers and followers are certainly involved, as well as environmental chemical cues brought into the colony by the dancers, and most likely also semiochemicals coupled to the dancer's wagging movements. Three-dimensional fields of air currents surrounding the body of the dancing bees and substrate-borne vibrations caused by the wagging movements of the abdomen also seem to play a role in dance communication (Esch, 1961; Wenner, 1962; von Frisch, 1967; Michelsen et al., 1987, 1992; Bozic and Valentincic, 1991; Kirchner and Towne, 1994; Tautz, 1996; Rohrseitz and Tautz, 1999). In addition to these external stimuli, propioceptive signals enable both dancers and followers to process mechanosensory information derived from the position of their body relative to the direction of gravity (von Frisch, 1967). Because the dance in *Apis mellifera* takes place on the vertical surface of the comb, the dancers have to transfer visual information gathered during their foraging flights to a reference system primarily defined by mechanosensory stimulation, a process called transposition also found in other insects (von Frisch, 1967). We shall focus on a few selected features of the waggle dance because they illustrate how learning may be involved in this form of social communication and also pose the question of how space is represented in the honeybee brain. Obviously, both

sides of the communication process, those from dancers and followers, must be taken into account if one is to understand what a successful follower actually learns from a dancing bee and how it combines the information available via the dance signals with that of its own spatial memory.

In the waggle dance (von Frisch, 1946, 1948, 1967), the dancer moves forward on the comb surface while moving its abdomen from side to side at about 15 times per second. This straight portion of the dance is called waggle-run. Without interruption, it then moves in a semicircular trajectory and returns to the starting point of its recent waggle-run; this portion is called return-phase. Once at this position, it repeats the forward, wagging portion of the dance. The dancer also tends to alternate clockwise and counterclockwise throughout successive return-phases. The followers tend to approach the dancer's body during the return-phase, which indirectly restricts the area on the comb in which the dance takes place, and if they begin following the dance maneuvers, their movements during a given return-phase will determine their subsequent position with respect to the dancer's body during the following waggle-run. Moreover, during the return-phase, dancers and followers interact repeatedly with their antennae and mouthparts, allowing mutual stimulation through chemical and mechanical signals. Finally, consecutive waggle-runs are performed with some directional scatter, which decreases when the distance to the indicated goal increases.

A major feature of the dance is that it can be triggered by different constellations of external stimuli, thereby conveying information about different types of goals. Honeybees dance for desirable sources of nectar and pollen (von Frisch, 1967), thus improving the colony's food collection (Sherman and Visscher, 2002), and also for water, essential to down-regulate the nest's temperature when the hive gets overheated (Lindauer, 1954). This undoubtedly speaks about how versatile the dance communication system is. But perhaps the most striking example of this versatility relies on its role during swarming (Lindauer, 1951, 1953, 1955). Upon leaving their old nest during a colony's seasonal division, honeybees rely on a complex group decision-making process for selecting a new nest site. Their ultimate success depends on an accurate, fast, and unified collective decision (Seeley and Visscher, 2004). During this process, numerous colony members locate and dance on the surface of the swarm for potential nest sites. The decision process thus relies on several groups of dancers indicating different sites and recruiting uncommitted bees to follow their own dancing; most of the swarm's members remain in place until all dancers achieve unanimity by indicating the same goal, then the swarm lifts off (Seeley and Visscher, 2004).

The number of dancing events varies across dances, thereby revealing the regulatory responses and amplification phenomena that operate on the signal production side of the communication process. The strength of the dance depends on the flow rate (Núñez, 1970) and sugar content (von Frisch, 1967) of the nectar that the dancers bring into the colony; the flown distance (Seeley, 1986) and the nature of the indicated goal, that is, either a nest site or a food source (Seeley and Buhrman, 2001); the colony's nectar influx (Lindauer, 1948; Núñez, 1970; Seeley, 1995; De Marco, 2006); the dancer's past foraging experience (Raveret-Richter and Waddington, 1993; De Marco and Farina, 2001; De Marco et al., 2005); and even weather conditions (Lindauer, 1948; Boch, 1956). Honeybees also adjust the rate of waggle-run production by modifying the duration of the return-phase based on specific properties of the indicated goal (Seeley et al., 2000; Seeley and Buhrman, 2001) and by means of signals derived from their interactions with their fellow mates (Lindauer, 1948, 1954; Núñez, 1970; Seeley, 1986; De Marco, 2006) and time-based cues coupled to the current foraging status of the colony as a whole (Lindauer, 1948, 1954; Seeley, 1995). These relations enable the dance communication system to be tuned according to both colony demands and availability of resource opportunities.

1.25.2.2.4 What is the information content of the honeybee waggle dance?

So far, we have briefly described the waggle dance as an intriguing example of multisensory convergence, central processing, and motor coordination. We shall now focus on how it relates to navigation. Flying bees are able to use the sun as a reference to maintain a course, a mechanism referred to as the sun-compass (von Frisch, 1967), and also recognize the sun's azimuth by the pattern of polarized light in the blue sky (von Frisch, 1949, 1967; Rossel and Wehner, 1984). They also compensate for the sun's time-dependent movement, even when neither the sun nor the pattern of polarized light is visible (Lindauer 1957, 1959). For this task to be accomplished, they must learn the sun's azimuth as a function of the time of

the day during their initial orientation flights (Dyer and Dickinson, 1996).

A waggle dance encodes the direction and distance of a goal. First, the average orientation of the successive waggle-runs relative to the direction of gravity approximates the angle between the direction toward the goal and toward the sun (von Frisch, 1949, 1967; Lindauer, 1963). Second, the average length of the waggle-runs increases together with the distance from the hive to the goal (von Frisch and Jander, 1957). Early studies suggested that a honeybee's estimate of the flight length depends on gauging the amount of energy expended while flying (Heran, 1956; Scholze et al., 1964). Cumulating evidence now suggests that honeybees gauge and control the distance that they travel by integrating self-induced optic flow during flight (i.e., the net amount of image motion over the retina accumulated during movement) (Esch et al., 1994; Esch and Burns, 1996; Srinivasan et al., 1996, 2000; Tautz et al., 2004; De Marco and Menzel, 2005). The functioning of this mechanism is not yet fully understood, but it seems to depend on flight height and initial calibration based on landscape features (Esch and Burns, 1996; Esch et al., 2001). These two correlations convey to a human observer the circular coordinates of specific locations in a two-dimensional space and also provide a direct access into the dancer's perceptual world.

Evidence indicates that some of the followers that keep close contact with a dancing bee subsequently fly the approximate direction and distance that the dance conveys to the researcher (Lindauer, 1967; Esch and Bastian, 1970; Gould, 1975; Judd, 1995; Riley et al., 2005). They also use additional cues (i.e., semiochemicals and visual cues provided by other colony members, as well as environmental odors) to pinpoint the location of the targeted goal (e.g., von Frisch, 1967; Tautz and Sandeman, 2002). Six decades after von Frisch's (1946) original discovery, however, the process of decoding information in the dance still remains obscure (Michelsen, 1999). Some reasons are probably to be found in the striking variability of the multiple dance signals (e.g., von Frisch and Lindauer, 1961; Esch, 1978), the rather suboptimal methods that have been used so far to record the movements of both dancers and followers, and the lack of suitable tools to track the behavior of the followers after they depart from the hive. Improvements arise along with new methods (see the following discussion).

However, it is also worthwhile to consider a general aspect of the dance communication system that has received little attention, namely, the interaction between two different sources of spatial information that the followers might be able to access simultaneously: (1) the actual dance signals and (2) their own spatial memory store, as derived from their previous flights and reward experience; we shall refer to this putative store as the animal's spatial knowledge. The interaction between these two sources of information refers to a fundamental question in any process of communication. Communication depends on reproducing at one point an abstract entity selected at and sent from another point, but the entity that is finally reproduced on the receiver's side also depends on stored variants of this entity, which the receiver computes together with the signals it receives from the sender. In other words, one needs to ask whether a follower recollects stored information while decoding information in the dance.

The extent to which individual honeybees are exposed to the waggle dance throughout their foraging life has been addressed only recently (Biesmeijer and Seeley, 2005). In their study, Biesmeijer and Seeley (2005) reported that no more than a quarter of an average bee's lifetime field excursions was preceded by dance following, and in most of the instances in which the bees did follow dances before resuming their field excursions, they did so by following those that appeared to be indicating the goals that they were already familiar with. These findings are in close agreement with previous results by von Frisch (1968), who reported that the followers' response to the dance depends on their background of experience with the indicated goal, and that dances for familiar goals lead to more effective recruitment. Biesmeijer and Seeley (2005) also reported that the honeybees with field experience followed an average of only two to four dance circuits before resuming their new flights to the target. This small number of dance circuits provides spatial information only roughly to a human observer (**Figure 1**) and poses the question how informative this sample can be to the followers (Haldane and Spurway, 1954). Taken together, the results of this study suggest that the most advantageous functioning of the dance communication system will depend not only on the dancer's ability to keep record and derive spatial features of its recent field excursion, but also on the follower's ability to acquire, store, and recall specific navigational memories in the dance context (Menzel et al., 2006).

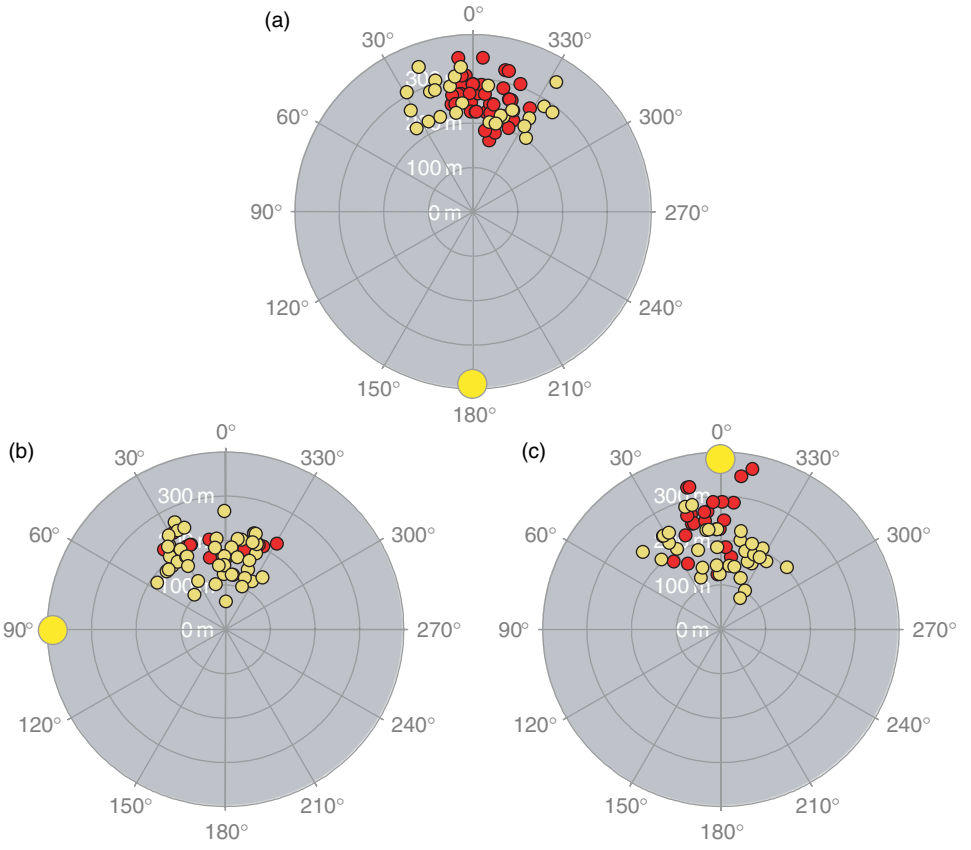

Figure 1 A waggle dance encodes the direction and distance of a goal: First, the average orientation of the successive waggle-runs relative to the direction of gravity approximates the angle between the directions toward the goal and toward the sun. Second, the average length of the waggle-runs increases together with the distance from the hive to the goal. These two correlations convey to a human observer the circular coordinates of specific locations in a two-dimensional space. The figure depicts radial maps indicating vectors' endpoints (in yellow and red) from waggle-runs performed by two dancing bees during single dances. These bees foraged regularly on a feeder placed 225 m west of an observation hive (52° 27′ 25″ N, 13° 17′ 46″ E) whose entrance pointed toward the north. In the radial maps, the direction of the feeder corresponds to 0°. Dances were video-recorded (at 88 frames s^{-1}) on the same day, in the morning (a), and the early (b) and late (c) afternoon, meaning that the sun (indicated by a yellow circle) was behind (a), to the side (b), or in front of the bees (c) during their flights toward the feeder, respectively. The coordinates indicated by the single waggle-runs are widely scattered around the actual position of the goal.

But is there any indication of some form of persisting spatial memory available to transitorily uncommitted honeybees (either dancers or followers)? Sometimes the waggle dance occurs in the absence of foraging. Under these conditions, it is performed in accordance with the current position of the sun and without any view of the sky, even during the night. These dances encode spatial information about goals that the dancers would have visited if they were guided by their sense of time (Lindauer, 1957, 1960; von Frisch, 1967). Furthermore, dancers seem to recall information related to goals visited several weeks earlier and estimate, at night, the closest goal in time after being trained to two different feeding places at two different times during the day (von Frisch, 1967). It follows, therefore, that honeybees use persisting memories to control their dances, which can be retrieved by specific stimuli (e.g., odors associated with the prospective goal) and whose content is appropriately combined with the time of day and complexes of signals that determine the animal's overall motivational state. The retrieval of long-term spatial memories has been observed in navigating bees (e.g., Menzel et al., 1998, 2000), but its appropriate incorporation into the dance context

poses additional questions. One of these questions is whether the waggle dance conveys to a follower only the approximate direction of and distance to the goal, or whether it also encodes a constellation of signals embedded in the follower's spatial knowledge, built throughout its previous flights and organized by reference to topographical features of the hive's surroundings. The structure of the spatial memory in honeybees will be addressed in the section titled 'Memory Structure'; we shall see that there is convincing evidence indicating that navigating bees may benefit from a topological representation of the environment, or a maplike spatial memory. It is thus conceivable that if honeybees are able to store spatial memories linked to specific locations in the field, and perhaps memories on specific features of their targets (e.g., food availability at a certain time of the day), the dance followers might also be able to combine information available through the dance with information from their own spatial memory, either already associated with the goals being indicated or in spatial relation to landmarks embedded in the seemingly topological structure of their spatial memory. What kind of spatial memory may be necessary for the waggle dance to encode information on past goals? How do these memories develop throughout the dancer's foraging life? These questions refer to the cognitive complexity underlying dance communication in honeybees. Future research on dance communication will certainly profit from the analysis of the interplay between the process of encoding and decoding spatial information in the dance and the structure and content of the honeybees' spatial memory.

1.25.3 Navigation

The term navigation denotes an animal's ability to efficiently travel between at least two specific distributions of concurrent signals (locations), even without having sensory access to the signals that define its targeted location. This notion removes any reference to the sensory modalities involved in gauging compass directions and distances and the control of the motor programs underlying the subject's locomotion. For the location to be reached, therefore, a navigating subject must be able to detect whether or not the immediate distribution of signals available within its current sensory horizon corresponds to the location it has been traveling to, a process that, in principle, only depends on innately stored information and programmed responses. In most animal species, however, survival involves moving regularly from and to several locations. It follows that to cope with such a complex navigational task, the single distributions of signals defining these locations (available from either idiothetic or allothetic sources or from both) must be stored in specific forms of persistent memories. Differences in the content and the organization of these complexes of memories may arise as long as task complexity varies across taxa.

1.25.3.1 Typology

Different classification schemes are used in the analysis of spatial behavior. Kühn's (1919) attempt to conceptualize orientation mechanisms on the basis of the relationship between sensory stimuli and an animal's response to them is an early example of these schemes. In recent decades, research on spatial behavior has also nurtured the development of biologically inspired artificial navigation systems. This gave researchers an opportunity to classify several theoretical accounts of spatial behavior within a single unifying framework centered on the structure and content of the information used by the navigating agents. The ensuing classification schemes are based on task complexity and experimentally tested features of an agent's spatial behavior (Trullier et al., 1997; Franz and Mallot, 2000); they tend to be purposely broad, ignore endogenously coordinated performances, and dissect complex behaviors found in nature into motor programs that can be reliably implemented in artificial systems. Although somewhat crude, these typologies provide a suitable basis for analyzing basic strategies of spatial behavior, feature detectors, and navigation learning. Their most salient characteristic is that they account for complex navigational tasks by means of hierarchically organized, interacting strategies. For example, Trullier et al. (1997) conceive taxes (Kühn, 1919; Fraenkel and Gunn, 1961) as the basic machinery of all navigating agents and then distinguish between local navigation and way-finding. Local navigation accounts for orientation in the immediate environment, where the agent acts based on information available within its perceptual range, whereas way-finding involves moving in a large-scale environment, where relevant cues lie beyond the perception range, and the goal is not in the immediate environment. Technically speaking, each of these categories can still be divided into several levels: search,

direction-following, aiming and guidance for local navigation, and recognition-triggered responses, topological, and survey navigation for way-finding (Franz and Mallot, 2000). Due to their hierarchical organization, way-finding relies on local navigation, but it is not yet clear how these strategies may interact in the brain, or how animals recognize specific locations, let alone how they may assign specific identities to these locations, a prerequisite of some high-level navigational tasks. Evidence indicates, however, that a hierarchical array of seemingly different, interacting strategies underlies the spatial behavior of some species of navigating insects (Wehner et al., 1996; Menzel et al., 2005). In the present context, we will use this basic typology to survey the structure and content of the spatial memory used by desert ants and honeybees, because data from these two navigating insects are frequently discussed using different terminologies and approached from different conceptual frameworks.

1.25.3.2 Navigation in Desert Ants

Desert ants of the genus *Cataglyphis* live in subterranean nests surrounded by relatively flat and featureless areas. They forage individually and travel over distances of hundreds of meters along circuitous paths during their foraging excursions. After grasping a food item, they quickly return in a straight line to the proximity of the starting point of their journey, where they finally break off their homeward runs and start a systematic search aimed at pinpointing the entrance of the nest; avoiding overheating is crucial in their environment. These ants primarily benefit from path integration (Mittelstaedt and Mittelstaedt, 1980), also referred as to dead-reckoning (*See* Chapter 1.12), to accomplish their remarkable homing performances (Wehner, 1992; Collett and Collett, 2000). This means that a navigating ant iteratively computes all its rotational and translational motion components, integrating them into a sort of global vector (Wehner, 2003) that connects, at any time, its current location and that of the starting point of the excursion. This navigation strategy can easily be revealed by displacing the animal over some distance; after being released, it chooses a compass direction and walks an approximate distance that brings it to a predictable, virtual reference point (Pièron, 1904; Santschi, 1911).

Desert ants appear to inexorably compute this type of vectorial information and are incapable of using more than one vector simultaneously. They benefit from inverse forms of these home vectors and efficiently move from the nest to previously visited field locations. Global vectors also appear to be stored and recalled in accordance with specific contexts, meaning, for instance, that when a returned ant is moved back to a recently visited location, it does not apply its recent home vector to once again navigate its way to the nest. Instead, it uses a systematic, time-consuming search strategy to find the nest's entrance (unless it navigates in familiar terrain offering conspicuous landmarks, as we will see). Under these circumstances, however, the information about its recent home vector does not disappear, and the ant is able to subsequently use an inverse form of it to quickly find its way to the previously visited location. This indicates, in turn, that path integration information is transferred from some form of working memory into a different, more persisting memory stage, from which it can be later recalled on the basis of context-dependent signals (Wehner, 2003).

In order to use path integration, a desert ant must be able to align its trajectory with a locally available compass direction and to reliably acquire distance information. *Cataglyphis* ants do not acquire directional information by means of idiothetic sources, such as an inertial compass or proprioreceptive signals; they do it using a celestial compass based on a specialized set of polarization-sensitive ultraviolet receptors located within a particular portion of the retina (Wehner, 1994, 1997), which detect the pattern of polarized light in the blue sky (Wehner and Müller, 2006). The functioning of this celestial compass involves an internal ephemeris function (Wehner and Müller, 1993) and demands recalibrations due to the inexorable changes in the pattern of polarized skylight that take place during the day. Desert ants do use idiothetic sources to compute translational motion: Distance information appears to be gauged by means of a step integrator (Wittlinger et al., 2006), and the control of distance by self-induced optic flow seems to be only slightly modified under specific test procedures (Ronacher and Wehner, 1995). These two path-related components – distances and directions – are combined via some sort of accumulator, the state of which encodes the ant's current coordinates relative to the reference point. The task of surveying the possible computational boundaries of this hardwired accumulator lies beyond the scope of this chapter (for comprehensive accounts of this issue, see Wehner 1997, 1999, 2003). In the present context, let us simply say that its functioning directly depends on locomotion (Seidl

et al., 2006), that it must process distance and compass information simultaneously (Sommer and Wehner, 2004), and that it allows an ant to gauge the ground distance while traveling undulating paths (Wohlgemuth et al., 2001; Grah et al., 2005). Its output can also be combined with external, sensory cues, thereby reducing search costs and improving the ants' general foraging strategy (Wolf and Wehner, 2000, 2005). This accumulator or path integrator also appears to continuously process information, that is, when homing ants are captured at the nest's entrance and displaced several times in a row to the initial position of their homeward runs, they move away from their reference location (the proximity of a virtual nest) when transferred to a featureless test channel (Andel and Wehner, 2004).

The findings described earlier illustrate how path integration, a basic local navigation strategy, enables *Cataglyphis* ants to reliably find the proximity of a virtual nest in unfamiliar terrain. Things are different in familiar terrain, however. The use of landmark-based information improves the efficiency of an ant's path integrator because the number of inaccurate alignments increases together with the length of the animal's excursion (Wehner and Wehner, 1986). Due to these unavoidable computational errors, a cross talk between path integration and guidance decreases the chance of missing the goal (Collett and Collett, 2000). Provided with an irregular environment, homing ants use landmarks while on their way to the nest's immediate surroundings (Bregy and Wehner, 2003; Knaden and Wehner, 2005), thus following well-defined paths or routes (Collett et al., 1992; Wehner et al., 1996; Kohler and Wehner, 2005). Moreover, it has recently been shown that they can also use memories of minute ground features to pinpoint the entrance of the nest (Seidl and Wehner, 2006). Guidance, therefore, leads navigating ants to locations where they have acquired a certain egocentric relationship with respect to a specific configuration of external signals (Wehner et al., 1996; Collett and Collett, 2000). They thus take advantage of a store of reliable landmark-based memories, which can be associated with specific motor routines and recalled in the appropriate context, and exhibit goal-directed movements at different locations (Collett et al., 1998; Collett and Collett, 2000, 2002; Åkesson and Wehner, 2002). Research on other ant species (e.g., Jander, 1957; Graham and Collett, 2002; Wehner et al., 2006) also provides evidence of local navigation and even more complex navigation strategies based on (1) the recognition of a catchment area from which a configuration of landmarks is perceived to be identical, (2) successful orientation within this area, and (3) the subsequent selection of a goal-directed movement. These strategies, therefore, rely on the combination of several recognizable areas associated with specific goals and directed actions (Barto and Sutton, 1981; Trullier et al., 1997; Collett and Collett, 2000).

The study of navigation in desert ants has led to a remarkable understanding of the basic mechanisms that these animals use for setting a directional bearing in the field (Wehner, 2003). Experience-dependent behavioral flexibility is conceived as a calibration process of path integration computations. Next, a context-dependent recollection of path integration coordinates may eventually lead to the ants' seemingly idiosyncratic routes. Landmarks provide information about turns to make and distances to travel next (Collett, 1996, 1998; Collett and Collett, 2000; Kohler and Wehner, 2005), such that seemingly complex performances might be based on simple rules that depend on learning sensory-motor routines. This is frequently referred to as procedural learning. Traditional thinking on ant navigation therefore conceives a toolbox of sensorimotor routines, whose stepwise application enables the animals to solve seemingly complex navigational tasks. Moreover, the recollection of single vectors does not require an overall representation of multiple locations, and the selection of goal-directed actions may exclusively depend on innately stored, calibrating information. This corresponds to the fact that ants do not appear to make decisions involving equivalent options. The question remains how ants use external signals to map several recognizable places. None of the current approaches to navigation in several ant species has yet reached the level of analysis achieved in the study of homing by desert ants, let alone the principles of navigation learning in walking insects.

Honeybees also exhibit procedural learning. They learn to negotiate complex mazes of adjacent boxes by associating colored disks with right or left turns, for example (Zhang et al., 2000; Srinivasan and Zhang, 2004), and also refer to compass directions in their dances on overcast days (von Frisch, 1967; Dyer and Gould, 1981). The latter result reveals that landmarks serve as a backup system, which conveys direction information to navigating bees and poses the question of how external signals are actually incorporated into the bees' representation of space (Gallistel, 1990). Interpretations from the study of ant navigation have often been transferred to bees. In

contrast to ants, however, bees fly over distances of a few kilometers, cruising well aboveground; they also use depth information extracted from motion parallax (Lehrer, 1996) and learn about the absolute size of landmarks (Horridge et al., 1992). Furthermore, honeybee foraging behavior involves a remarkable diversity of responses, including those underlying cooperative work during food gathering (see earlier discussion). When an experienced worker forages on a given flower species, for example, it leaves the colony and flies toward its targeted location for a certain amount of time, without interrupting its flight even when alternative flowers of the same species might be within reach. Once this motor program is extinguished, it begins searching for the flowers it recognizes according to their odors, colors, and shapes and inspects them by means of specific motor commands that allow it to efficiently find and collect the offered nectar (von Frisch, 1967). Meanwhile, it adjusts its estimate of how much nectar ought to be collected (Núñez, 1966). Finally, it initiates its return flight to the hive. Although exaggeratedly simplistic, this scheme illustrates an intriguing feature of the honeybee foraging strategy: each animal leaves the colony with a large – and diverse – amount of information, which is used in context-specific ways and involves expected outcomes of particular behaviors. The contexts are defined by both time and space, a fact that becomes strikingly evident when bees forage on multiple locations throughout the same day. Furthermore, there is a cross talk between navigation and collective foraging (see earlier discussion), which involves specific responses to numerous features and dynamic components of the animal's sensory world. As we shall see next, the repertoire of navigational performances in honeybees is far from simple. Together with complex modulatory processes, learning is at the heart of the animals' navigation skills.

1.25.3.3 Navigation in Honeybees

Foraging honeybees usually follow straight flight trajectories between specific locations and the hive (Beutler, 1954; von Frisch, 1967). If they are caught at the moment they depart from the hive and then released at a different spot in the field, they fly in the direction they would have taken if they had not been moved to the release site, meaning that they fly in the correct compass direction but along a false route relative to the goal they were originally traveling to. They perform in a similar manner when caught at the beginning of their homeward flight. Once again, they fly in the predisplacement compass direction which might have connected their foraging location and the hive, but along a false route with respect to the actual location of the colony (Wolf, 1927; Menzel et al., 2005). The bees' flown distances and compass bearings in this type of experiment resemble the global vectors observed in desert ants (see the section titled 'Navigation in desert ants'), supporting the view that honeybees also use vector memories that develop through their regular flights. Furthermore, when bees arriving at a foraging spot are held captive for several hours, they subsequently fly farther outward from the hive along the same hive-target direction (Dyer et al., 2002). After being trained along a fixed route, therefore, vector memories will reliably guide honeybees back to the hive and toward specific field locations; unless they have been artificially displaced.

In fact, navigation research in flying hymenoptera has long been based on displacement experiments and the analysis of the animals' homing abilities (Tinbergen and Kruyt, 1938; Thorpe, 1950; von Frisch, 1967; Tinbergen, 1972; Menzel et al., 2000, 2005). If navigating bees only rely on global vectors and random searches, displaced foragers might have trouble rapidly finding their way back to the colony. They do return home when released at a new, unexpected location, however, and they do it reliably and relatively fast when released within the range of approximately 1 km from the hive (Capaldi and Dyer, 1999; Menzel et al., 2000). Consider the following experiment: One group of bees was trained to forage on a stationary feeder placed 300 m away from the hive, and another group was trained to forage on a close feeder that rotated around the hive at a constant radius of only 10 m. Hence, the foragers from the latter group had not experienced a flight vector connecting the hive and a fixed, distant foraging location. However, despite lacking this experience, they returned home equally well from various possible directions and as quickly as the animals from the former group, which had experienced a predisplacement route training (Menzel et al., 2000). Furthermore, the results of this experiment could not be explained by reference to local navigation strategies, due to the lack of landmarks in the vicinity of the hive and the actual distance to the different released sites (Menzel et al., 2000). This indicates that successful homing in honeybees does not necessarily depend on a random, time-consuming search strategy. Recently, radar traces of the full flight

trajectories of displaced honeybees revealed that the last phase of homing is eventually accomplished by straight, goal-directed flights toward the hive (Menzel et al., 2005), supporting the view that honeybees are able to store and retrieve allocentric cues that help in defining compass directions in the field (Menzel et al., 1998).

The results described, in addition, pose the question of how the forager's working memory is organized and what role its content actually plays during navigation. Path integration is the subject of computational errors (Benhamou et al., 1990) and controls navigation as long as the animal combines it with multiple environmental cues. It is therefore reasonable to ask how landmarks provide honeybees with a basis for accurate homing. The complexity underlying such a strategy still remains open. How does it rely on guidance? How many configurations of landmarks can be processed and stored? How much does the animal perceive about these configurations, and how does it relate them? Are sequentially learned configurations generalized in such a way that they can be categorized, or counted, or even embedded into a more general, combined representation of space (Menzel et al., 2006; *see also* Chapter 1.12)? These questions are also at the heart of a long-lasting controversy (Wehner and Menzel, 1990), namely, whether navigating insects have at their disposal only minimal cognitive modules enabling them to store and retrieve ordered sequences of context-dependent actions (Wehner, 1999), or whether they also store and retrieve relations among points, lines, and surfaces somehow embedded in an internal representation of space (Menzel et al., 2006; *see also* Chapter 1.12 for a detailed account of this issue). Answering these questions, however, would only be possible after revealing the mechanisms underlying what we now merely label as specific responses to specific configurations of external signals, such as the response of a navigating bee to a familiar visual scene. Consider the term snapshot (Cartwright and Collett, 1983), for example; it denotes an insect's memory of visual landmarks, and it helps in formulating hypotheses based on matching algorithms and behavioral data, but its neurobiological basis is yet to be established. Similarly, we simply do not know how multiple and complex procedures might be combined in a common spatial memory store.

One of the reasons that led to differences in conceptualizing navigation in flying insects lies in the fact that most experiments were performed with animals trained along fixed, predisplacement routes and subsequently observed only during their initial postdisplacement flight paths. Most likely, only the motor routines based on the actual content of the animals' working memory can be revealed in this manner. The bees' exploration of the environment, however, does not begin with flights along fixed routes, which develop relatively late in the animals' foraging careers, and it is the spatial memory that develops during the bees' exploratory flights that might supply the animals with information for successful homing when vector memories fail. Therefore, an important aspect related to the questions listed earlier might be at stake – how spatial behavior develops.

Honeybees begin foraging only after executing a series of exploratory flights of increasing lengths (Becker, 1958; Vollbehr, 1975; Winston, 1987; Capaldi and Dyer, 1999), normally on several consecutive days (von Frisch, 1967). Using harmonic radar, Capaldi et al. (2000) showed that when honeybees are engaged in these exploratory flights, they keep the trip duration constant, but fly faster with increased experience of the terrain, so that the later flights cover a larger area than the earlier flights. Each flight, in addition, is typically restricted to a well-defined, narrow sector around the hive, and changes in this respect appear to be related to the number of previous flights. Taken together, these results indicate that early flights provide honeybees with repeated opportunities to become exposed to different landscape features (including the hive's position) from different viewpoints, supporting the view that they may store landscape information in a progressive fashion (Capaldi et al., 2000). At the individual level, however, the ontogeny of these flights remains a mystery, and the question of how the animals use information available throughout successive flights is still unanswered.

Tracing the full flight trajectories of free-flying bees allows evaluation of the complexity of the animals' spatial memory, and this is now possible using harmonic radar techniques (Riley et al., 1996). Menzel (2005) and colleagues recorded more than 200 flight trajectories in this manner (Menzel et al., 2005) and analyzed the flight paths of three different groups of animals: (1) honeybees that had been trained to forage on a stationary feeder located 200 m east of the hive, thereby repeatedly following a well-defined predisplacement route; we shall call them SF-bees; (2) honeybees trained to forage on a feeder that circled around the hive within a distance of 10 m, thereby experiencing no route prior to

displacement; here we call them VF-bees; and (3) honeybees that lacked training and had closely followed a waggle dance for the feeder placed 200 m east of the hive; we shall call these bees R-bees. Three phases of navigation can be distinguished among these groups of honeybees (Menzel et al., 2005): (1) vector flights, (2) circuitous flights, and (3) straight homeward flights. Vector flights were apparent in the SF- and R-bees, but not in VF-bees. Those from SF-bees showed compass directions and distances that matched the predisplacement route, and those from R-bees matched the spatial information that the waggle dances conveyed to a human observer (Riley et al., 2005). Hence, it follows that, when accessible, route memories are invariably applied first, and vector flights are based on directions and distances from these memories. The circuitous flights showed multiple returns to the release site and to the end of the vector flights in the case of SF- and R-bees. During this phase, the flight speed was significantly lower than during phases of straight flights. These flights were also considerably longer for the SF- and VF-bees (carrying full crops) and shorter for R-bees (captured before getting in contact with any sugar reward), suggesting that this type of motion might not only underlie a process of reorientation (necessary after displacement), but also some sort of exploratory behavior (Menzel et al., 2005).

The honeybees from all these three groups returned to the hive by means of fast, straight homeward flights, and a detailed analysis of the straightness of these flights led to a clear distinction between the second and third navigation phases, thereby revealing the field locations where the straight homeward flights began (Menzel et al., 2005). They originated along different directions relative to the hive's position and usually began far outside a radius of 60 m, where the animals might have used visual cues to find their way back to the colony by means of aiming or guidance or both. Furthermore, they also began at locations with conspicuous, artificial landmarks, and when these landmarks were either displaced or removed, the animals were equally successful during homing. The most consistent hypothesis that accounts for these homing performances is that the ground structure itself provided the displaced honeybees with reliable information to find their way back to the hive (Menzel et al., 2000, 2005). Most significant is this: A third of the SF-bees made straight and fast flights directed not only to the hive but also first to the feeder and then to the hive (**Figure 2**). This latter result fits well with a

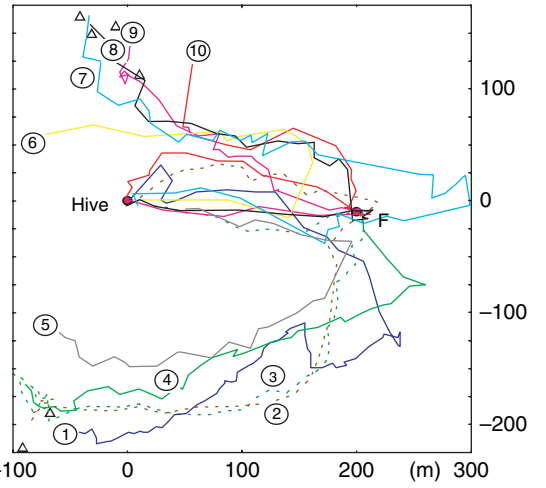

Figure 2 The homing flights via the feeder. Ten SF-bees (of the 29 bees tested under similar conditions) performed their homing flights via the feeder. Bees released south of the hive are shown by flight paths 1–5, and those released north of the hive are indicated by flight paths 6–10. The bee from flight path 4 landed at the feeder and flew to the hive after filling its crop. All bees were tested with the normal arrangement of tents under sunny weather conditions (for details see Menzel R, Greggers U, Smith A, et al. (2005) Honeybees navigate according to a map-like spatial memory. *Proc. Natl. Acad. Sci. USA* 102: 3040–3045).

topological representation of the environment (Trullier et al., 1997) and can also be explained by two mutually related hypotheses. First, homing bees might be able to integrate at least two vector memories. Assume the following premises: (I) they are able to associate vector memories defining homeward flights with specific configurations of external signals, and (II) when exposed to these signals, the corresponding vector memories can be recollected from a memory store. Next, if two of these memories are simultaneously recollected and transferred to the animal's active working memory, they might be combined to steer a seemingly new flight trajectory. The second hypothesis can be thought of as a more complex form of the first one. It assumes that the bees' orientation flights, together with their initial foraging excursions, lead to a memory of a network of several homeward vectors connecting specific distributions of external signals, including the hive's location. Such a process is believed to be possible in mammals and birds (Gallistel, 1989; O'Keefe and Nadel, 1978).

These concepts are closely interconnected to several issues about the honeybee dance communication

system, somehow embedded in the following question: Do dancers and followers have analogous memories? When von Frisch (1967) compelled honeybees to fly a two-legged detour path to reach an artificial feeder, the trained animals indicated in their dances the direction of a straight line toward the goal. They might have computed this compass direction from the two legs of the detour, but they also indicated the actual flown distance, and not the distance of the segment connecting the feeder and the hive. Thus the bees encoded in their dances the direction of a virtual flight vector, but not its length (von Frisch, 1967). This poses the question whether it is the outbound or the inbound flight or both that provides the dancer with the spatial information that is finally conveyed to the human observer. If spatial information available during the homeward flight (a directional bearing, for example) can successfully be incorporated into the dancer's maneuvers, the waggle dance might also be capable of conveying information that the dancer (and probably also a follower) has already linked to a specific spot in the field. It follows, therefore, that the efficiency of the dance communication system would greatly depend on the way in which both dancers and followers acquire, store, and retrieve navigational memories.

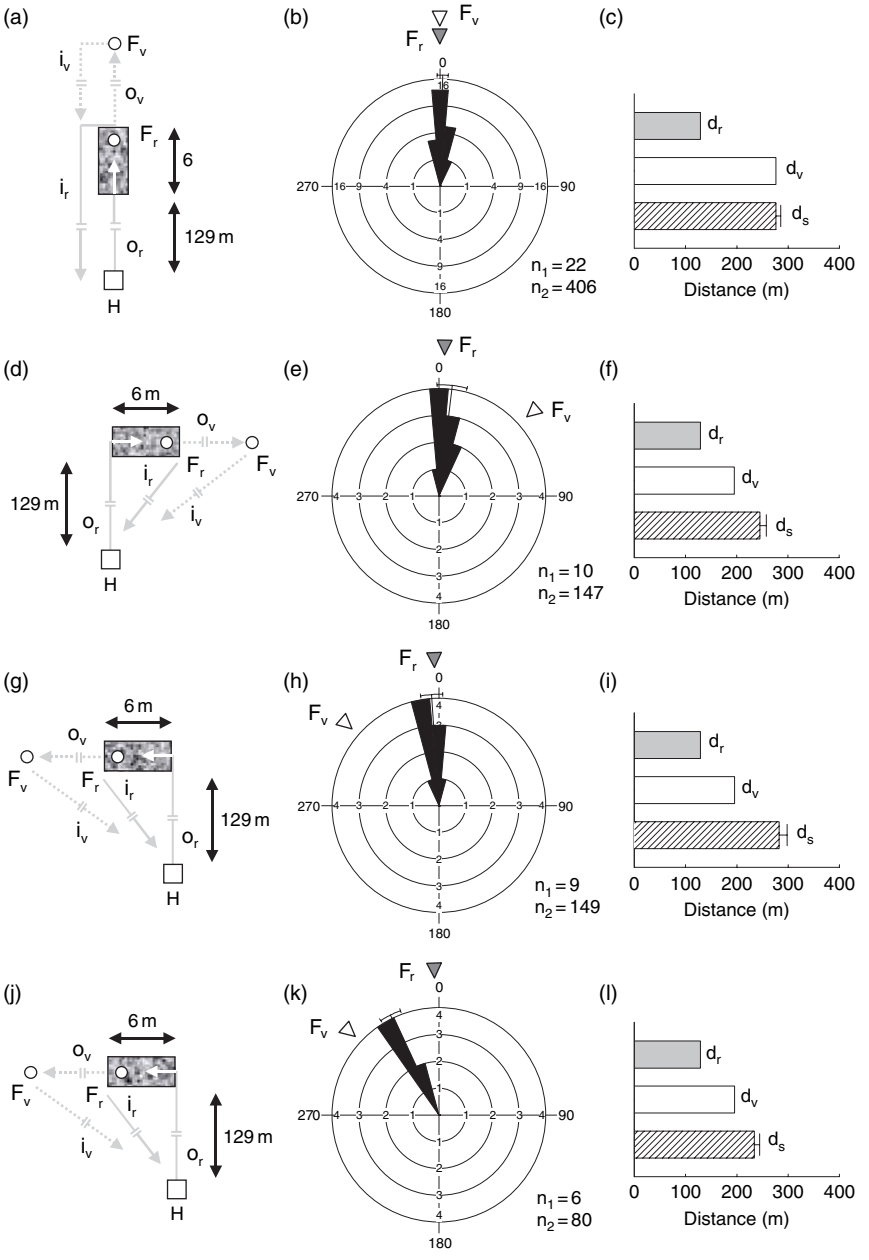
Behavioral studies of self-induced optic flow in honeybees (e.g., Srinivasan et al., 1997) take advantage of the following fact: Flying a short distance close to a surface gives the same integrated optic flow as flying a longer distance further from the surface. As a result, when honeybees fly through narrow tunnels with visually textured walls, they experience a subjectively flown distance that is greater than that actually flown (Srinivasan et al., 1996), also indicating a longer distance in their dances (Srinivasan et al., 2000). This allows manipulation of a bee's navigational experience of a subjective flight path (De Marco and Menzel, 2005). Honeybees perform longer waggle phases when they fly through a visually patterned tunnel on their outbound flight (**Figure 3(a)–(c)**). Thus, when the tunnel is set perpendicular to the straight line connecting its entrance and that of the hive, a mismatch arises between the animals' estimate of the goal's location (derived from path integration information from the outbound flight) and its actual location in the field. Under such conditions, the bees' waggle dances indicate a direction close to that of the straight line connecting the hive and the actual goal's location (**Figure 3(d)–(i)**), and the virtual detour has no significant effect on the duration of the bees' homeward flights, indicating that they fly directly back to the hive after leaving the tunnel through its far end. Moreover, path integration coordinates appear to be more strongly weighted in the dance maneuvers only with increasing experience of the terrain (**Figure 3(j)–(l)**), thus supporting previous interpretations (Otto, 1959; Edrich and Scheske, 1988) of the relationship between information available on-site and the encoding of direction in the dance. These results indicate that (1) a discrepancy between subjective measures of distances and directions and path integration coordinates already linked to visual scenes has no significant effect on the triggering of the waggle dance, and (2) the process of encoding spatial information in the dance involves detecting and processing such a discrepancy (De Marco and Menzel, 2005). It is not yet clear to what degree honeybees might refer in their dances to the inbound component of their journeys, or whether they embed the encoding spatial information in the dance into their maplike spatial memory.

1.25.3.3.1 Memory structure

It appears that honeybees develop spatial memories in three different contexts: (1) during their initial orientation flights, (2) while flying repeatedly from and to a specific field location, and (3) while following dances. We refer to these memories as (1) the general landscape memory, (2) the route memory, and (3) the dance memory, respectively. Note that the term general landscape memory makes no assumptions about the structure of the spatial information accessible through it, and that route memories may involve vector memories as well as procedures based on sequences of context-dependent actions. This typology, therefore, denotes processes not yet understood, but accounts for predictable actions. These memories might have different properties. Route memories provide information about directions and distances, and the same may be true for a dance memory, although the extent to which the latter may be combined with spatial information accessible from the bees' memory store remains an open question. Honeybees seem to transfer these two memory forms into their active working memory and apply them first. Once applied, however, they lose their influence on behavior. The directional component of these memories, in addition, is susceptible to updates according to changes in the animal's motivation. When at least two route memories are accessible, it becomes feasible to recognize that they have been linked to landmark-based information.

This led to the concept that honeybees use their route memories to estimate the sun's azimuth (von Frisch, 1967; Dyer and Gould, 1981), and that they may integrate at least two of them under specific circumstances (Menzel et al., 1998, 2005). The general landscape memory might be thought of as a structure of several recognizable locations within the range of the animals' orientation flights. It might arise through the integration of information provided by two or more route memories (Menzel et al., 2005) or by a process by which the bees innately store specific distributions of external signals and assign them specific identities based on idiothetic and allothetic cues. According to these hypotheses, honeybees may use their general landscape memory only when their active working memory has no access to route or dance memories.

The concept of multiple memories hierarchically organized is a generally accepted mind-set in neurosciences. Implicit and explicit knowledge, or



declarative and nondeclarative knowledge, develop from the various learning strategies, which involve various brain structures in mammals, including humans (Cohen and Squire, 1980; Packard and McGaugh, 1996; Schroeder et al., 2002; Chang and Gold, 2003). Navigation in mice and rats, intensively studied with respect to the role of the hippocampus and striatum, is actually embedded in a convincing theoretical framework, whereas hippocampal place cells are responsible for orientation based on specific distribution of signals and sequences of experiences that help in defining geometric relations among landmarks, and the striatum is responsible for those forms of learning based on signals sent by the goal (O'Keefe and Nadel, 1978; Moser and Paulsen, 2001; McNaughton et al., 2006; Witter and Moser, 2006). It might be interesting to evaluate whether and how the seemingly different navigational memories described earlier rely on the various neuronal structures in the bee brain. What can be behaviorally tested in the near future is whether dance memories are coupled to the general landscape memory.

1.25.3.4 Insect Migrations

Several insect orders exhibit far-distance movements referred to as migrations (Drake and Gatehouse, 1995). Populations of butterflies, moths, dragonflies, and locusts are seasonally engaged in far-distance migrations (e.g., Williams, 1958; Johnson, 1969; Holland et al., 2006). Costs and adaptations have long been addressed in migrating insects (e.g., Rankin and Burchsted, 1992), but the selective forces behind these movements are not yet fully understood. The distribution of offspring across a range of areas and conditions favorable for future reproduction might have played an important role in the evolutionary development of these movements (Wilson, 1995; Holland et al., 2006). At least two distinctive features of these far-distance movements distinguish them from the regular excursions of the central place (Orians and Pearson, 1979) foraging hymenopterans (i.e., bees, wasps, and ants). First, return migration has yet to be documented in insects (Holland et al., 2006), meaning that with a few exceptions (e.g., Urquhart and Urquhart, 1979), migrating individuals do not perform round-trip journeys that bring them into the areas from which they previously departed (Holland et al., 2006). In monarch butterflies, for example, several generations are produced during their northward migrations (Brower, 1995, 1996). Second, although migrating insects compensate for wind drift and maintain a heading using the sun compass (Srygley and Oliveira, 2001; Mouritsen

Figure 3 Experimental layout and results of an investigation of the encoding of spatial information in the waggle dance. A visually patterned tunnel was used to create a virtual detour. By compelling the bees to fly through such a tunnel, set up outdoors in various configurations, it is possible to add a virtual distance to the journey from the hive to the feeder – either straight ahead or to the right or left. Bees were trained to forage on a feeder placed at the far end of a 6-m-long, 30-cm-wide, and 30-cm-high tunnel. The tunnel's entrance was located 129 m away from the hive, and its walls and floor were decorated with a random visual pattern. (a) Experimental arrangements first had the tunnel oriented at 0° with respect to the direct line connecting its near entrance and the hive (h). The bees flew through the tunnel during their outbound flights (o_r) but not during their inbound flights (i_r). F_r and F_v correspond to the real and the virtual location of the feeder (white circle), respectively; whereas o_v and i_v correspond to the virtual outbound and inbound flights, respectively, as derived from the overestimated distance flown inside the tunnel. (b) Distribution of the individual mean directions signaled in the waggle dances recorded in the tunnel experiment described in (a), mean vector direction $\mu = 1.33°$, $r = 0.99$, $P < 0.001$, n_1 (number of animals analyzed) = 22, n_2 (number of waggle-runs analyzed) = 406. The frequencies within 10° class ranges are shown as the areas of the dark wedges. The dark spoke and segment indicate the mean vector μ and 95% confidence interval, respectively. The gray and white arrows indicate the directions toward the real (F_r) and the virtual (F_v) feeders shown in (a), respectively. (c) Shown are the flown distance (mean ± SE) signaled in the waggle dances recorded in the tunnel experiment described in (a) (d_s, striped bar), the distance to the virtual feeder (d_v, white bar, in this case equivalent to the signaled distance), and the real distance from the hive to the food site (d_r, gray bar). (d–f) Experimental arrangements and results as in (a–c) with the tunnel rotated 90° to the right. The distance flown inside the tunnel oriented at 0° (c) was used to compute the location to be signaled (F_v: direction and d_v: distance) if the global vector computed by the path integration of the outbound flight provides the dancers with the spatial information encoded in the waggle dance. In (e), mean vector direction $\mu = 6.77°$, $r = 0.98$, $P < 0.001$, $n_1 = 10$, $n_2 = 147$. (g–i) Experimental arrangements and results as in (d–f) with the tunnel rotated 90° to the left. In (h), mean vector direction $\mu = 356.1°$, $r = 0.99$, $P < 0.001$, $n_1 = 9$, $n_2 = 149$. (j–l) Experimental arrangements and results as in (g–i), obtained with the experienced bees. In (k), mean vector direction $\mu = 333.99°$, $r = 0.99$, $P < 0.001$, $n_1 = 6$, $n_2 = 80$. The reader will find a detailed description of this experiment in De Marco RJ and Menzel R (2005) Encoding spatial information in the waggle dance. *J. Exp. Biol.* 208: 3885–3894.

and Frost, 2002) and possibly also a magnetic compass (Etheredge et al., 1999), their flight routes depend strongly on atmospheric conditions and seasonal wind patterns (e.g., Rainey, 1951, 1976; Kanz, 1977; Drake and Farrow, 1988; Gatehouse, 1997; Chapman et al., 2002). It thus appears that insect migration is basically controlled by innate mechanisms and does not rely on learning, although the genetic control of flight direction in migrating insects has yet to be confirmed (Holland et al., 2006).

1.25.4 Conclusions and Future Prospects

We have argued that a distinction between instinctive and learned behaviors, a fundamental issue in behavioral research, is not possible without thoughtfully considering the interplay between an animal's possible phylogenetic boundaries and the sources of the external signals that belong to its specific sensory world, simply because the effects of learning on a subject's performance will always be superimposed onto those of its phylogenetic boundaries. We also claimed that it is in the context of communication and navigation that learning transcends elementary forms of association in particularly clear ways. Communication and navigation in insects have been extensively studied on the sensory processing level, but the structure and content of the spatial knowledge underlying such phenomena have yet to be addressed. This might be particularly feasible in honeybees, due to their extensive behavioral repertoire, which also seems to involve decisions, and their small, experimentally accessible brains, which allow the study of system-level neural correlates of learning and memory. In honeybees, in addition, these two behavioral domains appear strictly related to each other via the famous waggle dance, although their relation is not fully understood. We have explored new findings (Menzel et al., 2005) indicating that the spatial knowledge used by honeybees to navigate within the range of their orientation flights is much more complex than hitherto thought. Several interacting – and probably competing – memory systems seem to be at work. These findings also raise questions about the process of encoding and decoding information in the waggle dance (De Marco and Menzel, 2005). We reviewed published data (von Frisch, 1968) and recent evidence (Biesmeijer and Seeley, 2005) suggesting that the spatial knowledge available to followers is also involved in dance communication and that learning might be at the heart of this impressive communicating system. The flight paths of navigating bees can now be traced with radar techniques. Mechanical models of dancing bees and virtual environments allowing navigation experiments under controlled experimental situations can also be developed. Thus tools are available to tackle these questions.

1.26 Spatial Learning in Fish

C. Salas, C. Broglio, E. Durán, A. Gómez, and F. Rodríguez, Universidad de Sevilla, Sevilla, Spain

1.26.1 Introduction

Fish represent the largest and most diverse vertebrate radiation. Members of this taxonomic group have inhabited the earth for more than 500 million years, occupying an immense range of aquatic habitats and ecological niches and achieving an enormous diversity of morphological and functional adaptations. The prevailing views on vertebrate brain and behavior evolution have largely considered fish as the most primitive and least evolved vertebrate group. According to these rooted evolutionary notions that dominated neuroscience virtually to the present, vertebrate brain and behavior evolution occurred in successive stages of increasing complexity and advancement (fishes, amphibians, reptiles and birds, and finally mammals, to reach the superior cerebral and cognitive level of humans). In this context, fishes were thought to have developed relatively simple neural circuits allowing only elemental forms of behavior and extremely limited cognitive capabilities. Consequently, their behavior was considered as essentially reflex or instinctive. However, during the last few years a wealth of new comparative developmental, neuroanatomical, functional, and behavioral evidence has strongly contradicted this anthropocentric and misleading view, showing that vertebrate brain and behavior evolution has been far more conservative than previously thought. The new evidence shows that fishes exhibit a wide assortment of highly sophisticated behavioral and cognitive capabilities (Rodríguez et al., 2006), indicating that these vertebrate groups share with land vertebrates (including birds and mammals) a number of brain and behavioral organization features (for reviews, see Nieuwenhuys et al., 1998; Broglio et al., 2005; Butler and Hodos, 2005; Striedter, 2005; Salas et al., 2006). We review here the evidence available on spatial learning and memory capabilities in fish and on their neural basis. For this review, we concentrate mainly on ray-finned fishes and especially the teleost fish, because considerably more research has been conducted on this taxonomic group, which makes up nearly half of all vertebrate species.

1.26.2 Spatial Cognition in Fish: Observations in the Natural Environment

Naturalistic studies show that fishes, similar to mammals and birds, possess impressive spatial abilities for orienting, piloting, and navigating (*See also* Chapters 1.21, 1.25). Although traditionally research in this field has been focused mainly on the description of the innate fixed patterns of behavior and on the study of sensory and ecological factors involved in navigation, a number of naturalistic studies suggest the possibility that fish spatial behavior is a flexible and adaptive process that involves a variety of cognitive phenomena and diverse learning and memory mechanisms (for reviews, see Dodson, 1988; Kiefer and Colgan, 1992; Quinn, 1992; Dittman and Quinn, 1996; Odling-Smee and Braithwaite,

2003). For example, many fish species are territorial and remain within a restricted home range, guarding sites and resources from competitors (Hallacher, 1984; Matthews, 1990a; Kroon et al., 2000), whereas others perform intercontinental migrations (Quinn and Dittman 1990; Dittman and Quinn, 1996). Foraging, reproduction, and predator avoidance require accurate knowledge of the spatial distribution of resources, mates, and refuge areas obtained through spatial learning and memory and based on well-developed orientation and navigation capabilities (Dodson, 1988; Brown and Laland, 2006; Kelly and Magurran, 2006; Odling-Smee et al., 2006; Warburton, 2006; Witte, 2006).

Some fish species accomplish large-scale navigation, including transoceanic migrations, and spatial learning and memory could play an important role in this ability (for a review, see Quinn, 1982; Dodson, 1988). One of the best-studied long-distance migratory fish is the salmon. Salmon return to their natal stream for reproduction after long foraging migrations in the sea, and during these migrations, they travel through diverse habitats such as oceans, lakes, and rivers. The precision of the salmon homing ability is remarkable, with approximately 95% of the ocean survivors returning to their natal streams (Quinn and Dittman, 1990; Dittman and Quinn, 1996). A variety of navigational mechanisms underlie salmon migration and homing. Salmon navigation in the open ocean seems to be based on the use of celestial and magnetic compasses as well as on olfactory cues and pheromone tracking (Quinn and Dittman, 1990; Dittman and Quinn, 1996). Navigation based on odor memories associated with their natal-stream sites seems to be essential during the final freshwater phase of the migration (Scholtz et al., 1976; Hasler and Scholtz, 1983; Hansen et al., 1993; Unwin and Quinn, 1993; Pascual and Quinn, 1994; Heard, 1996; Hard and Heard, 1999). Home-stream odor imprinting appears to occur at the time of peak thyroid hormone levels during the smolt transformation process that prepares salmon for ocean navigation (Morin and Doving, 1992; Hasler and Scholtz, 1983). However, odor learning also seems to take place many times during migration, and thus salmon can use a sequence of learned odors to guide the homeward journey (Quinn, 1985; Hansen et al., 1987; Dittman and Quinn, 1996; Heard, 1996).

Other interesting examples suggesting well-developed spatial cognition capabilities in fish are provided by experimental studies conducted in natural environments. For example, studies on homing behavior showed that relocated intertidal rockpool fishes are able to accurately return to familiar hiding places even after 6 months of absence (Aronson, 1971; Green, 1971; Griffiths, 2003). The benthic fish *Ulvaria subbifurcata*, which lives in small home ranges, can home even after displacements of several hundred meters (Green and Fisher, 1977). Furthermore, this work showed that fish were significantly well oriented in the homeward direction at the release time, suggesting that they were able to determine their actual location with respect to home. Some sedentary and territorial rockfishes of different species, displaced from their home sites, navigate back home from long distances, in some cases even more than 20 km away (Carlson and Haight, 1972; Hallacher, 1984; Quinn and Ogden, 1984; Markevich, 1988; Matthews, 1990a,b).

Fish discover and remember the location of profitable food patches and prey location by exploration and individual sampling as well as by observing other foragers (Hart, 1986; Pitcher and Magurran, 1983; Pitcher and House, 1987; Hart, 1993; Warburton, 2006). Learning and remembering the location of particular food patches and mapping their status and renewal rates, as well as identifying and remembering the predation risk associated with different locations, improve fish foraging efficiency and survival probabilities. For example, butterflyfishes (*Chaetodontidae*) follow predictable paths as they swim from one food patch to another within their territories. When a coral outcrop is removed, the fish look for it in its former location before resuming their route along the reef (Reese, 1989). For these displacements, Reese (1989) suggested that butterflyfishes use a system of spatially learned route-specific landmarks, possibly in conjunction with sun compass orientation, and a cognitive map of their territories. Brown surgeon fish (*Acanthurus nigrofuscus*) undergo daily migrations of up to 1.5 km to feeding and spawning sites apparently following a sequence of landmarks (Mazeroll and Montgomery, 1998). Interestingly, the migrating brown surgeon fish changed direction in accordance with the position of experimentally displaced landmarks. The reliance of the migrating brown surgeon fish on particular landmarks could be reduced by moving the landmarks more than 6 m from their original location; nonetheless, the animals still accurately navigate to the feeding or spawning sites after key landmarks had been manipulated, suggesting that there were redundancies in the cues used.

Social transmission of foraging routes provides other interesting examples of the role of learning and cognition in fish spatial behavior (Hobson, 1972; Ogden and Ehrlich, 1977; Gladfelter, 1979;

MacFarland, 1980; Mainardi, 1980; Helfman, 1981; Helfman et al., 1982; Helfman and Schultz, 1984). For example, French grunts (*Haemulon flavolineatum*) introduced to new schooling sites and initially allowed to follow residents in their displacements, rapidly learn to use the novel foraging routes even in absence of the residents (Helfman et al., 1982; Helfman and Schultz, 1984). Laland and Williams (1997, 1998) reported that naïve guppies could learn a route to a foraging patch by observing and following experienced fish. When the experienced fish were removed, the observers continued using the same routes even when alternative itineraries were available. Warner (1988, 1990) reported culturally transmitted migratory traditions in bluehead wreasse (*Thalassoma bifasciatum*). These coral reef fish establish mating-site locations that remain constant over several generations. The experimental replacement of entire local populations led to the use of new sites, which remained constant over subsequent generations.

Field studies and experiments in natural environments provide a broad range of suggestive observations and raise interesting insights into the biological and ecological significance of fish spatial cognition capabilities. Frequently, however, given the enormous difficulty of defining, isolating, and controlling important variables in the field, these studies do not provide clear-cut conclusions on the nature of the cues and spatial strategies being used by the fish. Thus, controlled laboratory experiments are called for, as they can overcome some of these difficulties and provide optimal conditions to reveal the mechanisms that fish use for orientation and navigation.

1.26.3 Exploration and Environment Investigation

Fish apply systematic exploration in unfamiliar environments in order to acquire spatial knowledge. When introduced into a novel environment, most fish display an intensive exploratory activity, which progressively decreases. This decrease could correspond to a state in which the processing of the initial spatial information has been completed (Wilz and Bolton, 1971; Poucet et al., 1986; Thinus-Blanc et al., 1987). For example, when introduced into a novel environment, goldfish engage in an organized and systematic pattern of exploration, avoiding previously visited locations (Kleerekoper et al., 1974; Rodríguez, 1996). After performing a few ample initial turns near the edges of the tank, the fish thoroughly explore a particular area before moving to the next one, in a rather systematic way, thus exploring the entire tank (**Figure 1**). This pattern of exploration, area by area, which is never replaced by random exploration, requires some degree of spatial memory. According to this view, through its exploration behavior, the goldfish becomes familiar with a new environment faster when salient visual cues reduce the spatial (geometric) ambiguity of the environment (Warburton, 1990). A similar pattern of exploratory activity has also been observed in fish foraging in their natural environment. The planktivorous reef fish, the stout-body chromis (*Chromis chrysurus*), use a local search strategy consisting in swimming in a circuitous and stereotypic pattern over a specific foraging region, completing the search before moving to the next foraging area (Noda et al., 1994). The use of such an organized search pattern prevents revisiting depleted foraging areas and provides the basis for exploring and mapping unfamiliar areas.

In addition, the rate of activity of different species of fish correlates inversely with the degree of environmental novelty. Moreover, the fish show increases in exploratory activity in response to changes in familiar environments, indicating that these animals detect environmental modifications, be it in the location of the objects or in the identity of the objects themselves (Breder and Halpern, 1946; Breder, 1950; Welker and Welker, 1958; Russell, 1967; Kleerekoper et al., 1974). Blind cave fish (*Anoptichthys jordani*) orient and navigate accurately in the environment and can find a well-known place in the tank, even when that place is not directly accessible (Campenhausen et al., 1981). Interestingly, the swimming behavior of the blind cave fish differs in familiar and unfamiliar environments. When introduced into an unfamiliar environment, and also after alterations of a well-known one, these fish swim through it for several hours, exploring the surfaces of the walls and objects, using their lateral line to sense self-induced perturbations in the surrounding flow field. For this activity, fish increase their swimming speed, supposedly to optimize the stimulation of the organ of the lateral line. Campenhausen and coworkers suggested that during this high-speed swimming phase blind cave fish build a memory representation of the environment (i.e., an internal map). Once the representation has been elaborated, the fish can rely on this internal map to navigate and therefore can reduce the swimming speed below the optimal required by the lateral line organ,

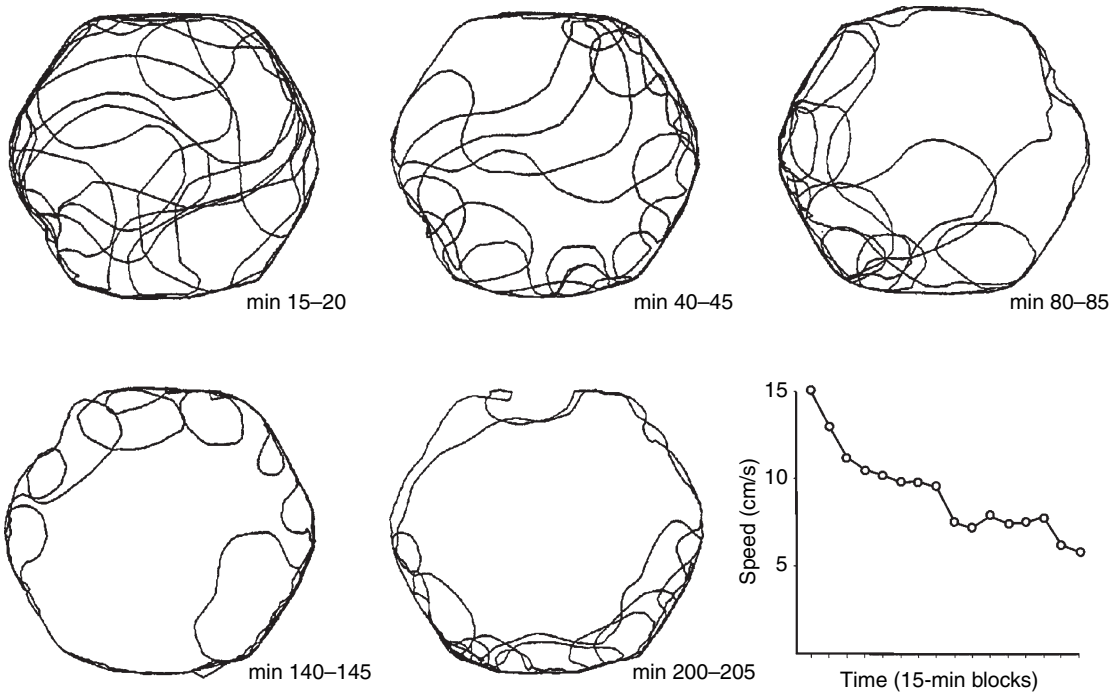

Figure 1 Exploratory behavior in goldfish. Examples of the exploratory pattern of a goldfish during a 4-h session of free exploration in a large open field. Each figure shows the fish trajectories during 5-min intervals throughout the session. Note the organized and systematic pattern of exploration area by area. The plot in the bottom right shows the mean swimming speed during the entire session of exploration in consecutive 15-min blocks.

without observable deficits in avoiding obstacles (Campenhausen et al., 1981; Teyke, 1989). Note that accurate navigation at speeds that are suboptimal for lateral-line organ stimulation implies that fish are using the internal map via feedback from senses other than those primarily used for map development (Demski and Beaver, 2001). Some additional evidence supports this hypothesis. For example, blind cave fish react by increasing swimming speed when changes are introduced in a familiar environment, such as the removal or the displacement of a familiar cue or the introduction of new objects in a well-known tank (Campenhausen et al., 1981; Teyke, 1985; Burt de Perera, 2004b). Teyke (1985) showed that the duration of the exploratory activity of the blind cave fish, *Anoptichthys jordani*, depends on the shape of the experimental tank, with bilaterally symmetrical tanks explored during longer periods of time than asymmetrical tanks or tanks in which objects have been introduced near the walls in asymmetrical positions (Teyke, 1985). Burt de Perera (2004a) showed that blind cave fish, *Astyanax fasciatus*, are able to remember the order of a landmark sequence. The ability to represent the order in which a series of places are spatially linked could be a mechanism that allows these animals to orient beyond the limits of their perceptual range. In addition, Teyke (1989) obtained evidence suggesting that the elaboration of these hypothetical internal maps by blind cave fish is a memory phenomenon that occurs in two phases, an initial volatile phase (short-term memory) and a resistant phase after consolidation (long-term memory). In fact, Teyke (1989) showed that if the fish is anesthetized by cooling only 4 h after the exploration of a new environment, when the animal recovers from the anesthesia it explores that environment again as if it were a completely unfamiliar one. However, a reactivation of the exploration is not observed when the anesthesia is produced 6–30 h after the habituation to the environment.

1.26.4 Spatial Learning in Fish: Cues and Strategies

Fish use diverse sources of spatial information, such as self-generated movement cues from different sensory modalities, directional cues that polarize the

environment, or positional landmarks that enable inferring the place locations relative to distances, angles, and the geometry of objects within an array (Thinus-Blanc, 1996; Burgess et al., 1999; Jacobs, 2003).

Teleost fish learn spatial tasks using visual cues and landmarks (Huntingford and Wright, 1989; Rodríguez et al., 1994; Girvan and Braithwaite, 1998; López et al., 1999; Hughes and Blight, 2000), as well as using nonvisual senses, such as olfaction (Quinn, 1985; Hansen et al., 1987; Dittman and Quinn, 1996; Heard, 1996), audition (Tolimieri et al., 2000; Simpson et al., 2004, 2005), the lateral line system (Campenhausen et al., 1981; Teyke, 1985, 1989), or electrolocation (Cain et al., 1994; Cain, 1995). Fish also use a variety of sources of directional information to orient and navigate, for example, sun position (Schwassmann and Braemer, 1961; Goodyear and Ferguson, 1969; Goodyear, 1970; Hasler, 1971; Loyacano et al., 1971; Goodyear and Bennet, 1979), polarized light (Dill, 1971; Davitz and McKaye, 1978; Hawryshyn et al., 1990), the earth's magnetic field (Kalmijn, 1978; Quinn, 1980; Quinn and Brannon, 1982), or water flow direction (Jonsson et al., 1994; Kaya and Jeanes, 1995; Smith and Smith, 1998; Girvan and Braithwaite, 2000; Braithwaite and Girvan, 2003; Hunter et al., 2004).

Fish learn and remember the location of profitable food patches. Pitcher and Magurran (1983) showed that goldfish (*Carassius auratus*) remember the spatial position of food patches in a tank and are able to shift to a different foraging strategy when the location of the feeders has been changed. The spined sticklebacks (*Gasterosteus aculeatus*) remember which of two patches were baited with food during training for at least 8 days (Milinski, 1994). Atlantic salmon (*Salmo salar*) trained in an artificial stream remembered the location of two feeding sites in the stream and were able to shift between these two alternative sites to continue feeding (Gotceitas and Godin, 1992).

A number of pioneering studies provide notable evidence on fish spatial learning and memory capabilities. For example, Aronson (1951, 1971) reported that gobiid fishes learn and remember the geographic features of their environment. The tide-pool-dwelling gobiid fish *Bathygobius soporator* leap with surprising accuracy from one pool to another, jumping over ledges and other obstacles. Although neighboring pools are not visible at the onset of the leap, the fish rarely, if ever, jump onto dry land, suggesting that these animals build a precise memory representation of the local topography during high tide. More recently, it has been reported that black-eye gobies (*Coryphopterus nicholsi*) increase their accuracy in escaping to their burrows if they previously had the opportunity to become familiar with the environment (Markel, 1994). Animals that were allowed to spend additional exploration time in the test tank were quicker to find the burrow. In addition, when the burrow position was shifted to a new location, the more experienced animals took longer than the less experienced fish to find the shifted burrow, suggesting that they have learned the spatial location of the burrow.

Goldfish use landmarks as direct cues or beacons but also are able to learn more complex spatial relationships and to use visual cues as indirect spatial reference points (Warburton, 1990), and they can also learn to swim in a constant direction relative to visual cues, even when their approach to the goal is from the opposite direction (Ingle and Sahagian, 1973). These abilities could reflect the capability of fish to discriminate spatial relationships in the environment independently of a body-centered reference system. Goldfish are able to use the visual angle of a familiar landmark to locate a food source (Douglas, 1996). Goldfish trained to search for food buried 20 cm from a landmark still searched in the correct location when the food was absent. Halving either the width or height of the landmark resulted in searches significantly closer to the landmark, suggesting that these animals determined their position relative to the landmark using their horizontal and vertical visual angles. In addition, fish use route-based orientation strategies, that is, a learned sequence of cues or an algorithm based on a sequence of turns (Braithwaite, 1998).

Roitblat et al. (1982) showed that Siamese fighting fish need fewer trials to learn a T-maze task when it is compatible with a win-shift strategy (i.e., to avoid revisiting the previously depleted maze arms) than in another task compatible with a win-stay strategy (to visit previously visited maze arms repeatedly). Mammals and birds typically use a win-shift strategy when solving T-maze tasks (Dember and Fowler, 1958; Uster et al., 1976; Olton et al., 1977; Withem, 1977; Kamil, 1978; Olton et al., 1981). More recently, it has been reported that spined sticklebacks (*Spinachia spinachia*) and corkwing wrase (*Crenilabrus melops*) can readily use visual cues to locate food sources in a radial maze and adequately track renewal frequencies and site productivity. These animals distinguished between renewable food sources differing in productivity, preferentially visiting those

containing more food. Fish showed preferentially win-shift strategies, avoiding recently visited locations, but switched from win-shift to win-stay strategies when appropriate (Hughes and Blight, 2000).

Roitblat et al. (1982) analyzed features of the Siamese fighting fish's (*Betta splendens*) spatial memory strategies using an aquatic version of a procedure widely used to test spatial memory in mammals, the Olton eight-arm radial maze (Olton, 1979). In this procedure, the optimal performance is achieved when the animals visit each arm only once, as the previously visited arms have already been depleted of the reinforcer. This study showed that although the performance of Siamese fighting fish in this task is characterized by a strong algorithmic component, it also involves some measure of spatial memory. The fish showed a strong tendency to choose the adjacent maze arms, turning in a consistent direction, either clockwise or counter-clockwise. This algorithmic behavior plays an important role in the sequential choice of the arms. However, the algorithmic component alone does not completely explain the performance of the *Betta splendens* in this radial arm maze task, and memory of the recently visited places is necessary to explain the fish's accurate behavior. Roitblat et al. (1982) suggested that the algorithmic component of the fish behavior in these training conditions could represent a choice strategy more than memory limitations. The fish could be using a list of the previously visited and already depleted arms or a list of the baited arms (probably including three or four items). That is, although the fish may be able to remember more information, in the Olton task they use the apparently rigid, but highly efficient, algorithmic search pattern, shadowing the use of spatial memory. In a follow-up experiment, the same researchers confirmed the participation of short-term memory in the Siamese fighting fish's performance in the radial arm maze procedure. They used a standard procedure consisting of confining the animals in the maze's central platform between choices 4 and 5 during periods of 0 s (no confinement), 30 s, and 5 min. This procedure assesses the memory component relative to the algorithm component in the eight-arm maze performance: Because the accuracy of the algorithm-based performance depends on a continuous chain of choices, any interference would restart the algorithm, increasing the number of errors after the interruption. Thus, it can be expected that the interruption by itself, independently of the confinement time, will produce greater deleterious effects if the performance only depends on a strategy based on algorithms. On the contrary, if the performance has a memory component, the effects of the interruption *per se* will be smaller, and they will depend on the duration of the confinement period. The results of this test showed that the performance accuracy depended on the duration of the confinement period as it deteriorated progressively with increasing durations. This indicates that the fish retain information on their previous choices for some time during the confinement period (spatial working memory). More recently, Hughes and Blight (1999) provided converging evidence as they observed that 15-spined sticklebaks and corkwing wrasse adopted an algorithmic strategy to solve an eight-arm maze task consisting of visiting every third arm in absence of spatial cues, but in the presence of visual cues they used spatial memory. The imposition of a delay within trials reset the algorithm, decreasing foraging behavior efficiency, but the delay in itself had no effects on performance if spatial cues could be used.

1.26.5 Separating Egocentric and Allocentric Navigation

A growing amount of evidence indicates that fish, like land vertebrates, are able to orient and navigate using a variety of cognitive mechanisms based on distinct spatial learning and memory systems (*See also* Chapters 1.20, 1.21). Fish use multiple, parallel spatial learning and memory systems to orient and navigate that show distinctive properties and depend on separate neural substrata. These multiple spatial orientation mechanisms range from simple reflex egocentric orientation mechanisms and stimulus–response simple associations to allocentric, map-like representations of the environment.

Several experiments provide direct evidence on the use of multiple spatial learning strategies in fish. For example, Rodríguez et al. (1994) aimed to ascertain whether goldfish are able to use egocentric (turn) or extramaze visual cue–based navigation strategies. The fish were trained to locate a baited feeder in a four-arm maze surrounded by an array of widely distributed distal visual cues, in one of the three following tasks (see **Figure 2(a)**):

1. an egocentric task, in which two opposite start arms were randomly used (50% each), but for all trials, the goal arm was determined by a fixed-turn

relative to the start arm (e.g., always right). As the extramaze cues were irrelevant for solving the task, this procedure made it possible to determine whether or not the fish could choose the correct arm on the basis of a particular turn response.

2. an extramaze visual cue task, in which two opposite start points were also randomly used (50% each), but the fish were always rewarded in the arm with the end located in a determined, stable place in the room. This procedure was used to determine whether or not the fish could learn to go to a rewarded place solely on the basis of the information provided by widely distributed (extramaze) cues. No fixed-turn direction was relevant to task solution, because, depending on the location of the start-box, the subjects were required to make a left- or a right-hand turn.

3. a mixed egocentric–extramaze visual cue task, in which the fish, in contrast to the procedures described previously, always left from the same start box and were rewarded exclusively in a goal arm ending in another constant place. This task thus allowed selecting the correct arm on the basis of a specific turn direction and/or extramaze cues.

The animals in all the groups quickly learned to reach the goal (**Figure 2(b)**). Interestingly, although the fish in the different groups achieved similar levels of performance, the transfer and probe tests revealed that these animals were using very different spatial strategies.

The test trials revealed that the goldfish trained in the extramaze visual cue procedure navigate directly to the rewarded place regardless of start position and swimming direction, even during the trials when the maze was displaced and they were required to start from previously unvisited locations (**Figure 2(d)**). In addition, these animals were able to accurately reach the goal when the extramaze cues were individually removed but not when all of them were occluded by a curtain that surrounded the maze (**Figure 2(c)**). The fish trained in the egocentric task also performed with accuracy, although they used a very different strategy. These animals mainly chose the arm corresponding with the fixed 90° turn learned during training, independently of the starting point and maze location (**Figure 2(d)**). Moreover, the performance of these animals was not affected by removing any one of the extramaze cues or all of them simultaneously. Thus, the choices of these animals were purely egocentric, and the environmental information was not taken into account for selecting the arm. Moreover, the results of the ego-allocentric group indicate that fish are also able to use both types of strategies (body-centered orientation and extramaze visual cue–based navigation) simultaneously, to solve spatial tasks, and use one or the other according to task requirements (**Figure 2(d)**). The use of both types of strategy simultaneously could explain the tendency of this group to perform more accurately and steadily than the other groups.

López et al. (2000a) also obtained evidence on the simultaneous and cooperative use of multiple spatial learning strategies in fish. In this study, goldfish were trained in a mixed place-cue procedure to find food at the end of a maze arm that occupied a constant room location, and that was, in addition, signaled by a distinct intramaze visual cue (**Figure 3**). That is, the fish were trained in a test environment where they could simultaneously rely on the spatial information provided by the extramaze distal landmarks and on a single intramaze cue that directly indicated the location of food. Subsequent probe trials were conducted in which the two sources of spatial information were set in conflict (the local cues were switched between sides; **Figure 3(a)**) or one of the two sources, the extramaze distal cues or the intramaze proximal cue, were removed (**Figure 3(b,c)**). When the intramaze visual cue was eliminated, the goldfish were still able to locate the goal using a place strategy based on the information provided by the extramaze visual cues (**Figure 3(c)**). Conversely, when the use of the extramaze distal visual cues was precluded by means of a curtain that surrounded the maze, the animals relied exclusively on the intramaze visual cue signaling the goal during training to accurately reach the goal (**Figure 3(b)**). These results indicate that goldfish implement place and guidance strategies simultaneously to solve spatial problems, and that they switch from one strategy to the other depending on the available information. Convergent results were obtained using a different apparatus and experimental procedure (Salas et al., 1996b; López et al., 1999; see **Figure 4**). Goldfish trained in a spatial constancy task or in a cue task to locate a goal in a small, stimulus-controlled enclosure, where only proximal visual cues were available, implemented guidance (orientation) or spatial relational strategies according to task demands. Whereas the performance of the fish in the cue task was dramatically impaired when the cue associated directly with the goal was removed (López et al., 1999), goldfish in the spatial constancy task navigated accurately to the goal from different start locations regardless of route direction and response requirements (Salas et al., 1996b) and despite the partial deletion of any subset of visual cues (López et al.,

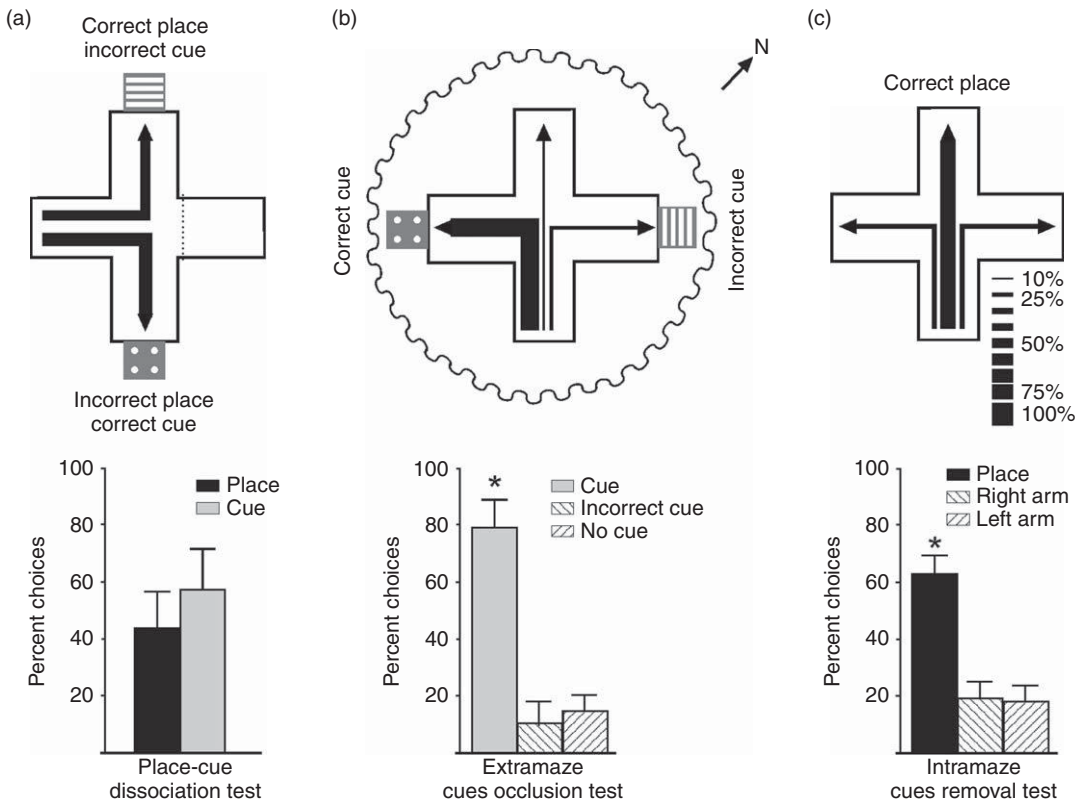

Figure 3 Simultaneous use of multiple spatial learning strategies in goldfish trained in a mixed place-cue procedure in a plus maze. In this experiment, the goal was in the arm end situated in a constant location in the room, and was, in addition, signaled by an intramaze visual cue. The figure shows the results of three different probe tests conducted following learning: (a) place-cue dissociation test; (b) extramaze cues occlusion test; (c) intramaze cues removal test. In the upper diagrams, the arrows show the trajectories chosen during each test from the start position, and their relative thickness denotes the percentage of times that each choice was made. The histograms show the mean percentage of choices to the various arms. Asterisks denote significant differences. Modified from López JC, Bingman VP, Rodríguez F, Gómez Y, and Salas C (2000a) Dissociation of place and cue learning by telencephalic ablation in goldfish. *Behav. Neurosci.* 114: 687–699.

Figure 2 Spatial learning strategies used by goldfish to find a goal in a plus arm maze. (a) Schematic diagrams of the four training procedures. The arrows mark the most appropriate trajectory from the start to the goal (asterisks) for each group. Note that for the extramaze cues and egocentric tasks two opposite start positions (50% each) were employed (see text for more details). The fish in the control group left from a start box always situated in a fixed place of the room. However, their training involved two possible correct goals, which were randomly assigned across trials. This group was used to ascertain whether or not the goal was reached by attending to odor or other uncontrolled variables. (b) Mean percentage of correct choices of goldfish trained in the four different experimental conditions, during acquisition, overtraining, and reversal of the task. (c) Percentage of correct choices when one salient cue was hidden or removed from the room and when all distal cues were removed by curtains surrounding the maze. The percentage of correct choices during training is also shown for comparison. (d) Trajectories chosen by the animals in the different groups during training and transfer trials. Once the animals learned their task, transfer tests were run to elucidate whether the animals of the different groups solved their respective tasks on the basis of turn or place strategies. In the type 1 transfer tests, the maze remained in its usual position but the animals were released from a novel start position. In the type 2 tests, the maze was displaced in the room in such a way that the end of one arm was located in the same place where the fish was rewarded during training trials, but the start positions were different from those used during training. The numbers and the relative thickness of the arrows denote the percentage of times that a particular choice was made. The dashed lines indicate the position of the maze before it was displaced for type 2 tests, and the asterisks mark the goal location. The histograms on the right show the accumulated mean percentage of choices for both types of transfer tests. Note that the animals in the allocentric group consistently chose the arm with the end at the place rewarded during training trials. In contrast, the arm most frequently chosen by the fish in the egocentric group was the one coinciding with the learned turn, independently of the location of the start arm. Asterisks on the histograms denote significant differences. Modified from Rodríguez F, Durán E, Vargas J, Torres B, and Salas C (1994) Performance of goldfish trained in allocentric and egocentric maze procedures suggests the presence of a cognitive mapping system in fishes. *Anim. Learn. Behav.* 22: 409–420.

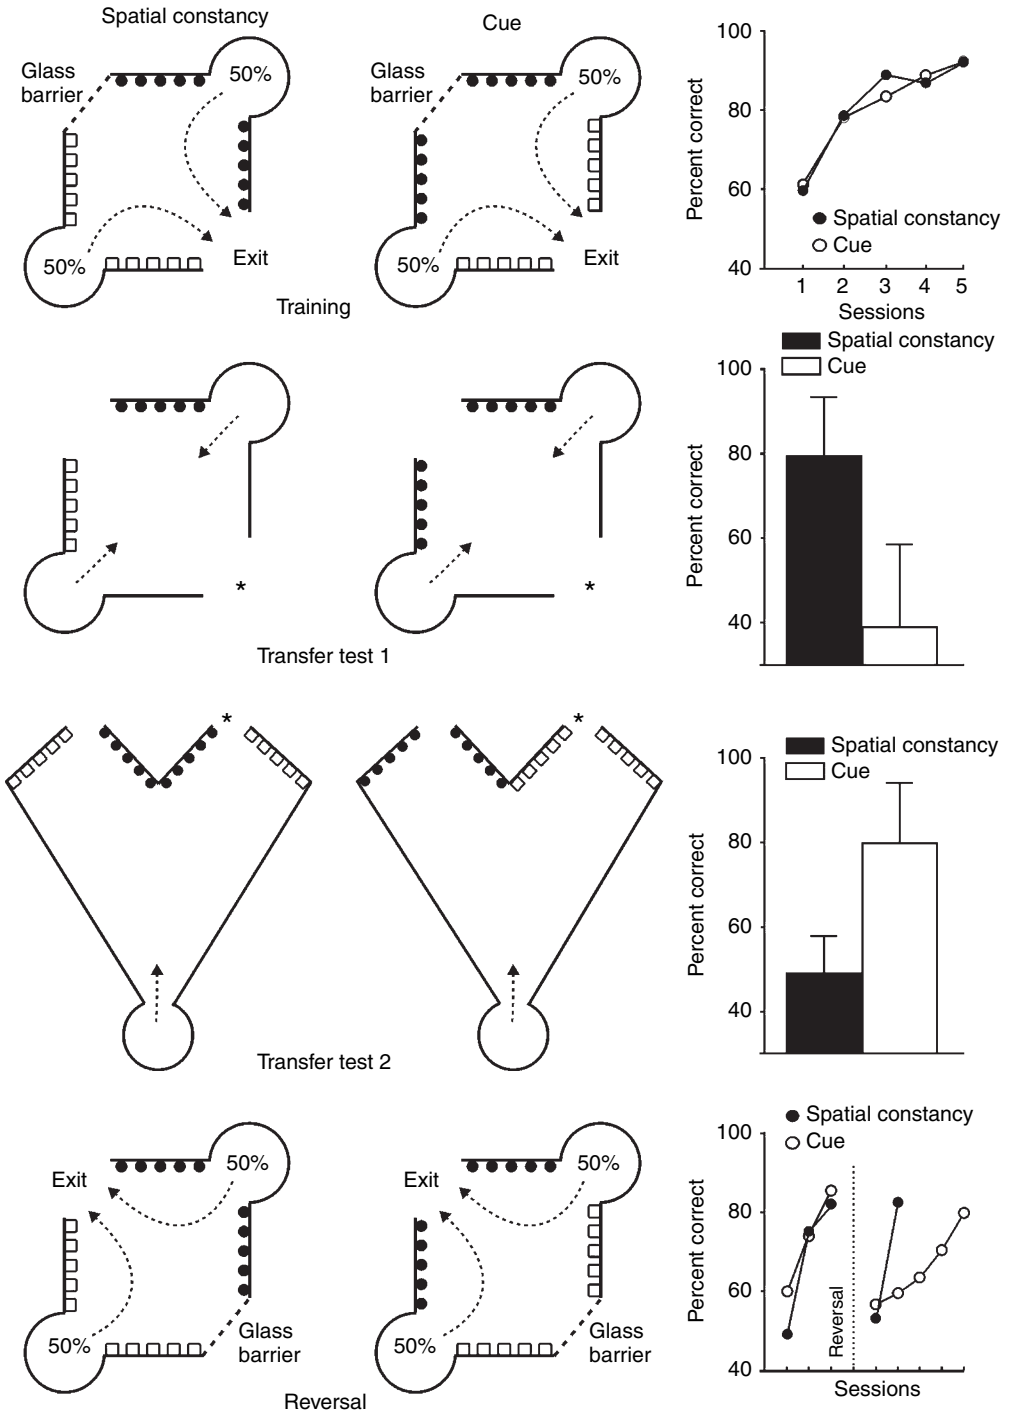

Figure 4 Multiple spatial learning strategies in goldfish trained in a spatial constancy or a cue task to locate a goal in a small, stimulus-controlled enclosure. The access from the start compartments, the distribution of the experimental visual cues (black circles and hollow squares), the position of the glass barrier, and the location of the goal (asterisk) are shown for the two experimental training conditions, transfer tests, and task reversal. The numbers indicate the percentage of trials initiated from each starting compartment. The arrows show the most efficient routes to the goal. The figures on the right show the percentage of correct responses during each experimental situation. Asterisks denote significant differences. Modified from López JC, Broglio C, Rodríguez F, Thinus-Blanc C, and Salas C (1999) Multiple spatial learning strategies in goldfish (*Carassius auratus*). *Anim. Cogn.* 2: 109–120.

1999). In fact, one might expect that the use of multiple orientation systems would increase navigational efficiency in an environment with redundant cues. The cooperative use of different spatial strategies has been described previously in other vertebrate groups (Schenk and Morris, 1985; Whishaw and Mittleman, 1986; Able, 1991).

1.26.6 Map-like Memory Representations of the Environmental Space

In the preceding sections, we mentioned the possibility that, in addition to using egocentrically referenced mechanisms for orienting, fish may also use allocentric spatial representations. In the present section, we discuss this point in more detail. Although this has been one of the most controversial topics in animal spatial cognition research, thorough studies carried out during the last few decades indicate that mammals, birds, and reptiles can use allocentric representations of space for navigation (O'Keefe and Nadel, 1978; Eichenbaum et al., 1990; Sherry and Duff, 1996; Bingman et al., 1998; Burgess et al., 1999; López et al., 2000b, 2001; Salas et al., 2003; Chapters 1.20, 1.22, 1.25). These allocentric representations, defined as map-like, world-centered cognitive representations (i.e., cognitive maps; Tolman, 1948; O'Keefe and Nadel, 1978), are the result of processing and encoding the properties and features of the environment in terms of the spatial relationships between multiple cues. These memory representations allow the subject to represent itself within a stable spatial framework and navigate accurately and flexibly within it, regardless of its own actual position and local view. These map-like spatial memory representations, which can be considered true relational memories, show some of the properties that distinguish the human declarative or episodic memory (Clayton and Dickinson, 1998; Eichenbaum, 2000; Chapters 1.22, 1.23). In comparative psychology and neuroscience, relational and allocentric spatial memories have long been considered attributes that distinctly characterize humans and other mammals, as these high-order cognitive capabilities are assumed to require complex associational brain structures, in particular the hippocampus and the six-layered neocortex. However, the results of some experiments indicate that teleost fish can implement allocentric, map-like spatial representations to navigate, based on processing multiple, reciprocal associations among different environmental features (for reviews, see Broglio et al., 2003; Salas et al., 2003).

For example, the results from the above-cited study by Rodríguez and coworkers (1994) showed that goldfish trained in an allocentric procedure were able to navigate directly to the rewarded place independently of start position and swimming direction, since they were able to reach the goal even when released from novel start arms (**Figure 2(d)**; transfer test, type 1) and from previously unvisited room locations (**Figure 2(d)**; transfer test, type 2). In fact, these animals chose spontaneously the most direct trajectory to the goal place from different, never experienced start locations, establishing new routes without a history of previous training (see trajectories in **Figure 2(d)**) The results of the probe and transfer trials are especially significant because they can rule out the possibility that these fish could be using guidance or other egocentric referenced orientation mechanisms, by relying on a particular landmark or in a direction sense, for example, approaching or avoiding a sensory cue, be it visual, auditory, odor, polarized light, or geomagnetic gradients. These results show that goldfish spontaneously use the most appropriate of the available routes from previously unvisited places, using shortcuts or detours, as convenient, although the new trajectories imply new, never experienced, egocentric relations to landmarks. These data provide solid evidence of the fish's capacity to represent spatial relationships in the environment independently of a body-centered reference system, that is, to perform place responses by using allocentric frames of reference.

Another important property proposed for map-like, relational spatial memory representations is the storage of redundant information on the encoded cues and environmental features. This property implies that the disappearance of any subset of environmental cues will not impair accurate navigation, because the animals can rely on the remaining cues (Suzuki et al., 1980; Morris, 1981; Mazmanian and Roberts, 1983). The study by Rodríguez et al. (1994) provided interesting evidence in this regard (**Figure 2(c)**): On the one hand, the performance of the fish trained in the allocentric task did not deteriorate when the most salient visual cues were individually removed or hidden, and on the other hand, when all the cues were simultaneously removed, performance became as poor as that of the control fish, indicating that the performance of the allocentric group was based on the knowledge of the relationships among the goal

location and many environmental cues. These data agree with the above-mentioned requirement for cognitive mapping, concerning the encoding of redundant information, as it was not impaired by the removal or occlusion of any one of the component elements of the landmark array, that is, none of those cues, taken individually, was essential to locate the goal.

Recently, Schluessel and Bleckmann (2005), using behavioral procedures that closely match those used in the above-cited study by Rodríguez et al. (1994), have obtained results that indicate that elasmobranchs, a sister group of actinopterygian and sarcopterygian vertebrates, can also use allocentric strategies for navigation. Rays (*Potamotrygon motoro*), in addition to using egocentric strategies, use the information provided by the extramaze visual cues to reach the goal using novel routes starting from unfamiliar locations, suggesting that the spatial mapping could be a widely extended cognitive capability in vertebrates.

Further studies have provided direct evidence of additional characteristics of the allocentric strategies in fish. For example, a number of recent studies indicate that besides using landmarks to build map-like spatial representations, fish can use the geometry or the shape of the environmental boundaries (Broglio et al., 2000; Sovrano et al., 2003; Vargas et al., 2004; Sovrano et al., 2007). In fact, these studies showed that fish match birds, rodents, monkeys, and humans in the capability to encode geometric spatial information for orientation and navigation (Tinklepaugh, 1932; Cheng, 1986; Vallortigara et al., 1990; Hermer and Spelke, 1994; Kelly et al., 1998; Gouteaux et al., 2001; Gouteaux and Spelke, 2001). These results are specially relevant, because the capability to encode and use the geometrical features of the environment for allocentric navigation reflects the knowledge of the spatial features as a whole, that is, the metric and geometrical relationships among the constituent elements (Cheng and Gallistel, 1984; Cheng, 1986; Hughey and Koppenaal, 1987; Gallistel, 1990; Cheng and Sherry, 1992; Cheng, 1994; Hermer and Spelke, 1994; Kamil and Jones, 1997).

Lopez et al. (1999) showed that goldfish trained in a spatial constancy task were impaired when a spatial modification was introduced in the experimental apparatus that altered the global shape (geometry) and the topography of the apparatus, although it left unchanged the local visual and geometric features of the areas corresponding to each of the doors. In contrast, the performance of the fishes trained in a cue task using the same apparatus was unimpaired by the global topographical alteration if the local cues were maintained (López et al., 1999, see **Figure 4**). In addition, recent experimental studies, directly addressing this issue in fish, demonstrated that fish use the geometry of the surroundings for spatial orientation. For example, Sovrano et al. (2003) showed that, when disoriented in a closed rectangular tank, redtail splitfin (*Xenotoca eiseni*) are able to reorient according to the shape of the environment and to combine geometric and nongeometric information of the environment such as the color of the walls or the features provided by the visual cues. Fish encode geometric information even when distinct feature information is sufficient to solve the task. In addition, Vargas et al. (2004) showed that goldfish locate a place in an environment by encoding the goal location with respect to the geometrical features of the experimental space, even in the absence of feature information. Goldfish trained in a symmetrical, rectangular apparatus, and in the absence of additional visual cues, made systematic rotational errors by confusing geometrically equivalent places (**Figure 5(a)**). In the test trials in which the geometric features were modified by means of replacing the rectangular apparatus used during training by a square one, the performance was significantly impaired, indicating that the fish used no other source of spatial information but the geometry of the rectangular arena (**Figure 5(a)**). In addition, the results of this study indicate that goldfish encode geometric and nongeometric information simultaneously when the environment provides both types of information and use one or the other according to task requirements. The dissociation tests showed that goldfish encoded the geometric information even when information provided by distinct visual cues was sufficient to solve the task, and that the fish's representation of the spatial environment was flexible and resistant to losses of redundant but relevant spatial information (**Figure 5(b)**, geometry test and feature test). However, the performance was disrupted when the metric and topological relationships among the composing elements were altered (**Figure 5(b)**, dissociation test). In fact, whereas the fish were able to solve the task successfully by using either the geometrical (**Figure 5(b)** geometry test) or the featural cues (**Figure 5(b)**, feature test), they chose at random between the possible exits when the information provided by both types of cues was dissociated and made contradictory (**Figure 5(b)**, dissociation test). Furthermore, this pattern of results suggests that goldfish elaborate a complex representation of the environment, in which the different elements and properties of the environmental space (geometry and featural information) are not only simultaneously

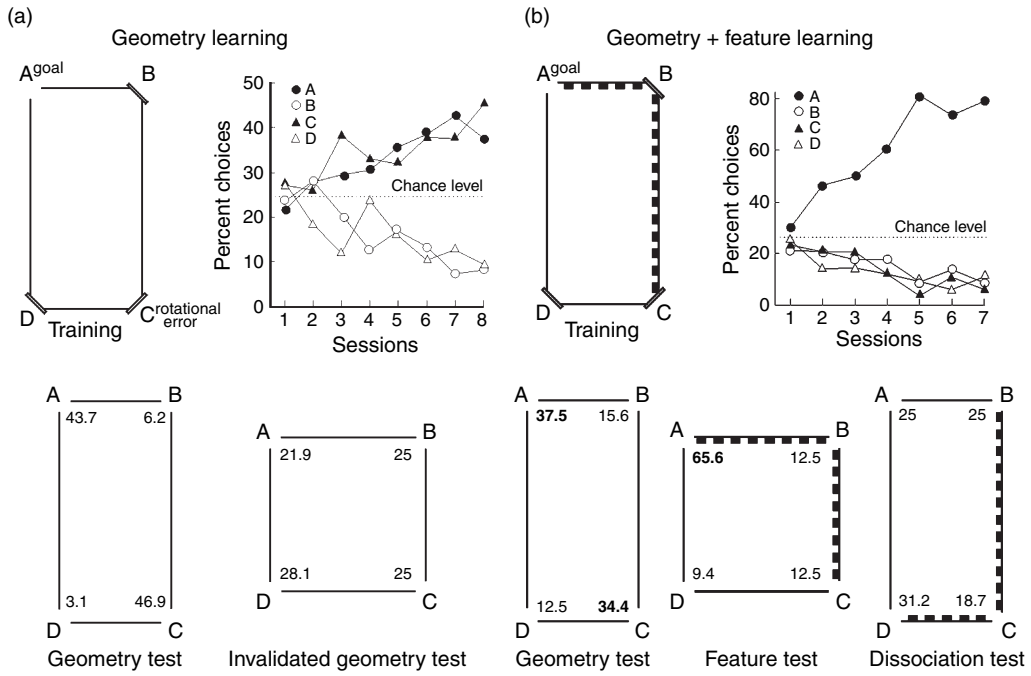

Figure 5 Encoding of geometric and featural spatial information by goldfish. (a) Geometry task. Fish were trained to find the exit door (goal) placed in a corner (A) of a rectangular arena that had three identical blocked openings in the other three corners (B, C, and D). Because of the geometric properties of the apparatus, the correct corner was indistinguishable from the diagonally opposite corner (rotational error). The curves show the percentage of choices for the four corners during training. The diagrams in the bottom show the percentage of choices (numbers) for each corner during the two different probe tests conducted for this group. (b) Geometry + feature task. Fish were trained in the same rectangular box but in which additional feature information was provided by alternate dark grey and white vertical stripes on two walls. The curves show the percentage of choices for the four corners during training. The diagrams on the bottom show the percentage of choices (numbers) for each corner during the three different probe tests conducted for this group. Modified from Vargas JP, Lopez JC, Salas C, and Thinus-Blanc C (2004) Encoding of geometric and featural spatial information by Goldfish (*Carassius auratus*). *J. Comp. Psychol.* 118: 206–216.

encoded but also are probably integrated in a single configuration, a relational, map-like representation (O'Keefe and Nadel, 1978; Eichenbaum et al., 1990; Poucet, 1993; Eichenbaum et al., 1994; Thinus-Blanc, 1996).

These data show that some significant features of the spatial capabilities of fish resemble those of reptiles, birds, and mammals, including primates (O'Keefe and Nadel, 1978; Schenk and Morris, 1985; Whishaw and Mittleman, 1986; Sherry and Vaccarino, 1989; Whishaw, 1989; Sherry and Duff, 1996; Bingman et al., 1998; López et al., 2000c, 2001) and suggest that spatial cognition is organized in a similar way in every vertebrate radiation. Such striking cognition similarities in vertebrate groups that diverged millions of years ago from a common evolutionary ancestor suggest the possibility that these multiple spatial memory systems may be a primitive feature in vertebrates, that is, that all of them could have inherited some common features in the behavioral and neural organization, maintained with little modification through phylogenetic branching. However, if the cognitive capabilities observed in fish and amniotes really have a common evolutionary origin, then they must stem from a conserved neural basis. This possibility is discussed in the next section.

1.26.7 Neural Basis of Spatial Cognition in Teleost Fish

In the preceding sections, we reviewed evidence suggesting that spatial orientation and navigation in teleost fish, as in land vertebrates, involves a variety of cognitive, perceptive, and motor mechanisms. We now summarize experimental evidence showing that these spatial cognition processes and memory systems are based on separate brain substrata and outline the central question of whether they are supported by neural centers and circuits equivalent to those that underline spatial cognition in land vertebrates.

Comparative evidence shows that separate brain systems contribute in different ways to spatial orientation and navigation in vertebrates, such that sensorimotor information is processed and integrated by a number of brain mechanisms, and the information about environmental space and the position of the body and body parts in space is coded and translated into a series of coordinate systems, from the receptive surfaces to head-centered and body-centered coordinates and to allocentric, world-centered coordinate systems. For example, in mammals, perception and action based on egocentric frames of spatial reference depend on brain circuits that involve the superior colliculus, cerebellum, basal ganglia, and parietal and frontal motor cortical areas (Stein and Meredith, 1993; Burgess et al., 1999). However, the use of allocentric frames of reference for navigation, based on the encoding of the reciprocal spatial relationships between the goal and multiple sensory and spatial features, depends on other neural systems, mainly the hippocampal formation and associated brain circuits (O'Keefe and Nadel, 1978; Burgess et al., 1999; Chapters 1.21, 1.33).

Unfortunately, the psychological and neurobiological research concerning the neural basis of learning and memory in fish has been largely limited by the misleading, but very common and deeply rooted, idea that vertebrate evolution occurred in successive stages of increasing complexity and advancement in brain organization and cognitive capabilities, following a lineal progression from inferior to superior forms (i.e., fishes, amphibians, reptiles, birds, and mammals; *Scala naturae*; Hodos and Campbell, 1969; Deacon, 1990; Hodos and Campbell, 1990; Preuss, 1995; Butler and Hodos, 2005). Thus, the classical theories on vertebrate brain and behavior evolution propose that fishes, the most primitive and least evolved vertebrate group, have developed relatively simple neural circuits. According to these theories, the forebrain of fishes was thought to consist mainly of a subpallium (paleostriatum) and a very reduced and primitive pallium (paleocortex), both entirely dominated by olfactory inputs and consequently allowing only elemental forms of behavior and learning capabilities. In fact, these theories considered that neural structures equivalent to the hippocampus and the neocortex were completely absent in the fish telencephalon. All these telencephalic structures (the neoencephalon) were thought to have evolved later, in supposedly more recent and complex vertebrate groups. However, by the end of the twentieth century, a fast-growing amount of comparative developmental, neuroanatomical, and functional evidence had led to an entirely different understanding of vertebrate brain and behavior evolution, as the traditional, anthropocentric view of linear brain evolution was consistently contradicted by the data: Vertebrates have not evolved linearly, but the lineage initiated in a remote common ancestor branched in different radiations, which evolved independently, and increases in brain size and complexity occur in every one of these branches. Furthermore, this new evidence reveals that the evolution of the vertebrate brain has likely been more conservative than previously thought and that the extant vertebrates share some inherited features of brain and behavior organization. Thus, although showing conspicuous morphological and cytoarchitectural differences, their brains can be considered as variations of a common vertebrate plan (Wiley, 1981; Northcutt, 1995; Nieuwenhuys et al., 1998; Butler and Hodos, 2005). The comparative evidence reveals not only that the central nervous system of vertebrates is organized in homologous main subdivisions (i.e., telencephalon, diencephalon, mesencephalon, rhombencephalon, and spinal cord) but also that the telencephalon of every vertebrate group, including fish, consists of equivalent pallial and subpallial zones. Moreover, we now know that the olfactory areas represent only a limited portion of the fish telencephalic pallium and that the main pallial subdivisions in the actinopterygian fish telencephalon are likely to be homologous to the main pallial subdivisions of tetrapods (Braford, 1995; Northcutt, 1995; Wulliman and Rink, 2002; Butler and Hodos, 2005).

1.26.8 Teleost Fish Telencephalon and Spatial Cognition

The results of the initial studies on the neural basis of behavior in teleost fish seemed consistent with the theories on vertebrate brain evolution prevailing at the time. For example, early studies reported that ablation of the entire telencephalon in teleost fish produced few (if any) deleterious effects on fish behavior, that gross sensory or motor deficits were not apparent, and that the motivation of the ablated animals appeared to remain at normal levels (see, e.g., Polimanti, 1913; Nolte, 1932; Janzen, 1933; Hosch, 1936; Hale, 1956; Savage, 1969b). However, more careful analyses revealed that telencephalon ablation causes profound learning and memory deficits in fishes as well as significant alterations in emotional and social behavior (Aronson, 1970; Hollis and

Overmier, 1978; de Bruin, 1980; Davis and Kassel, 1983; for revisions, see Savage 1980; Overmier and Hollis 1983, 1990). These studies showed that whereas telencephalon ablation in fish does not impair simple instrumental learning and classical conditioning (Overmier and Curnow, 1969; Flood and Overmier, 1971; Frank et al., 1972; Overmier and Savage, 1974; Farr and Savage, 1978; Hollis and Overmier, 1982), it does produce severe impairments in other learning instances, such as avoidance learning (Hainsworth et al., 1967; Savage, 1968; Overmier and Flood, 1969; Savage, 1969a), as well as instrumental learning when there is a delay between the response and the reward (Savage and Swingland, 1969; Overmier and Patten, 1982).

Interestingly, the involvement of the teleost fish telencephalon in spatial cognition was also already suggested by early ablation studies, although the initial reports were often contradictory. Thus, no deficits, impairments, or even improvement in spatial learning have been observed following telencephalon ablation in fish trained in alleys and mazes (Hosch, 1936; Zunini, 1954; Hale, 1956; Warren, 1961; Ingle, 1965; Frank et al., 1972; Flood et al., 1976; Farr and Savage, 1978). The inconsistency of the reports could be attributed to the fact that these experiments were not specifically aimed to analyze spatial cognition and therefore did not include a precise definition of the spatial requirements of the tasks nor adequate control tests, which are essential for identifying the effects of ablation on spatial performance. Moreover, spatial learning and memory and spatial cognition frequently involve somewhat confusing concepts that include a mixture of still poorly characterized perceptive and cognitive processes actually based in separate neural substrata.

More recent studies, designed specifically to analyze the nature of the spatial cognition deficits produced by telencephalic lesions, have provided strong evidence for the central role of the telencephalon in spatial cognition in teleosts. The data from the more recent ablation studies show that the teleost telencephalon is necessary for some specific spatial learning and memory functions, as it contains essential components of the neural network that underlies map-like spatial memories in fish (Rodríguez et al., 1994; Salas et al., 1996a, 1996b). For example, Salas et al. (1996b) trained goldfish in place (allocentric), turn (egocentric), or mixed place–turn procedures in a four-arm maze. After the animals had mastered their task, they were subjected to complete telencephalic ablation or sham operations. The results showed that the ablation dramatically and irreversibly impaired the ability of the fish trained in the place procedure to recognize goal location during postsurgery training (**Figure 6**). In contrast, telencephalon ablation did not alter the performance of the animals using egocentric orientation strategies. Interestingly, the lesion appeared to produce no deficit in the fish trained in the mixed place–turn procedure, as during postsurgery training their performance remained at the previous levels. However, the transfer trials revealed that the telencephalon ablation did produce a remarkable spatial cognition impairment: Whereas before ablation these animals used place (allocentric) or turn (egocentric) strategies in a flexible and cooperative way according to the experimental conditions, after surgery, their performance was based exclusively on turn responses (**Figure 6**).

Consistent results were obtained in an experiment in which intact and telencephalon-ablated goldfish were trained in a mixed place–cue procedure (López et al., 2000a). Sham-operated and telencephalon-ablated goldfish were trained in a test environment where they could simultaneously rely on the spatial information provided by a number of extramaze distal landmarks on the periphery of the experimental room and on an intramaze single cue that directly indicated the location of food. Paradoxically, telencephalon-ablated goldfish showed better performance during training relative to sham-operated animals (see **Figure 7(a)**). However, the results of the probe tests designed to examine the relative importance of the two sources of information (extra- vs. intramaze cues) revealed that these animals suffered a profound spatial learning deficit: their performance was based exclusively on egocentric strategies (**Figure 7(b)**). In the place–cue dissociation tests, in which the two sources of information were set in conflict (the place and the cue responses were incompatible), the control fish did not have a significant preference for either the cue or the place responses. In contrast, the performance of the telencephalon-ablated fish was notably biased in these test trials; they showed a significant preference for the arm containing the cue that signaled the goal during training. In the extramaze occlusion tests, when the maze was completely surrounded by curtains precluding the use of the extramaze visual cues, both telencephalic and control fish showed a strong preference for the arm containing the cue associated with the goal during training. However, in the intramaze cue-removal test, whereas the control goldfish consistently chose the arm placed at the location of the room where they were rewarded during training, the

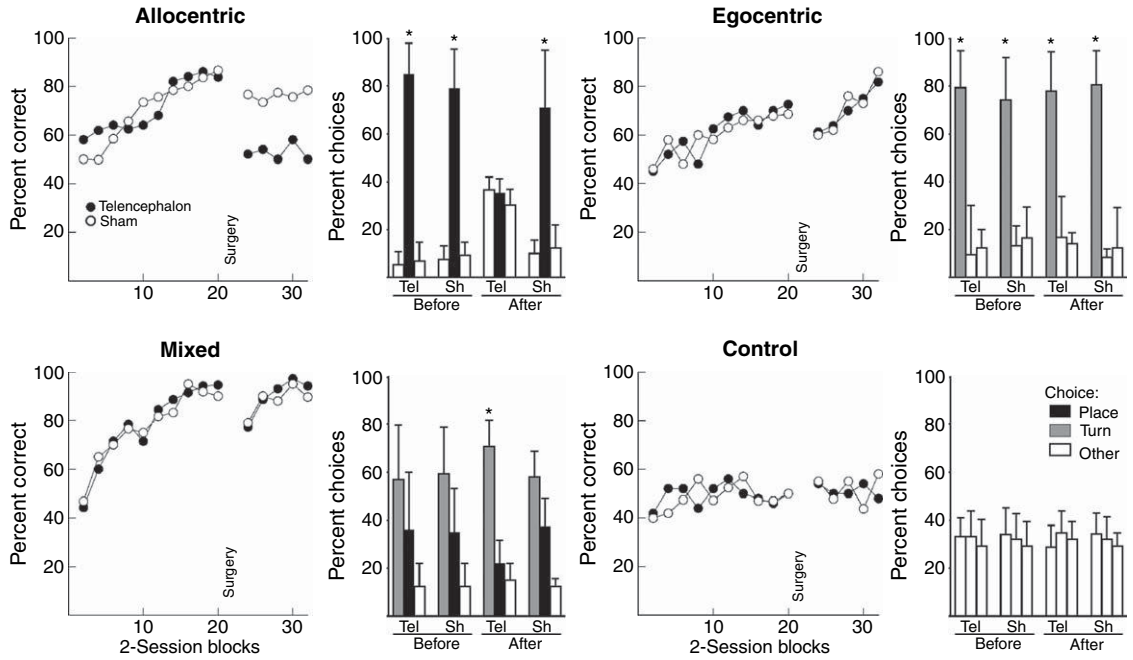

Figure 6 Spatial learning deficits after telencephalic ablation in goldfish trained in egocentric and allocentric maze procedures. The curves show the mean percentage of correct choices of telencephalon-ablated and sham-operated goldfish trained in different spatial procedures as described in **Figure 2**. The bars show the percentage of choices during the transfer tests conducted before and after surgery for each experimental group. Asterisks denote significant differences. Modified from Salas C, Rodríguez F, Vargas JP, Durán E, and Torres B (1996b) Spatial learning and memory deficits after telencephalic ablation in goldfish trained in place and turn maze procedures. *Behav. Neurosci.* 110: 965–980.

telencephalon-ablated fish chose at random between the maze arms, indicating that these animals were not able to use the array extramaze cues as a source of useful spatial information. These results indicate that although both groups learned the task, the sham-operated and the telencephalon-ablated goldfish differed in their capacity to use complementary navigational strategies; the control animals used both place and cue strategies, but the telencephalon-ablated animals solved the task exclusively on the basis of a cue strategy. Additional experiments using different behavioral procedures provided converging evidence on the role of the teleost fish telencephalon in spatial cognition. Thus, telencephalon ablation disrupted the postsurgery performance (Salas et al., 1996b) and reversal learning (López et al., 2000b) of goldfish trained in a spatial constancy task but did not produce any observable deficit in a cue procedure (Salas et al., 1996b). In summary, the place memory impairments observed in these experiments strongly suggest that forebrain ablation in fish produces a selective but severe disruption in a telencephalon-dependent spatial memory system, which sustains the use of allocentric, relational map-like representations of space.

In mammals, birds, and reptiles, map-like or relational spatial memories depend on the hippocampus and associated structures (O'Keefe and Nadel, 1978; Sherry and Duff, 1996; Bingman et al., 1998; Burgess et al., 1999; Rodríguez et al., 2002a, b; López et al., 2003a, b; Chapters 1.21, 1.22, 1.33). Similarly, compelling evidence suggests that specific areas and circuits of the teleost forebrain, in particular the lateral pallium, proposed as homologous with the hippocampus of land vertebrates, provide an essential neural substratum for cognitive mapping abilities in fish (Salas et al., 1996a, b; López et al., 2000a, b; Rodríguez et al., 2002b; Salas et al., 2003, Broglio et al., 2005; Salas et al., 2006).

1.26.9 Telencephalic Hippocampal Pallium and Map-like Memories in Teleost Fish

The telencephalon of ray-finned fishes presents morphological features that are unique among vertebrates; for instance, it consists of solid telencephalic hemispheres separated by a single ventricular cavity, instead of hemispheres with internal ventricles.

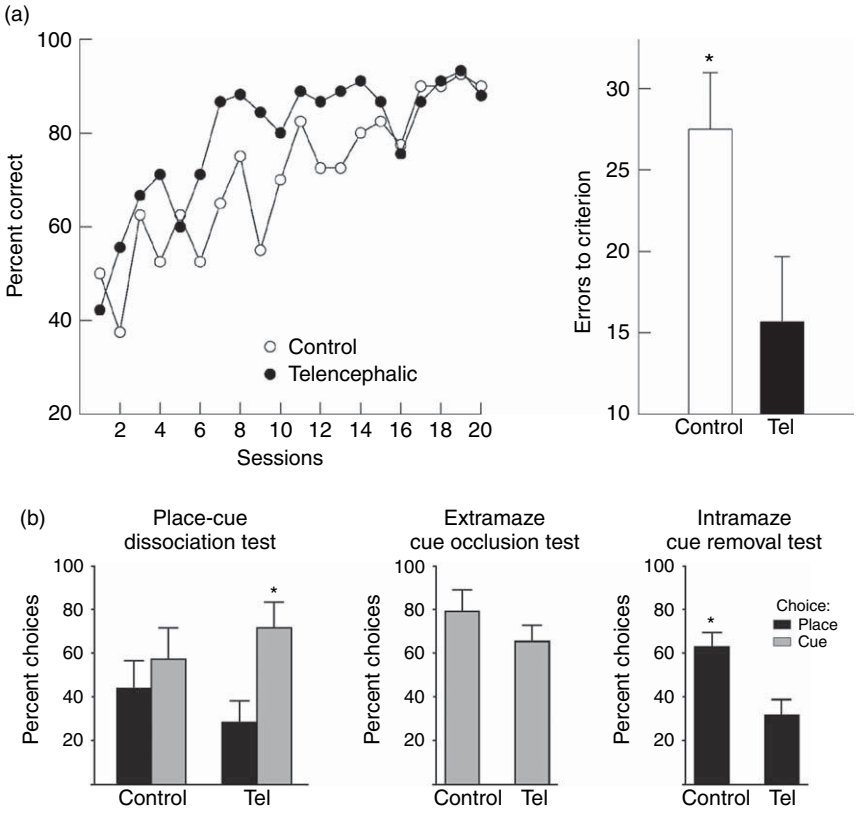

Figure 7 Spatial learning deficits by telencephalic ablation in goldfish trained in a mixed place–cue arm-maze procedure. (a) Percentage of correct choices and errors to criterion of sham-operated and telencephalon-ablated goldfish trained in a mixed place–cue procedure as described in **Figure 3**. (b) Mean percentage of choices in the three different probe tests conducted following learning of the task by both groups. Asterisks denote significant differences. Modified from López JC, Bingman VP, Rodríguez F, Gómez Y, and Salas C (2000a) Dissociation of place and cue learning by telencephalic ablation in goldfish. *Behav. Neurosci.* 114: 687–699.

Ray-finned fishes represent a particular case because their telencephalon develops by a process of eversion or bending outward of the embryonic prosencephalic alar plate, contrasting with the evagination that characterizes the telencephalic development of every other vertebrate group (Nieuwenhuys, 1963; Northcutt and Braford, 1980; Braford, 1995; Northcutt, 1995, 2006; Striedter and Northcutt, 2006). This developmental peculiarity implies that the medial-to-lateral topography of the pallial areas observed in the vertebrates with evaginated telencephalon is reversed in ray-finned fishes. In fact, the ray-finned fish's lateral telencephalic pallium (i.e., the embryonary distal pallium) is considered homologous to the medial pallium or hippocampus of the tetrapods (Northcutt and Braford, 1980; Nieuwenhuys and Meek, 1990; Braford, 1995; Northcutt, 1995; Butler, 2000; Northcutt, 2006; see **Figure 8**). This hypothesis of homology of hippocampus is supported by the neuroanatomical and developmental data (Northcutt, 1995; Wulliman and Mueller, 2004; Northcutt, 2006). Like the hippocampus, the lateral pallium is characterized by widespread reciprocal connections with other pallial areas, as well as with the contralateral lateral pallium, by means of commissural projections. In addition, the lateral pallium is reciprocally connected with the ventral nucleus of the area ventralis (Vv) considered homologous to the septal nucleus (Butler and Hodos, 2005), from which it receives a cholinergic input. The extratelencephalic pattern of connectivity of the lateral pallium is also similar to that of the hippocampus, as it projects to the preoptic area and other diencephalic regions and receives inputs from the preoptic area, the locus coeruleus, and the superior raphe. Particularly, the ventral subdivision of the lateral pallium (Dlv) is the most likely candidate as the specific homolog of the

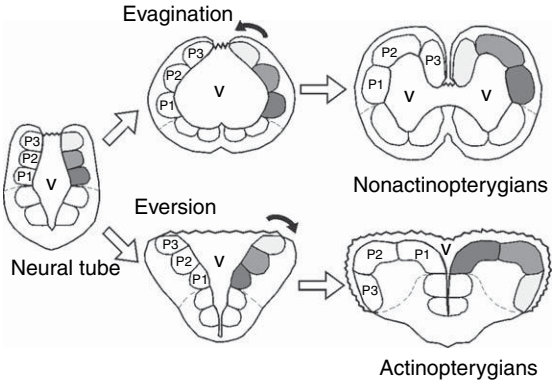

Figure 8 Schematic representation of the process of evagination and inversion that occurs in the telencephalon of nonactinopterygian vertebrates during embryonic development compared with the process of eversion or bending outward that occurs in actinopterygians. P1, P2, and P3 correspond to the three main subdivisions of the pallium. V, ventricle.

tetrapod medial pallium; it occupies the most distal topological position in the pallium and has extensive interconnections with the likely homologs of the septal nuclei and preoptic area. The hypothesis of homology concerning the teleost fish Dlv region and the hippocampus is also supported by the distribution pattern of several histochemical and molecular markers. For example, the dopamine receptor subtype D1B, which is characteristic of the mammalian hippocampus, is selectively expressed in the Dlv subdivision of the teleost pallium (Kapsimali et al., 2000), and this area, like the mammalian dentate gyrus, shows neurogenesis and migration of interneurons (Grandel et al., 2006).

Functional evidence also supports the hypothesis of homology between the lateral pallium of teleost fish and the hippocampus, as the ventral lateral pallium of teleost fish, like the amniote hippocampus, is selectively involved in spatial cognition (Rodríguez et al., 2002b; Broglio et al., 2005). Extensive lesions to the lateral pallium produce a dramatic impairment in place memory in goldfish trained in a plus maze surrounded by widely distributed distal visual cues (Rodriguez et al., 2002b; see **Figure 9(a)**). Following surgery, lateral pallium–lesioned fish showed a severe and permanent impairment to reaching well-trained goal locations. In addition, these animals were not able to locate the goal from new starting places during transfer tests in which reaching the goal involved the use of novel routes. The spatial learning and memory deficits following lesions restricted to the lateral pallium in goldfish are as severe as those produced by the ablation of the entire telencephalon (Salas et al., 1996b; López et al., 2000a; Rodríguez et al., 2002a,b). In addition, the involvement of the lateral pallium in spatial cognition is highly selective, as the damage to this area does not disrupt cue learning or other egocentrically referenced spatial behaviors (Salas et al., 1996a,b; López et al., 2000a; Rodríguez et al., 2002b; see **Figure 9(b)**). These results indicate that, like the hippocampal pallium of land vertebrates, the lateral pallium of teleost fish is selectively involved in the use of map-like or relational spatial memory representations for allocentric navigation, but it is not critical for simple stimulus–response associations or cue learning. In contrast, the medial and dorsal pallium lesions do not produce any observable impairment in spatial memory in goldfish (Rodríguez et al., 2002b; see **Figure 9**). In contrast, the teleost fish medial pallium, likely homologous to the pallial amygdala of amniotes (Northcutt and Braford, 1980; Northcutt, 1995; Wulliman and Mueller 2004; Yamamoto et al., 2007), seems to be involved in emotional behavior (Portavella et al., 2004a,b; Broglio et al., 2005; Salas et al., 2006), and the dorsal pallium, which contains several multisensory and motor representations, appears to be the homolog of the amniote dorsal cortex or isocortex (Northcutt, 1995; Prechtl et al., 1998; Saidel et al., 2001; Northcutt, 2006; Yamamoto et al., 2007).

The involvement of the lateral telencephalic pallium of teleost fish in spatial cognition is suggested also by studies using complementary techniques to reveal neural activity. Vargas et al. (2000) showed that training goldfish in a spatial task induces a significant and selective spatial learning-related increase in the transcription activity (protein synthesis) of the neurons in the lateral pallium, evaluated by means of a silver stain with high affinity for the argyrophilic proteins of the nucleolar organizing region (AgNORs). The size of the AgNORs in the cell nucleus indicates the level of transcriptive activity of rDNA, and heightened rDNA activity indicates increases in protein synthesis (Davis and Squire, 1984; Crocker and Nar, 1987; Dámaso et al., 1988; Lafarga et al., 1991; Underwood, 1992; González-Pardo et al., 1994). Vargas et al. (2000) showed that the size of the AgNORs in the neurons of the ventral part of the goldfish telencephalic lateral pallium (Dlv region) increased significantly and selectively after learning a spatial constancy task, compared with the same area of the brain in the animals of the control group (trained in a noncontingent procedure) or with

the neurons of the medial pallium of both groups (see **Figure 10**). An interesting result is also provided by Carneiro et al. (2001), who showed spatial cognition-related sex differences in the lateral pallium of Azorean rock-pool blennies (*Parablennius parvicornis*). In this species, males establish nest sites and remain in their nest area during the entire breeding season. In contrast, females need to move relatively long distances in order to visit different nests and spawn with males. Interestingly, Carneiro et al. (2001) found that female blennies have a larger lateral pallium compared to males. These authors related the greater size of the female blennies' lateral pallium with the increased spatial cognition demand on females, which need to displace greater distances than males and need to remember the nest location of different males.

Recently, Saito and Watanabe (2004, 2006) reported results apparently contradictory to this view, as they found that not lateral but, rather, medial pallium lesions produced spatial memory deficits in goldfish tested in a hole-board analog task. However, these experiments lack an adequate set of test trials to identify the spatial strategies used by the animals; therefore, the possible deficits observed in these experiments cannot have been clearly defined. In fact, the performance deficits observed in the medial pallium-lesioned animals in these studies could be better explained by nonspatial impairments, such as motivation, attention, and general activity alterations (Davis and Kassel, 1983; Riedel, 1998). Furthermore, the lateral pallium lesions in the experiment by Saito and Watanabe do not include the ventral portion of the lateral pallium but affect mostly the pallial region extending between the lateral and the medial pallium, which is most likely homologous with the dorsal cortex of land vertebrates (Northcutt, 1995; Pretchtl et al., 1998; Butler, 2000; Saidel et al., 2001; Northcutt, 2006; Yamamoto et al., 2007). In fact, it has not been possible to replicate the results of Saito and Watanabe in experiments when care was taken to lesion the medial pallium and the ventral part of lateral pallium selectively (Durán, 2004; Rodríguez et al., 2005). Durán (2004) trained lateral and medial pallium–lesioned goldfish to locate one baited feeder (goal) within a 25-feeder matrix surrounded by an array of intramaze visual cues, in a procedure analogous to the hole-board task used with rats and similar to the procedure and apparatus used by Saito and Watanabe. In this experiment, transfer and probe tests were performed to analyze carefully and identify the spatial strategies used by the animals. The results of this work are consistent with previous lesion studies and do not support Saito and Watanabe's conclusions. The lateral pallium–lesioned goldfish, as well as the medial pallium–lesioned and the control animals learned to solve the task with accuracy. However, the test trials when the different visual cues were independently removed showed that the lateral pallium–but not the medial pallium–lesioned fish suffered a spatial learning impairment. Thus, the lateral pallium–lesioned animals, but not the medial pallium–lesioned and the control fish, failed to reach the goal when the particular subset of visual cues situated in the proximity of the goal was excluded. These results reveal that the lateral pallium animals relied on a guidance strategy to solve the task (i.e., they learned to approach a particular visual cue that they associated with the goal), suggesting that these animals lack the capacity to encode the goal location relative to multiple environmental features in a map-like representation (place learning). The probe tests also showed that, in contrast, the medial pallium–lesioned goldfish are able to navigate readily to the goal independently of the removal of any particular subset of visual cues. These data clearly indicate that the lateral pallium of teleost fish, but not the medial pallium, provides the neural substratum for the ability of fish to use allocentric, relational representations of the environment.

1.26.10 Neural Mechanisms for Egocentrically Referenced Spatial Orientation

Fish spatial cognition also involves a variety of egocentrically referenced perceptive and motor mechanisms based on the function of different neural centers and circuits, for example, the reticulospinal and vestibular circuits, the cerebellum, and the optic tectum.

The optic tectum is a crucial center for the generation of egocentrically referenced actions in space. The anatomical and functional organization of the optic tectum (superior colliculus in mammals) appears to be quite well conserved in vertebrates (Vanegas, 1984; Stein and Meredith, 1993). The teleost optic tectum is a crucial center for sensorimotor integration and for the generation of egocentrically referenced actions in space. As in other vertebrates, the optic tectum of teleost fish presents a spatially ordered motor map in the deep tectal layers in correspondence with the retinotopic visual map in the superficial layers (Salas et al., 1997; Sparks, 2002). For example,

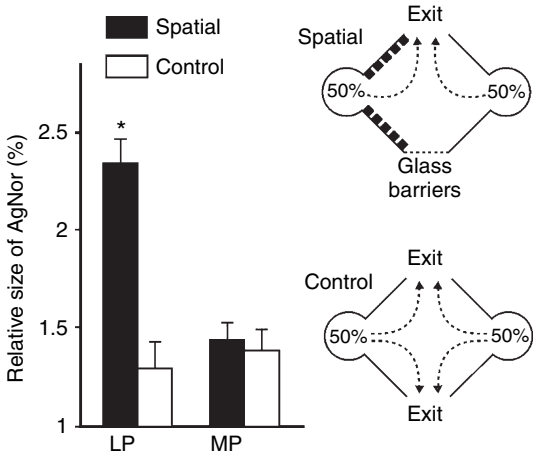

Figure 10 Spatial learning induced a significant increase in protein synthesis in the neurons of the lateral pallium of goldfish trained in a spatial task. The figure shows the size of the nucleolar organizing regions (NORs) relative to the size of the nucleus in lateral (LP) and medial (MP) pallium neurons of goldfish trained in a spatial or a control task as described in the diagrams. Asterisks denote significant differences. Modified from Vargas JP, Rodríguez F, López JC, Arias JL, and Salas C (2000) Spatial learning-induced increase in the argyrophilic nucleolar organizer region of dorsolateral telencephalic neurons in goldfish. *Brain Res.* 865: 77–84.

electrical microstimulation in the optic tectum elicited egocentrically referenced coordinated eye and body movements and postural adjustments in teleost fish (Meyer et al., 1970; Demski, 1983; Al-Akel et al., 1986; Salas et al., 1995, 1997; Herrero et al., 1998; see **Figure 11**). The optic tectum provides common body-centered frames of reference for multisensory integration and for sensorimotor transformation, based in their specialized intrinsic circuits and in their profuse connectivity with other motor and sensorial centers (Vanegas, 1984; Stein and Meredith, 1993; Salas et al., 1997), and probably participates in a neural interface for transforming the tectal information, coded in spatial coordinates, into a temporal signal in separate brainstem generators in the reticular premotor centers (Torres et al., 2002, 2005).

However, the distinction between only two main types of reference frames (egocentric vs. allocentric) is probably too restrictive. For example, both the egocentric and allocentric reference frames require a geocentric frame based on the invariant direction of the gravity forces (Trevarthen, 1968; Paillard, 1991; Berthoz, 1999). The vestibular information is essential in orientation and perceptual and motor stabilization, by providing an egocentric reference frame for orientation (Paillard, 1991), and is also likely to have a role in navigation based on inertial information (Mittelstaedt and Glasauer, 1991). In addition, different egocentrically referenced orientation mechanisms can interact to provide integrated behavioral outputs. For example, in the dorsal light response (DLR), the incident angle of the light, in addition to gravity, determines the postural position of fish (Holst, 1950). When the light angle of incidence is not completely vertical, fish assume a tilted posture, with the dorsal body area oriented somewhat toward the light source. The exact angle of deviation from the vertical position depends on light incidence angle and light intensity. Thus, this relatively simple reflex response involves an interaction between the visual and vestibular sensory inputs. Lesion studies in goldfish indicated that this response is abolished after lateral valvula cerebelli or pretectal nuclei lesions, but not after optic tectum lesions (Watanabe et al., 1989; Yanagihara et al., 1993b,c). The visual information is relayed to the cerebellum by the pretectal nuclei, which project to the valvula cerebelli directly, not via the optic tectum. In addition, the lateral valvula cerebelli receives vestibular and lateral line inputs indirectly, via the eminentia granularis and the medial nucleus of the octavolateralis column (Yanagihara et al., 1993a). As in land vertebrates, even these relatively simple and apparently mechanical fish reflexes are submitted to learning and memory modulation and undergo plastic modifications, adjustments, and recalibrations, with the cerebellum playing a central role in such plasticity (Löwenstein, 1932; Holst, 1935; Paul and Roberts,

Figure 9 Spatial memory deficits after lateral pallium lesion in goldfish. (a) Left, mean percentage of correct choices during pre- and postsurgery training in an arm-maze place task by goldfish with different pallial lesions or sham-operated goldfish. Right, mean percentage of correct choices during pre- and postsurgery transfer trials in which new start positions were used (see **Figure 2**). (b) Left, mean percentage of correct responses during postsurgery training in a cue task as described in **Figure 4**. Right, percentage of correct responses in the cue removal probe test. (c) Schematic representation of the largest (grey shading) and smallest (black shading) extent of the lateral (LP), dorsal (DP), and medial (MP) pallium lesions in goldfish, reconstructed in coronal sections. Asterisks denote significant differences. Modified from Rodríguez F, López JC, Vargas JP, Gómez Y, Broglio C, and Salas C (2002b) Conservation of spatial memory function in the pallial forebrain of amniotes and ray-finned fishes. *J. Neurosci.* 22: 2894–2903.

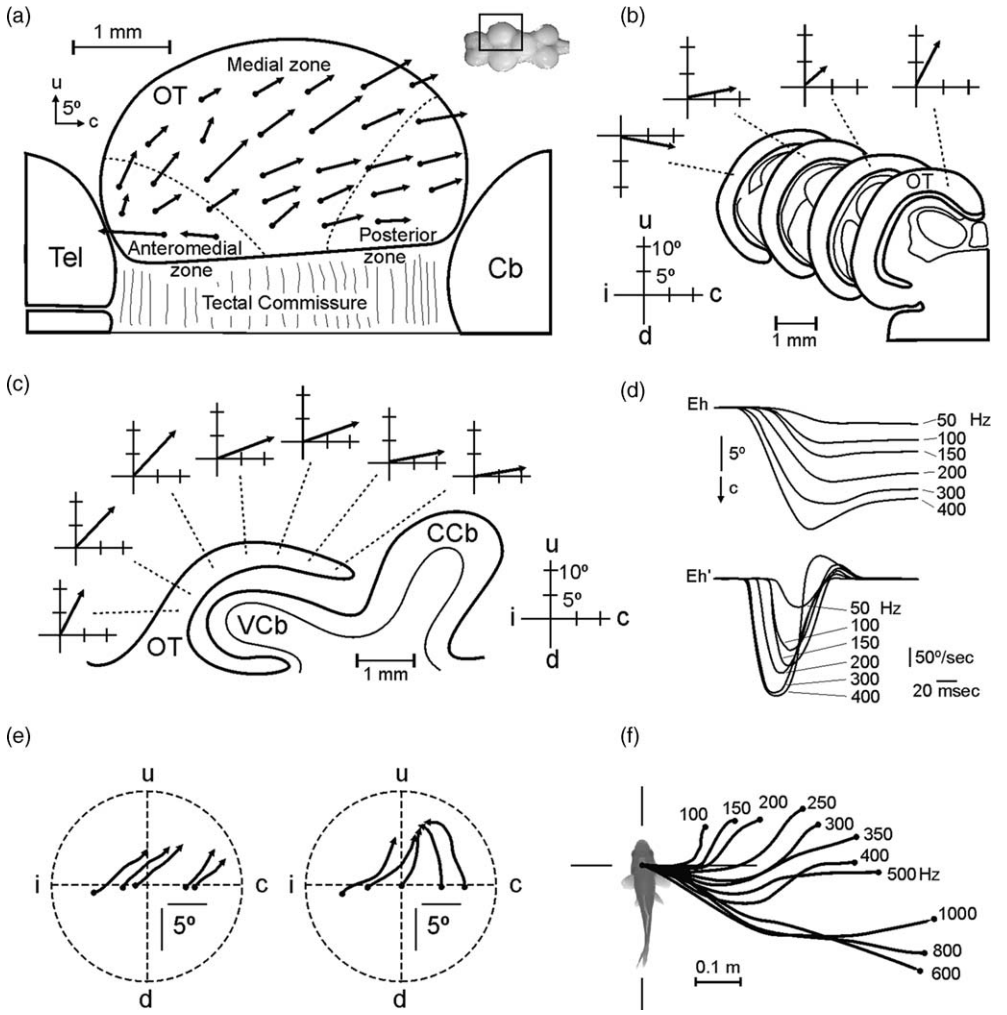

Figure 11 Focal electrical stimulation in the optic tectum of goldfish elicits coordinated eye and body movements, revealing that the optic tectum of teleost fish is a crucial center for the generation of egocentrically referenced actions in space. The amplitude and direction of eye movement vectors depend on the stimulation site within the tectum (a). Varying the stimulation site in the medial-lateral axis produces an increase in the vertical component (b), whereas varying the stimulation site in the rostrocaudal axis produces a systematic change in the amplitude of the horizontal component of the saccade (**c**). Varying the stimulation parameters (v.g. frequency) produces systematic changes in the metric and kinetic of the evoked orientation responses (d). Stimulating anatomically separated tectal areas evokes different types of eye movements (e). The electrical microstimulation of the optic tectum in free-swimming fish elicits body movements (f). Evoked movements consist of complete orientation responses including coordinated movements of the axial musculature, fins, and eyes, which closely resemble the natural responses. The direction and amplitude of the orienting responses depend on both the tectal stimulation site and the stimulus parameters. Abbreviations: Cb, cerebellum; CCb, corpus cerebellum; Eh, horizontal component of eye position; Eh′, eye velocity trace; OT, optic tectum; St, electrode for microstimulation; Tel, telencephalon; VCb, valvula cerebellum; d, u, i, c, downward, upward, ipsiversive, and contraversive direction of evoked eye saccade, respectively. Modified from Herrero L, Rodríguez F, Salas C, and Torres B (1998) Tail and eye movements evoked by electrical microstimulation of the optic tectum in goldfish. *Exp. Brain Res.* 120: 291–305; Salas C, Herrero L, Rodríguez F, and Torres B (1997) Tectal codification of eye movements in goldfish studied by electrical microstimulation. *Neuroscience* 78: 271–288.

1979; Burt and Flohr, 1988; Ott and Platt, 1988; Burt and Flohr, 1991; Pastor et al., 1994; Li et al., 1995; McElligott et al., 1998; Straka et al., 2006). However, like the mammalian cerebellum, the teleost fish cerebellum is likely not only an essential center for motor coordination and adjustment but is also involved in learning and memory and in spatial cognition. For example, the goldfish cerebellum is involved in eye blink–like classical conditioning (Rodríguez et al., 2005; Salas et al., 2006). In addition,

cerebellum lesions produce profound spatial cognition deficits in goldfish (Durán, 2004; Rodríguez et al., 2005, 2006). In this study, when goldfish were required to learn the location of a baited feeder within a 25-feeder matrix surrounded by a stable array of visual cues, the cerebellum-lesioned animals never reached the level of accuracy of the control and sham-operated animals. This could be due to the fact that their search pattern is stereotyped and inefficient. The results of test trials showed that the performance of the cerebellum-lesioned fish depends on approaching a particular subset of cues, suggesting that they are unable to use the entire array. These data indicate that these animals are impaired in their ability to generate or use map-like representations of the environment. Interestingly, the cerebellum lesions also impair orientation based on egocentric frames of reference. Durán (2004) showed that whereas telencephalic lesions disrupt goldfish performance in a spatial constancy task but spare cue orientation learning (see also Salas et al., 1996b), cerebellum lesions are equally disruptive in both tasks. These results indicate that the teleost cerebellum is also involved in the association of motor responses with single landmarks and in other egocentric orientation mechanisms. Remarkably, whereas the effects of cerebellum lesions in goldfish are profound and widespread in spatial learning, they do not produce observable sensorimotor impairments or deficits in posture, swimming ability, or obstacle avoidance, indicating that also in teleost fish the role of the cerebellum goes far beyond just motor-control modulation.

1.26.11 Concluding Remarks

The data presented here show that the complexity and plasticity of spatial behavior in fish parallels that of mammals and birds. Moreover, as in land vertebrates, spatial behavior in fish depends on a variety of learning and memory mechanisms and cognitive processes, supported by particular brain circuits. The fish's lateral pallium, likely homologous to the hippocampus of amniotes, is essential for simultaneously processing and encoding spatial information from multiple sources and forming map-like or relational representations of the environment. Also as in land vertebrates, other brain circuits, involving, for example, the optic tectum or the cerebellum, underlie egocentrically referenced spatial orientation. The notable similarity observed in the spatial cognition capabilities and their neural substrates in groups that diverged millions of years ago suggest that some features of these spatial learning and memory systems and their neural basis might be a primitive feature in vertebrates, conserved through evolution.

1.27 Reconsolidation in Invertebrates

D. Eisenhardt and N. Stollhoff, Freie Universität Berlin, Berlin, Germany

1.27.1 Introduction

1.27.1.1 Memory Consolidation after Training and Retrieval

Formation of long-term memories (LTMs) can be disturbed during a discrete time window after learning with amnestic agents. It has been therefore concluded that LTMs undergo a labile phase of memory fixation, which is termed consolidation, and that an LTM, once consolidated, is stable (Dudai, 2004). Nevertheless, it has been known since the late 1960s that retrieving a memory in combination with the application of a consolidation inhibitor disturbs memory retention in a later memory test (Misanin et al., 1968; *See* Chapter 1.24) (**Figure 1(a)**). This observation of a retrieval-dependent amnesia first resulted in the theory that memories do not undergo a consolidation process but, rather, exist in an active or an inactive state (Lewis, 1979). In the active state, memories are vulnerable to inhibitors; in the inactive state, inhibitors have no effect. Memory retrieval transfers an inactive memory into an active memory, which makes the memories vulnerable again. Some years ago Nader and colleagues (2000) took on the issue of retrieval-dependent amnesia. They interpreted their findings in combining the consolidation theory with the hypothesis of active and

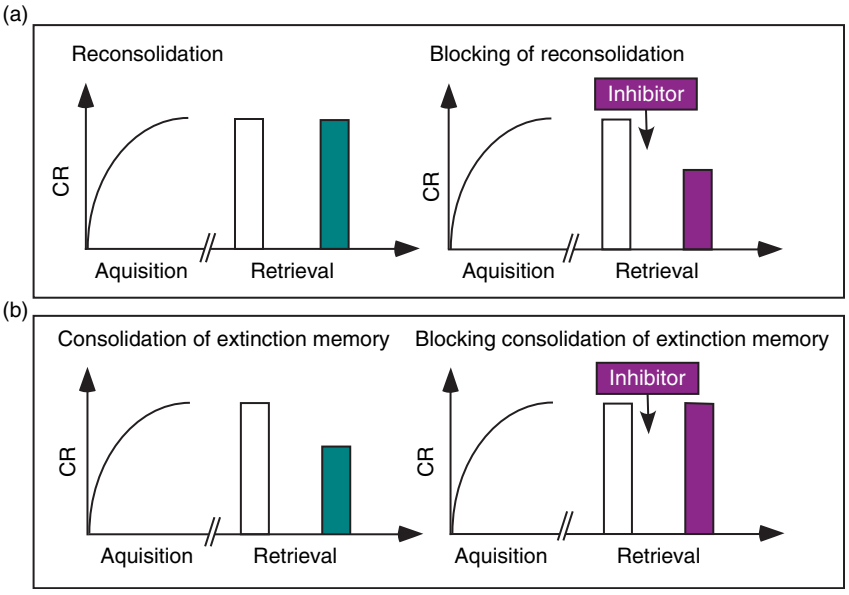

Figure 1 Consolidation processes following memory retrieval. Schematic diagram of the behavioral outcome of consolidation processes following memory retrieval. (a) Reconsolidation. The combination of memory retrieval and the application of an inhibitor of consolidation leads to a decrease of the conditioned response (CR) (right) in comparison to animals that are retrieved but not treated with the inhibitor (left). (b) Consolidation of an extinction memory. The CR is decreased after memory retrieval (left). This reduction of the CR is blocked by application of an inhibitor of consolidation after the first memory retrieval. Blocking is visible at the second retrieval trial (which is a retention test for the memory following memory retrieval) (right).

inactive memories (Nader, 2003). They proposed that retrieval makes the consolidated memory labile and that a second consolidation round is required to stabilize the retrieved memory. This second round of consolidation is targeted by the inhibitor, resulting in a decrease of the conditioned response (CR) at a later memory test. Accordingly, the process in question is called reconsolidation (Spear, 1973; Przybyslawski and Sara, 1997; Sara, 2000; Nader, 2003; Dudai and Eisenberg, 2004; *See also* Chapter 1.24). Meanwhile, an extensive study began of the neuronal and molecular basis of reconsolidation in vertebrates and invertebrates, and it is under dispute whether this hypothesis holds true. Several other hypotheses have been put forward to explain this phenomenon either based on the consolidation theory (Dudai and Eisenberg, 2004; Alberini, 2005; Eisenhardt and Menzel, 2007) or based on the assumption that the retrieval rather then the memory itself is affected (Riccio et al., 2002).

Sometimes memory retrieval leads to a decrease of the CR. This phenomenon is termed extinction (Pavlov, 1927). When a consolidation inhibitor like a protein synthesis inhibitor is applied around the time point of memory extinction, the CR increases in a later memory test (**Figure 1(b)**). It has therefore been concluded that the extinction memory undergoes a consolidation process that is blocked by the application of the inhibitor (Berman and Dudai, 2001; Vianna et al., 2001, 2003; Pedreira and Maldonado, 2003; Power et al., 2006). Accordingly, retrieving a memory induces two processes that result in contrasting behavioral phenomena – reconsolidation and consolidation of an extinction memory.

Meanwhile, reconsolidation has been described in several invertebrate model organisms, namely, four gastropod species, *Hermissenda* (Child et al., 2003), *Lymnaea stagnalis* (Sangha et al., 2003a; Kemenes et al., 2006), *Helix lucorum* (Gainutdinova et al., 2005), and *Limax flavus* (Sekiguchi et al., 1997); the crab, *Chasmagnathus granulatus* (Pedreira et al., 2002); and the honeybee, *Apis mellifera* (Stollhoff et al., 2005). Findings in each of these organisms contributed to the study of the reconsolidation phenomenon. Many of the results known from vertebrates have also been found in invertebrates, demonstrating generalities and differences in the reconsolidation phenomenon and its underlying mechanisms. To illustrate the generalities and differences, we present experiments on reconsolidation in gastropods, the crab *Chasmagnathus*, and the honeybee, *Apis mellifera.*

1.27.2 Studies on Reconsolidation in Invertebrates

1.27.2.1 The Terrestrial Slug *Limax flavus*

1.27.2.1.1 Memory for aversive odor-taste conditioning is cooling sensitive

The slug *Limax flavus* (**Figure 2(a)**) is native to Europe but has been imported throughout the world. To study memory formation in *Limax flavus*, an odor-avoiding paradigm is used (Yamada et al., 1992). A starved animal is placed in a box lined with carrot juice–moistened filter paper. Carrot juice is used as the CS. After a 2-min exposure, the animal is immediately transferred to another box with bitter-tasting quinidine sulfate, which presents the unconditioned stimulus (US). For memory testing a slug is placed into the center of a three-chambered apparatus (**Figure 2(b)**). The walls of the center chamber are perforated to allow odor sensing. The two side chambers contain moistened filter-paper with the trained carrot juice or frog chow, which is normally fed to the snails.

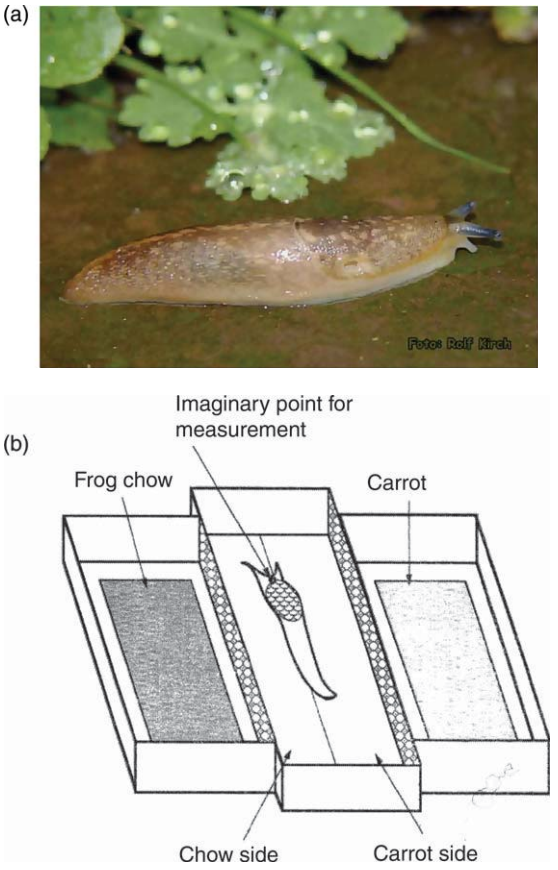

Figure 2 The slug *Limax flavus*: The odor-avoidance paradigm. (a) The yellow garden slug *Limax flavus*. Photo provided by Rolf Kirch. (b) The three-part test chamber: Carrot and frog chow are placed in opposite side chambers. The walls of the center chamber are perforated. A center line divides the room into a chow side and a carrot side. Individual slugs, marked with a dot on the head, which is used for measurement, are placed into the center chamber; the time the slug's head spent on the carrot side is recorded during three testing trials. Adapted from Figure 1 in Yamada A, Sekiguchi T, Suzuki H, and Mizukami A (1992) Behavioral analysis of internal memory states using cooling-induced retrograde amnesia in *Limax flavus*. *J. Neurosci.* 12: 729–735.

After a single CS–US pairing, slugs show an avoidance behavior for the trained carrot odor. Cooling the animal within 1 min after training induces retrograde amnesia, but later cooling has no effect (Yamada et al., 1992).

1.27.2.1.2 Reconsolidation in Limax flavus

The first study that found the reconsolidation phenomenon in an invertebrate was done in *Limax flavus*. In this study the authors focused on the temporal evolution of a memory (Sekiguchi et al., 1997). Although the authors did not term their findings reconsolidation, they revealed retrieval-dependent amnesia when trained snails were exposed to the CS and were cooled immediately afterward.

The combination of memory retrieval and cooling was applied at different time points after training, and the resulting memory was tested 1 day later. It turned out that by memory retrieval, a cooling-sensitive process can be induced until 3 days after training (**Figure 3**). After 3 days the memory becomes insensitive to retrieval-dependent amnesia. Nevertheless, when an additional CS–US pairing was presented before combining memory retrieval and cooling, a retrieval-dependent amnesia occurred even though the initial training had been applied more than 3 days before (**Figure 4**).

Interestingly, this induced susceptibility for retrieval-dependent amnesia followed the same temporal gradient as occurred after initial training, and it was supposed that the additional CS–US pairing results in a new memory with the same temporal gradient as the initial memory. To test this, a second-order conditioning trial, where a CS (CS 2) is paired with the formerly reinforced CS (CS 1), was presented instead of the additional CS–US pairing. The presentation of the CS1 in combination with cooling after the second-order conditioning resulted in a retrieval-dependent amnesia for the initial memory. But the presentation of the CS 2 in combination with cooling leads to retrieval-dependent amnesia for the initial memory and the

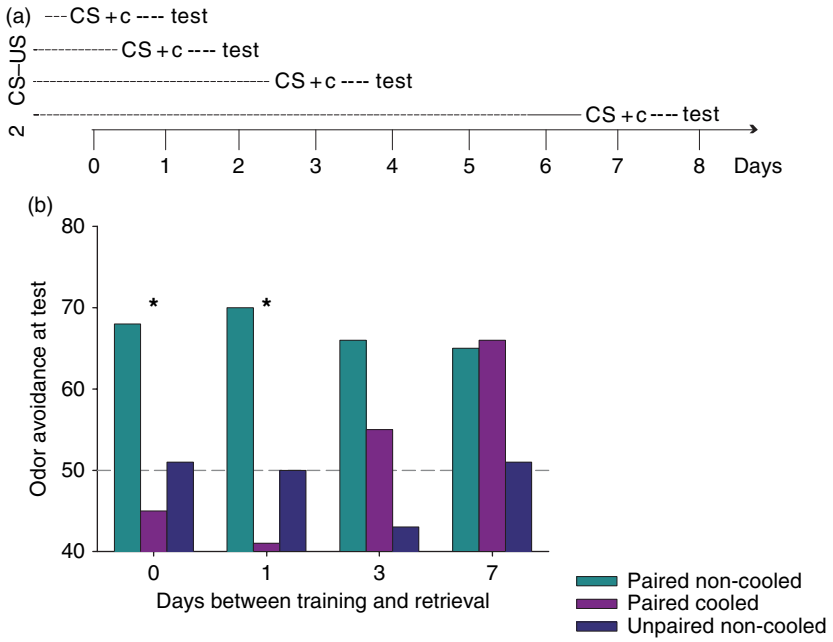

Figure 3 The slug *Limax flavus*: Retrieval-induced amnesia is dependent on the age of the memory (a) experimental schedule: Animals were trained to avoid an odor on day 0 by pairing the odor (conditioned stimulus, CS) with quinidine sulfate (unconditioned stimulus, US). Animals were divided into four experimental groups. For each group the memory was retrieved once by CS presentation at different time points (on day 0, 1, 3, or 7) followed immediately by a cooling procedure (CS + c). The slugs were tested 24 hours later in the three-chambered apparatus. Their odor avoidance behavior in the test was measured; the means are presented in (b) (paired cooled, violet bars). An additional group of slugs was trained, but not retrieved and cooled (paired noncooled, green bars). A second control group received unpaired presentation of the CS–US on day 0, but was not retrieved and cooled (unpaired noncooled, blue bars). The odor avoidance behavior of the experimental group (violet bars) is significantly decreased (indicated by an asterisk) in comparison to the trained noncooled group if the memory was retrieved > 3 days after training. Afterward, the reconsolidation phenomenon is not visible. The gray dashed line at 50% indicates no odor preference. Adapted from Figure 1 of Sekiguchi T, Yamada A, and Suzuki H (1997) Reactivation-dependent changes in memory states in the terrestrial slug *Limax flavus*. *Learn. Mem.* 4: 356–364.

second-order conditioned memory. Sekiguchi et al. (1997) concluded that the CS 1 in the second-order conditioning trial activates the initial memory. Accordingly, an additional CS–US pairing should also activate the initial memory rather than resulting in the formation of a new memory. According to this conclusion, Sekiguchi et al. (1997) stated that a memory becomes inactive after it matures and can no longer be inhibited by cooling. When the memory is retrieved, it becomes active again but might still be insensitive to cooling, depending on its age. Only additional CS–US pairings or second-order conditioning trials activate the initial memory that was insensitive to cooling, pushing it from a cooling-insensitive state back to a cooling-sensitive state. This model is based on Lewis's theory of activated and inactivated memories (1979) (see section titled "Memory Consolidation after Training and Retrieval") but extends beyond it. In contrast to Lewis (1979), Sekiguchi et al. (1997) posed an active and an inactive memory state, but in addition, showed a cooling-sensitive and a cooling-insensitive state. Accordingly, although memories are retrieved and are thus activated, they are not necessarily cooling sensitive. Only additional CS–US pairing or second-order conditioning leads to a memory that gets cooling sensitive by retrieval 24 h later. Interestingly, the findings by Sekiguchi et al. (1997) cannot be easily explained by the reconsolidation theory (Nader, 2003). The reconsolidation theory proposes a direct reactivation of a consolidated memory by a retrieval trial. Here, instead, the additional CS–US pairing enables a memory to be reactivated 24 h later.

1.27.2.2 The Pond Snail *Lymnaea stagnalis*

To study the reconsolidation phenomenon in the snail *Lymnaea stagnalis*, two learning paradigms have been used: the operant aerial respiration paradigm and the classical chemosensory conditioning paradigm.

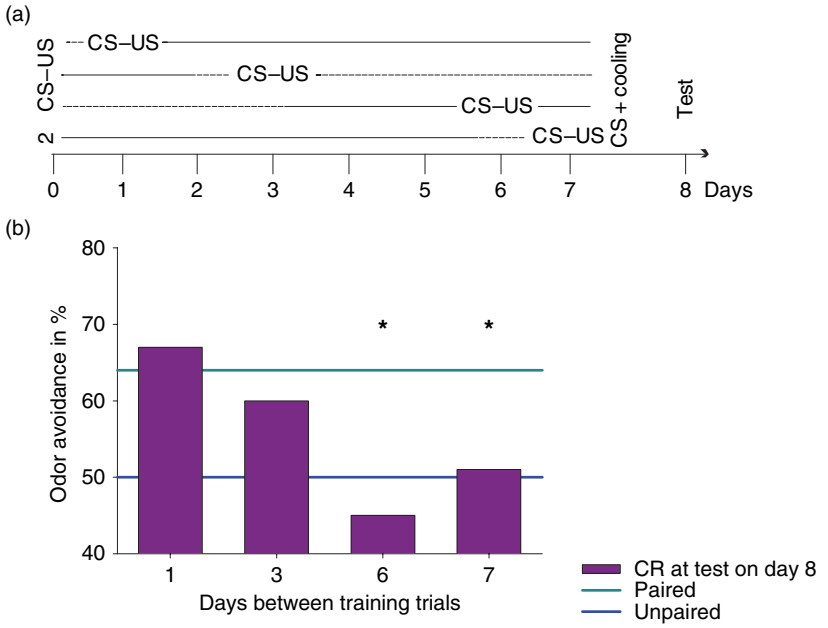

Figure 4 The slug *Limax flavus*: Additional training reactivates the memory. (a) Experimental schedule. Slugs received two conditioned stimulus (CS)–unconditioned stimulus (US) pairings on day 0. Afterward the animals were divided into four subgroups. Additional CS–US pairings were applied at varied time points (1, 3, 6, 7 days) after training. Memory was retrieved by CS presentation on day 7, and slugs were immediately cooled afterward. (b) Memory avoidance behavior was tested on day 8. Retrieval-induced amnesia is only detectable if an additional training was applied on day 6 and day 7. Significant difference in response between experimental group (bars) and paired control group are indicated by asterisks. The means of paired and unpaired control groups are presented as a blue or a green line, respectively. Adapted from Figure 2 in Sekiguchi T, Yamada A, and Suzuki H (1997) Reactivation-dependent changes in memory states in the terrestrial slug *Limax flavus*. *Learn. Mem.* 4: 356–364.

1.27.2.2.1 Lymnaea stagnalis: *The operant aerial respiration paradigm*

Lymnaea stagnalis is an aquatic pulmonate snail (**Figure 5**). It is a bimodal breather and can breathe via its skin (cutaneous respiration) or through a simple lung (aerial respiration). When the animal stays in stagnant water where the oxygen content is low, it becomes hypoxic. Then the snail comes to the water surface for aerial respiration. It opens and closes its respiratory orifice, the pneumostome, and breathes through the lung (**Figure 6(a)**). This behavior by the snail is used in the operant aerial respiration paradigm (Lukowiak et al., 1996). Here the snails are put in beakers of water, which is made hypoxic by bubbling N_2 through it. When the animal attempts to open its pneumostome as a reaction to the hypoxic water, it receives a gentle tactile stimulus to the pneumostome area, reducing its aerial respiration, without affecting cutaneous respiration. The number of openings is recorded during training periods and retention tests. Learning takes place if the number of attempted pneumostome openings is significantly decreased between the first and the last training trial. It is important to note that in this paradigm memory retrieval and retention tests consist of the same procedure as the training sessions. They are only designated differently for the reader's convenience.

Figure 5 The snail *Lymnaea stagnalis* The snail *Lymnaea stagnalis* sinks from the water surface to the ground of the pond. Photo by Kathrin Spöcker.

1.27.2.2.2 A long-term memory for the tactile stimulus is already formed after 4 h

Memory for the tactile stimulation of the pneumostome is defined by two criteria: (1) the number of

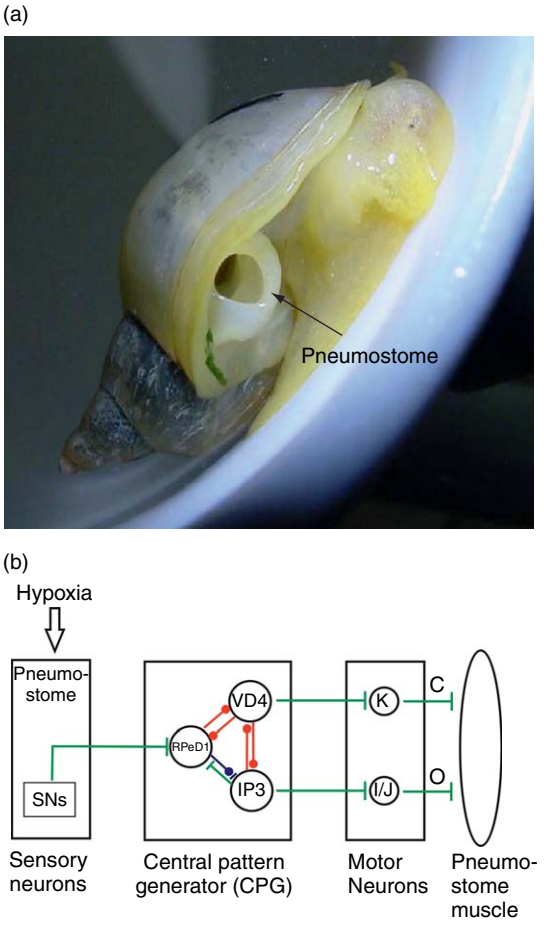

Figure 6 The snail *Lymnaea stagnalis*: Neuronal network underlying respiratory behavior. (a) *Lymnaea stagnalis* with opened pneumostome (arrow). From Lukowiak K, Sangha S, Scheibenstock A, et al. (2003) A molluscan model system in the search for the engram. *J. Physiol.* 69–76. (b) Schematic drawing of the central pattern generator (CPG). A chemosensory stimulus (here hypoxia) activates sensory neurons (SNs) in the pneumostome area, which in turn provide excitatory input (green line) to the right pedal dorsal 1 interneuron (RPeD1). Once stimulated, RPeD1 activates the input3 interneuron (IP3) via a biphasic effect (inhibition followed by excitation) (blue line) and inhibits visceral dorsal 4 interneuron (VD4) (red line). IP3 in turn excites both RPeD1 and the I/J motor neurons involved in pneumostome openings (O). IP3 also produces an inhibitory effect on VD4, and after release from this inhibition, VD4 fires, resulting in pneumostome closure (C). Tactile stimulation of the pneumostome area evokes closure of the pneumostome, and the aerial respiratory behavior stops. Adapted from Figure 1 in Sangha S, Varshney N, Fras M, et al. (2004) Memory, reconsolidation and extinction in *Lymnaea* require the soma of RPeD1. *Adv. Exp. Med. Biol.* 551: 311–318. Syed NI Winlow W (1991) Coordination of locomotor and cardiorespiratory networks of *Lymnaea stagnalis* by a pair of identified interneurones. J. Exp. Biol. 158: 37–62.

pneumostome openings is significantly reduced between the memory test and the first training session, and (2) the number of pneumostome openings at the memory test is not significantly different from the last training session (Lukowiak et al., 1996). Memory persists for at least 4 weeks if a spaced training protocol is used (Lukowiak et al., 1998). Within 1 h after the last training session, the consolidation process is susceptible for amnesic treatment. Memory that lasts beyond 4 h is considered long-term memory (LTM) because its consolidation depends on protein synthesis and RNA synthesis (Sangha et al., 2003b).

1.27.2.2.3 The neuronal network underlying the aerial respiration paradigm

One advantage of the aerial respiration paradigm is that the circuit of neurons controlling this behavior is known. Rhythmic behaviors like respiration and feeding are often controlled by neurons known as central pattern generators (CPGs). The respiratory CPG in *Lymnaea* consists of three neurons, named right pedal dorsal 1 (RPeD1), input 3 (IP3), and visceraldorsal 4 (VD4) interneurons. The latter two provide synaptic inputs to identified motor neurons, which mediate the opening movement (expiration) and the closing movement (inspiration) of the pneumostome (Syed et al., 1991; Syed and Winlow, 1991). The third neuron, RPeD1, receives excitatory chemosensory and mechanosensory input from the pneumostome area, which in turn initiates the CPG activity, and hence the respiratory behavior (**Figure 6(b)**).

Procedural memories are thought to be stored within the same network that mediates behavior (Milner et al., 1998), and therefore learning-induced changes were believed to be stored in the CPG. Indeed, neural correlates of learning and memory have been found in RPeD1 (Spencer et al., 1999). Removing the soma of RPeD1 by poking it gently with a glass microelectrode does not alter aerial respiratory behavior in a hypoxic environment, and the remaining neurite is electrophysiologically functional for at least 10 days after ablation (Scheibenstock et al., 2002). This preparation allows analyzing the function of RPeD1 in LTM formation in the aerial respiration paradigm. Snails with a soma-less RPeD1 are able to learn, but an LTM is not formed. Nevertheless, when RPeD1's soma is ablated after LTM consolidation has occurred, LTM can still be accessed. Accordingly, the soma of RPeD1 is a site of LTM consolidation but is not needed for memory retrieval (Scheibenstock et al., 2002).

1.27.2.2.4 Reconsolidation in the aerial respiration paradigm

To test for a possible reconsolidation process, snails are cooled in 4°C cold water immediately after memory retrieval. The memory of the control group is not retrieved, but the animal is also cooled. Memory retention is tested 4 hours after memory retrieval. The retrieved and cooled animals do not demonstrate memory. In contrast, the control group, which was cooled but was not retrieved, shows a memory for the tactile stimulus. Therefore, the reconsolidation process induced by memory retrieval is disturbed by the cooling procedure (Sangha et al., 2003a).

Similar results are obtained with the systemic application of the RNA synthesis-inhibitor, actinomycin D, after memory retrieval (**Figure 7(a)**). Only animals receiving the retrieval in conjunction with the actinomycin D treatment do not show memory in a test 4 hours later. Comparable to the results with this RNA inhibitor, RPeD1 soma ablation after retrieval blocks memory retention at the later test (**Figure 7(b)**). The memory remains intact in RPeD1 soma-ablated snails that were not retrieved before the ablation. Accordingly, the soma of RPeD1 is required for reconsolidation.

These experiments demonstrate that a single neuron is necessary for consolidation and reconsolidation. Accordingly, in *Lymnaea* both processes take place not only in the same structure but also in the same neuron (Sangha et al., 2003a, 2004). Interestingly, vertebrate studies on this issue reach contradicting results. Some demonstrate that consolidation and

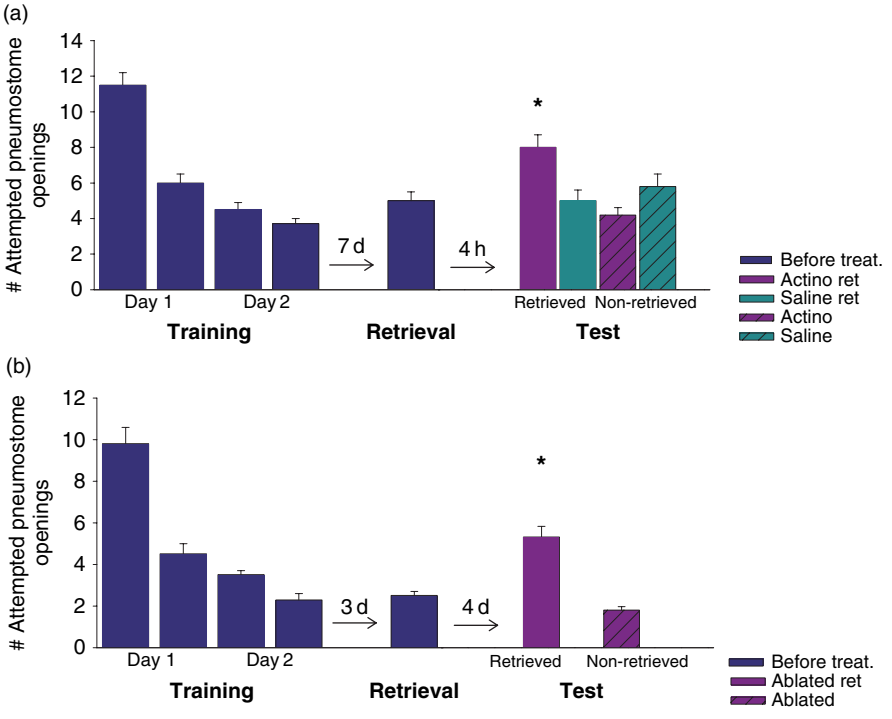

Figure 7 *Lymnaea stagnalis*: Reconsolidation is RNA syntheses dependent and takes place in a single neuron. (a) Training consisted of 4 45-min sessions in N_2-enriched hypoxic water. Sessions were dispersed over 2 days. On a single day the intertraining interval was 1 h. The memory was retrieved 7 days after training, and snails were injected with actinomycin D (Actino ret, violet bar) or saline (Saline ret, green bar) immediately after retrieval. The control groups (striped bars) received the injection (Actino ret, striped violet bar; Saline, striped green bar), but not the retrieval session. Memory retention was tested 4 h later. The retrieved and actinomycin D–injected animals (Actino ret) did not demonstrate memory. In contrast, the control group, which received the actinomycin D but was not retrieved, showed a memory for the conditioned response. (b) Operant training was administered as described above. Three days later half of the animals received the retrieval session immediately followed by the ablation of the soma of RPeD1 (Ablated ret, violet bar), whereas the other half was not reminded but underwent the ablation procedure (Ablated, striped violet bar). Animals were tested 4 days later. Memory was not observed in retrieved and ablated snails, whereas ablated snails that did not receive the retrieval procedure showed memory. Adapted from Figures 3 and 4 in Sangha S, Scheibenstock A, and Lukowiak K (2003a) Reconsolidation of a long-term memory in *Lymnaea* requires new protein and RNA synthesis and the soma of right pedal dorsal 1. *J. Neurosci.* 23: 8034–8040.

reconsolidation take place in different brain structures (Tronel and Sara, 2002; Salinska et al., 2004), whereas others find that reconsolidation can be disrupted with protein synthesis inhibitors targeting the same brain structure as in consolidation experiments (Rose and Benjamin, 1979; Nader et al., 2000; Debiec et al., 2002; Koh and Bernstein, 2003).

1.27.2.2.5 Lymnaea stagnalis: *The classical chemosensory conditioning paradigm*

The second paradigm used in *Lymnaea* is an appetitive classical conditioning based on its feeding behavior. Feeding behavior consists of a series of rasps that can be divided into three phases: (1) protraction phase, in which the animal opens the mouth and the radula, a toothed chitinous tissue, is extended to contact the food; (2) retraction phase, when the food substrate is grazed and lifted into the mouth; and (3) the swallow phase, during which the mouth is closed and the food is swallowed (Rose and Benjamin, 1979; Benjamin et al., 2000; Elliott and Susswein, 2002). Similar to the respiratory behavior described earlier, a known network driven by a CPG controls this behavior (Benjamin et al., 2000: *See also* Chapter 1.30).

Using sucrose as a stimulus increases the feeding behavior in terms of the number of rasps (Kemenes et al., 1986; *See also* Chapter 4.09). Therefore, sucrose is used as a US in an appetitive classical conditioning paradigm. Here food-deprived snails are put into a Petri dish with water and are allowed to acclimatize. Amyl acetate, used as the CS, and the sucrose solution are added to the Petri dish, one after another and the animals are exposed to the CS–US mixture for 10 s. Afterward, the trained snails are transferred to their home tanks. To test the taste memory, the animals are put back into the Petri dish, the CS (amyl acetate) is added after a resting period, and the number of rasps is counted. Following a single paired CS–US presentation, animals show significant higher feeding response to amyl acetate compared with their own naïve response and with that of control groups (unpaired, CS alone, US alone) (Fulton et al., 2005).

1.27.2.2.6 *A consolidated long-term memory in the appetitive chemosensory conditioning paradigm is formed after 5 hours*

An LTM is formed about the amyl acetate-sucrose association that lasts at least 19 days (Alexander et al., 1984). Applying the widely used protein synthesis-inhibitor anisomycin at different time points after single-trial training demonstrates a protein-dependent consolidation phase 10 min after training, whereas later tested time points (1–6 hours) no longer reveal any sensitivity to the inhibitor. An impairment of memory retention can be seen already 5 h after training and injection. Therefore, memory retention 5 h after learning is protein synthesis dependent (Fulton et al., 2005).

1.27.2.2.7 *Reconsolidation in the appetitive chemosensory conditioning paradigm*

A study by Kemenes et al. (2006) asked if the age of a memory has an influence on the molecular mechanisms that underlie a reconsolidation process. This study distinguishes between fresh and old memories. Protein synthesis shortly after conditioning (between 10 min and 1 h) is required for the formation for a memory expressed more than 5 h after training (Fulton et al., 2005). Therefore, a 6-h memory was considered to be a freshly consolidated memory, whereas a 24-h memory was regarded as an old consolidated memory. To demonstrate the reconsolidation phenomenon, the animals receive a CS presentation to retrieve the memory 6 or 24 h after conditioning, followed by an injection of the protein synthesis inhibitor anisomycin. At a retention test 18 h after the injection, the CR (number of rasps) of the anisomycin-injected and retrieved animals was reduced in comparison to the control groups. This demonstrates that protein synthesis is required for reconsolidation when a 6-h or a 24-h memory is retrieved (Kemenes et al., 2006).

A follow-up experiment directly measured the retrieval-induced activation of cAMP-dependent protein kinase A (PKA) in the cerebral ganglia. The cerebral ganglia were chosen because they are known to be a site for neuronal plasticity (Straub et al., 2004). Again the study differentiated between fresh and old memories (Kemenes et al., 2006). Interestingly, the PKA activity was increased in the group with trained animals subjected to a CS presentation 6 h after training in comparison to nonretrieved or unpaired trained control groups. This retrieval-induced increase of PKA activity was not found if the memory was retrieved 24 h after CS–US pairing. A PKA inhibitor was used to verify that retrieval-induced PKA activity is dependent on the age of the memory. Animals showed a reduced CR at the retention test if a freshly consolidated memory was retrieved followed by an injection of the PKA inhibitor. If the memory was

retrieved 24 h after training, the application of the PKA inhibitor did not lead to a reduced CR (**Figure 8**).

This confirmed the biochemical data. Accordingly, retrieval of a consolidated memory induces a protein synthesis–dependent reconsolidation process, but only reconsolidation of freshly consolidated memories requires the activation of PKA. It can be concluded that the molecular requirements for reconsolidation depend on the age or the maturation of the retrieved memory (Kemenes et al., 2006).

Reconsolidation's dependency on the age of the retrieved memory has been reported before, although on a different timescale. Rats trained in an inhibitory avoidance task, show the reconsolidation phenomenon only when a recent memory has been retrieved in combination with the application of a protein synthesis-inhibitor. When the memory for the inhibitory avoidance task is 14 days old or older, a decrease of the CR can no longer be observed after combining memory retrieval with a systemic application of a protein synthesis inhibitor (Milekic and Alberini, 2002). Similar results have been demonstrated by other authors in several paradigms in vertebrates (e.g., Eisenberg and Dudai, 2004; Suzuki et al., 2004; Frankland et al., 2006; Power et al., 2006). Nevertheless, contrasting findings have also been reported (Nader et al., 2000; Debiec et al., 2002). Debiec et al. (2002) demonstrated in rats that retrieval of a 45-day-old memory for contextual fear conditioning, in combination with protein synthesis inhibition in the hippocampus, still results in the reconsolidation phenomenon (Debiec et al., 2002). Taken together the reason for different temporal requirements for reconsolidation remains unknown.

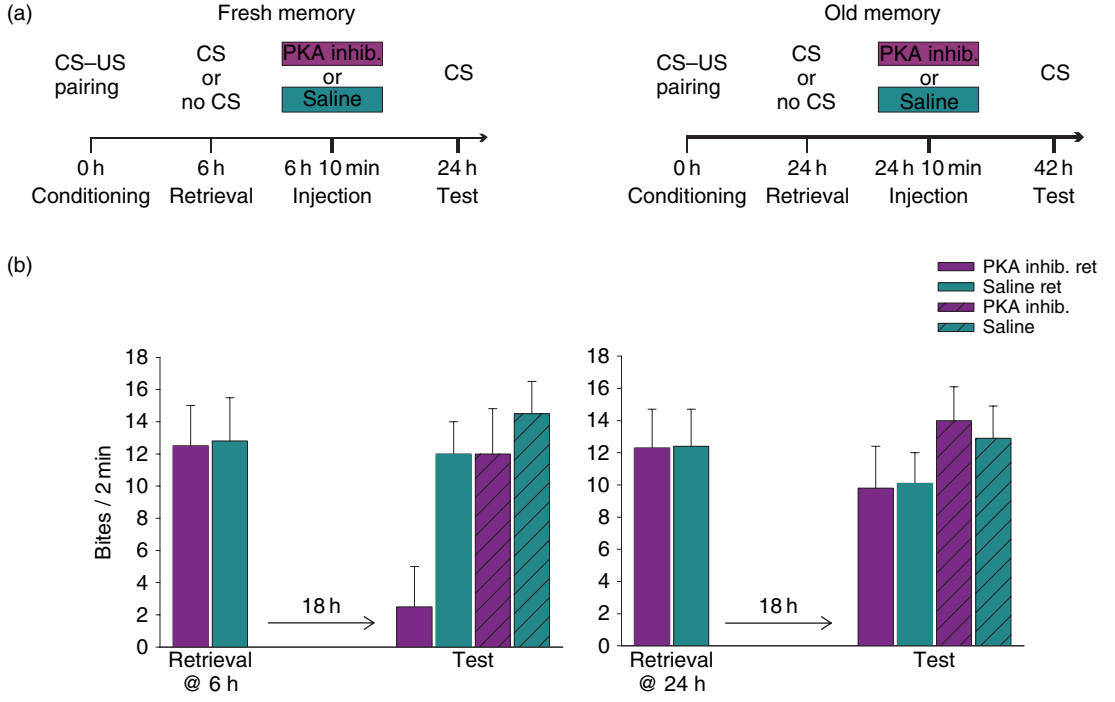

Figure 8 *Lymnaea stagnalis*: Reconsolidation in an appetitive conditioning paradigm. (a) The experimental scheme. Food-deprived snails were put in a Petri dish with water. Amyl acetate, as conditioned stimulus (CS), was added to a final concentration of 0.004%. After 15 s, a the sucrose solution was added and the animals remained in this CS + unconditioned stimulus (US) mixture for an additional 105 s. After this single CS–US pairing, the animals were rinsed. Animals were divided into two groups, and half of the animals received a CS presentation to retrieve the memory 6 h (fresh memory, left panel) or 24 (old memory, right panel) hours after conditioning. The other half received no CS stimulation. Ten minutes later, all animals were injected with PKA inhibitor (violet) or saline (green). All animals were tested 18 h after injection for their response to the CS in a 2-min test. (b) Animals that were retrieved at 6 h after training followed by an injection of the PKA inhibitor (PKA Inhib. ret, violet bars) show reduced conditioned response (number of rasps) during testing in comparison to retrieved and saline-injected (Saline ret, green bars) animals or to the nonretrieved groups (striped bars) (left panel). This significant reduction of CR of the retrieved and inhibited group is not observable if the memory is retrieved 24 h after training (right panel). Adapted from Figures 1 and 3 in Kemenes G, Kemenes I, Michel M, Papp A, and Muller U (2006) Phase-dependent molecular requirements for memory reconsolidation: Differential roles for protein synthesis and protein kinase A activity. *J. Neurosci.* 26: 6298–6302.

But the study in *Lymnaea stagnalis* illustrates that differences in the molecular events induced by memory retrieval might play a role.

1.27.2.3 The Terrestrial Snail *Helix lucorum*

1.27.2.3.1 Context memory in Helix lucorum *is protein synthesis dependent*

Helix lucorum is an edible snail, sometimes called escargot turc (**Figure 9(a)**). It is found in central Italy, from Yugoslavia through the Crimea to Turkey, and around the Black Sea. *Helix lucorum* is trained in an aversive conditioning paradigm, where it learns to associate the context, a rotating ball, with an electric shock (Gainutdinova et al., 2005). To do so, the animals receive an electric shock to the dorsal surface of their foot after they are fixed at their shell and placed on a ball, which rotates in water (**Figure 9(b)**). To test for the acquired context memory, the animals are placed onto the ball (the reinforced context) again or on a flat glass plate (the nonreinforced context), and a tactile stimulus is applied to the skin in both contexts. The defensive tentacle withdrawal amplitude is measured. A significantly different withdrawal amplitude between the reinforced and the nonreinforced context indicates an associative memory for the context.

To study memory consolidation, animals are trained over 5 days and receive an injection of anisomycin or saline every day after the first shock. Memory is tested 2 days after the last training day (**Figure 10**). Saline-injected snails show a significantly higher response to tactile stimulation in the trained context compared to the nonreinforced context. Therefore, the animals are able to differentiate between the context in which they get a sensitizing shock and the control context. Anisomycin-injected snails show no significant difference in the withdrawal amplitude between the two contexts. This indicates that the formation of a context memory depends on protein synthesis (Gainutdinova et al., 2005).

1.27.2.3.2 Reconsolidation in Helix lucorum

The training protocol used in the reconsolidation experiments is the same as in the consolidation experiment (see previous section). To remind the animals of the training situation, they are placed in the reinforced context, and neither a shock nor a tactile stimulus for testing is delivered. Anisomycin or saline are applied immediately after the reminding procedure. Testing the animals the next day does not reveal context memory in reminded and anisomycin-injected snails (**Figure 11**). In contrast, animals treated with saline show context memory. If the reminding process is omitted, the injection of anisomycin does not affect the context memory. Therefore, the reminder procedure induces a protein synthesis–dependent process, and hence reconsolidation. If in the reminding situation (the reexposure to the context) the reinforcing stimulus (the shock) is applied in combination with a protein synthesis inhibitor, the reconsolidation

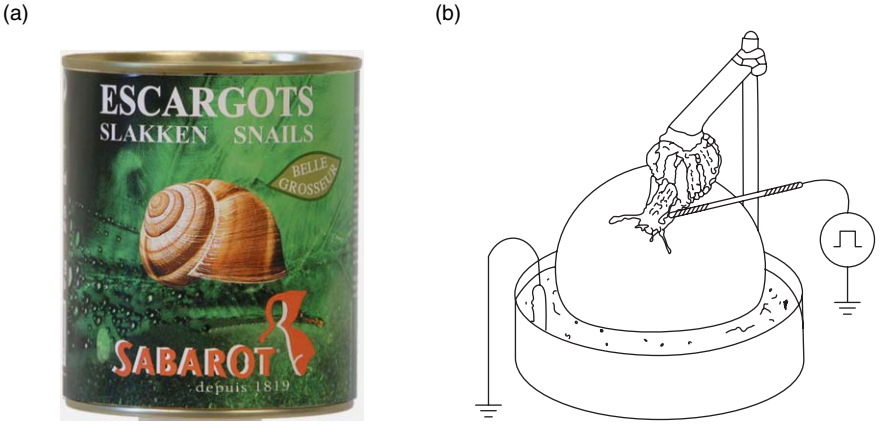

Figure 9 *Helix lucorum*: Aversive context learning. (a) *Helix lucorum* is sometimes called escargot turc. (b) The training apparatus. A snail is fixed at its shell and placed on a ball in a manner that allows crawling. The ball rotates freely in water and is laced with stainless steel wire to complete an electrical circuit between the animal's foot and a carbon electrode placed in the water. Electric shock is delivered through a macroelectrode applied manually to the dorsal surface of the foot. Adapted from Figure 1 in Gainutdinova TH, Tagirova RR, Ismailova AI, et al. (2005) Reconsolidation of a context long-term memory in the terrestrial snail requires protein synthesis. *Learn. Mem.* 12: 620–625.

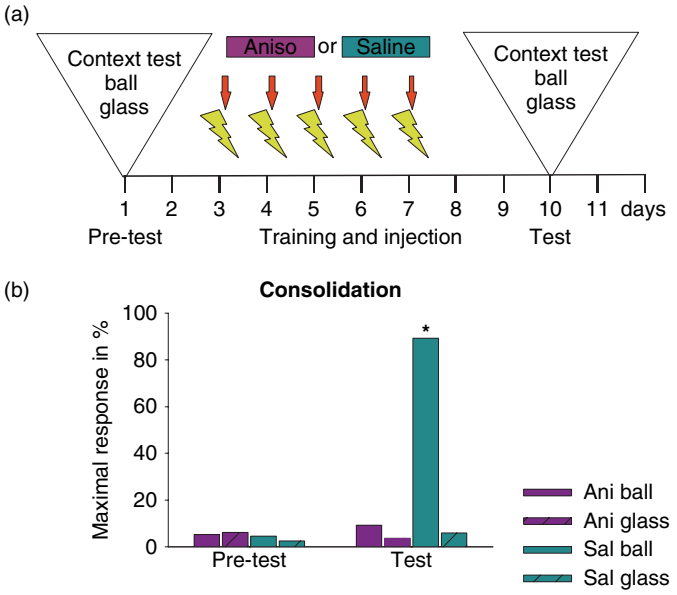

Figure 10 *Helix lucorum*: Memory consolidation. (a) Protocol of context conditioning. Snails received a pretest. Two days later all animals received five electrical shocks (flash) per day with a 20-min interval for 5 days. Every day, 3–5 min after the first shock, they were injected (arrow) with anisomycin (aniso, violet) or saline (green). A test was applied 3 days later. (b) Average of withdrawal response in the two contexts, reinforced context ball (plain) and nonreinforced context flat glass (striped). No difference in response to test stimulus was found in anisomycin-injected groups (Ani, violet bar), whereas the control group (Sal, green bar) showed context memory. Adapted from Figure 3 in Gainutdinova TH, Tagirova RR, Ismailova AI, et al. (2005) Reconsolidation of a context long-term memory in the terrestrial snail requires protein synthesis. *Learn. Mem.* 12: 620–625.

phenomenon is not visible (e.g., the animal can discriminate the two contexts) (Gainutdinova et al., 2005). This finding resembles a result in the crab *Chasmagnathus granulatus* (described in the next section), showing that reconsolidation can only be induced when the reminder is not accompanied by the reinforcer.

1.27.2.4 The Crab *Chasmagnathus granulatus*

1.27.2.4.1 Learning about a visual danger stimulus (VDA) leads to an associative and a nonassociative memory component

Chasmagnathus granulatus is a semiterrestrial crab that lives at the coast of South Brazil, Uruguay, and Argentina. Memory formation is studied on adult, male crabs (**Figure 12(a)**). They are caught in their natural habitat and transferred to the laboratory, where they are tested in an aversive learning paradigm. In this paradigm a danger stimulus (an opaque screen termed the visual danger stimulus = VDS) is passed over an animal that sits in a plastic container (**Figure 12(b)**).

The movement of this danger stimulus leads to an escape response that declines with further movements of the stimulus (Brunner and Maldonado, 1988). This decrease in the escape response has been initially assigned to habituation (Brunner and Maldonado, 1988). Depending on the training protocol, the decline of the escape response to the presentation of the VDS persists for several days (Lozada et al., 1990; Pedreira et al., 1995, 1998). Accordingly, a long-term memory about the VDS has been formed, which is termed long-term habituation (LTH). It consists of an associative component and a nonassociative component (Hermitte et al., 1999). The associative component is based on an association between the context and the signal (the VDS), and the resulting memory is termed context-signal memory (CSM) (Hermitte et al., 1999;Tomsic et al., 1998).

It is only induced by spaced training, depends on protein synthesis (**Figure 13(a)**), and lasts at least 5 days (Pedreira et al., 1995). The nonassociative component depends on the invariance of the VDS and is independent of the context of training. It is termed signal memory (SM). Massed training is sufficient to induce this nonassociative component of

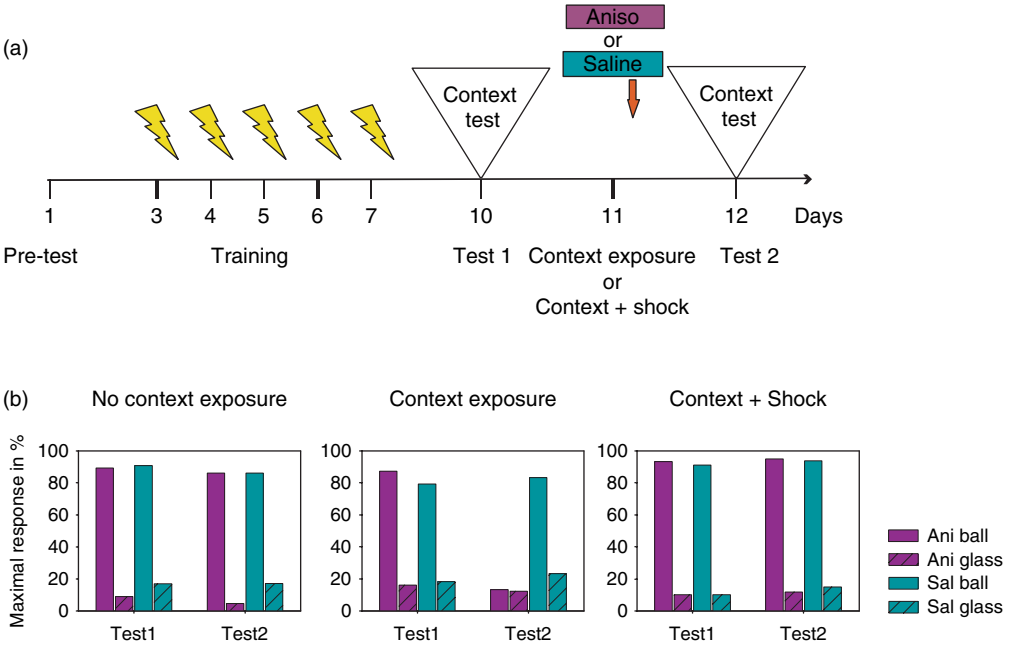

Figure 11 *Helix lucorum:* Reconsolidation. (a) Protocol of reminded context conditioning. Snails received a pretest on day 1 and were trained with five electrical shocks (flash) per day over 5 days. Three days later they received the test stimulus (test 1) to control if the animals had learned. Next day snails were reminded of training by placing them in the same context (context exposure, b middle panel) for 20 min or administering an electrical shock during the exposure (context + shock, b right panel), or as a control group received no context exposure (b left panel). All groups were injected (arrow) immediately afterward with anisomycin (aniso, violet) or saline (green). Next day all groups were tested again (Test 2) in both contexts. (b) Average response of withdrawal response in the two contexts, reinforced context ball (plain bars) and nonreinforced context glass (striped bars) before treatment (Test 1) and afterward (Test 2). In all experiments the context memory was intact in test 1. When the context exposure is omitted, injection of anisomycin (Ani, violet bars) or saline (Sal, green bars) has no influence on the context memory in test 2 (left panel: no context exposure). But reminded and anisomycin-treated snails show no context memory on test 2 to the trained context (ball), in contrast to the reminded saline-injected snails (middle panel: context exposure). If the reinforcer (shock) is presented during context exposure, injecting anisomycin does not lead to a loss of context memory (right panel: context + shock). Adapted from Figures 1, 2, and 4 in Gainutdinova TH, Tagirova RR, Ismailova AI, et al. (2005) Reconsolidation of a context long-term memory in the terrestrial snail requires protein synthesis. *Learn. Mem.* 12: 620–625.

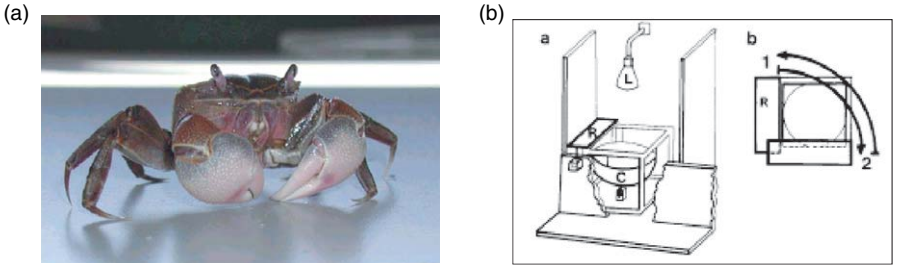

Figure 12 The crab *Chasmagnathus granulatus*: Learning about a visual danger stimulus (VDA). (a) The crab *Chasmagnathus granulatus*. (b) Left: The actometer, one of 40 units of the apparatus in which the crabs are trained. C, plastic container; R, rectangular screen used for the visual danger stimulus; M, motor; L, lamp; P, pizoelectric transducer; Right: Movement of the screen during a trial cycle (from 1 to 2 and vice versa). From Beron de Astarda M and Maldonado H (1999) Two related forms of long-term habituation in the crab *Chasmagnathus* are differentially affected by scopolamine. *Pharmacol. Biochem. Behav.* 63: 109–118.

the LTH (Pedreira et al., 1998; Hermitte et al., 1999) (**Figure 13(b)**).

It is important to note that memory for habituation can only be tested if the VDS is presented to the trained animals. Only then do the crabs show the learned freezing response. This means that retrieval of the initial memory and retraining occur in the same test session. Accordingly, when the usual series

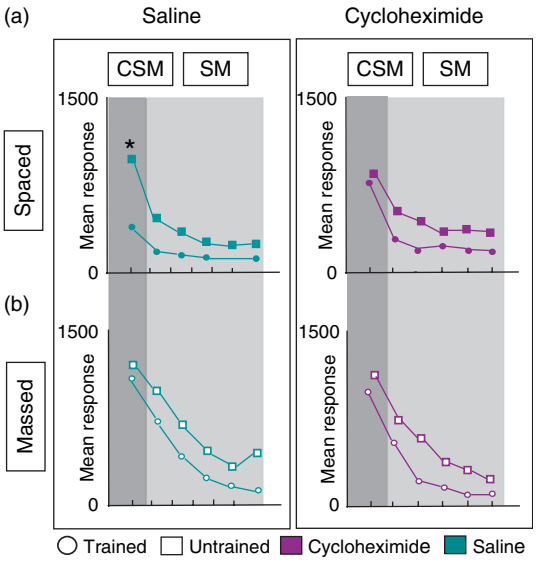

Figure 13 The crab *Chasmagnathus granulatus*: The induction of the context-signal memory (CSM) depends on the training protocol and is inhibited by a protein synthesis inhibitor. Crabs were systemically injected with 15 μg Cycloheximide (Cycloheximide; violet) or saline (Saline; green) immediately after spaced training (spaced, filled symbols) or massed training (massed, open symbols). Memory retention was tested 24 h later with six trials with the same intertrial interval that was used during training. Conditioned responses (mean response) at each test trial are shown here. The first test uncovers memory retention of the context-signal memory (CSM; dark gray); five following tests show memory retention of the signal memory (SM, light gray) and include a retraining phase. In each of the experiments, a trained group (trained, circles) is compared with an untrained control group (untrained, squares). (a) Memory retention after spaced training (15 trials; intertrial interval 171 s). The CSM is induced in the trained group in comparison to the untrained group (saline) and CSM but not SM depend on protein-synthesis (Cycloheximide). (b) Memory retention after massed training (300 training trials without intertrial interval). The CSM is not induced in the trained group in comparison to the untrained group (saline) and CSM and SM do not depend on protein synthesis (Cycloheximide). Adapted from Figure 3 in Hermitte G, Pedreira ME, Tomsic D, and Maldonado H (1999) Context shift and protein synthesis inhibition disrupt long-term habituation after spaced, but not massed, training in the crab *Chasmagnathus*. *Neurobiol. Learn. Mem.* 71: 34–49.

of six memory tests is applied, only memory retention at the first memory test resembles the memory for the initial training, and only this memory is based on the associative component of the LTM, the context-signal memory (CSM). Further memory tests in the same test session resemble a retraining phase (Pedreira et al., 1998).

1.27.2.4.2 Reconsolidation of the CSM

CSM retention can be observed 24 h after spaced training when the crabs are exposed to the VDS in the training context. When the crabs are exposed to the training context without the presentation of the VDS, a conditioned response is not elicited (Pedreira et al., 2002). Nevertheless, this exposure to the training context has an impact on subsequent memory retention. Namely, the combination of a 5-min context exposure 24 h after training with an injection of protein synthesis inhibitor leads to the inhibition of CSM memory retention 1 day later (Pedreira et al., 2002) (**Figure 14(a)**). The reconsolidation phenomenon has been induced accordingly.

1.27.2.4.3 The duration of the reexposure defined by its offset is critical for reconsolidation to occur

The reconsolidation phenomenon is only induced when reexposure to the training context endures for less then 40 min. A longer reexposure to the training context leads to a new, context–no signal association, and hence extinction learning. This extinction learning results in an extinction memory that depends on protein synthesis (Pedreira and Maldonado, 2003) (**Figure 14(b)**). Also in studies on vertebrates, the reconsolidation phenomenon becomes apparent when extinction is weak (Eisenberg et al., 2003; Suzuki et al., 2004; Power et al., 2006). On the basis of these findings, Nader (2003) and Dudai (2004) proposed the hypothesis of trace dominance. They interpreted these results as indicating a competition between two consolidation processes, the consolidation of extinction memory and the consolidation process underlying the reconsolidation phenomenon (Eisenberg et al., 2003; Nader, 2003). However, in the meantime, two studies, one in the honeybee and one in rats, reveal that the hypothesis of trace dominance is only half of the truth (see "The Honeybee *Apis mellifera*").

In crabs, the duration of the reexposure of the training context is critical for the consolidation process induced by the reminder. Accordingly, it has been found that the offset of the reminder stimulus without the appearance of the VDS is critical for either reconsolidation or consolidation of the extinction memory to occur (Pedreira et al., 2004). These data suggest that reconsolidation or the consolidation of an extinction memory occurred only when the nonoccurrence of the reinforcement (here the VDS) is irreversible due to the termination of the reminder (Pedreira et al., 2004). Accordingly, Pedreira et al. (2004) concluded

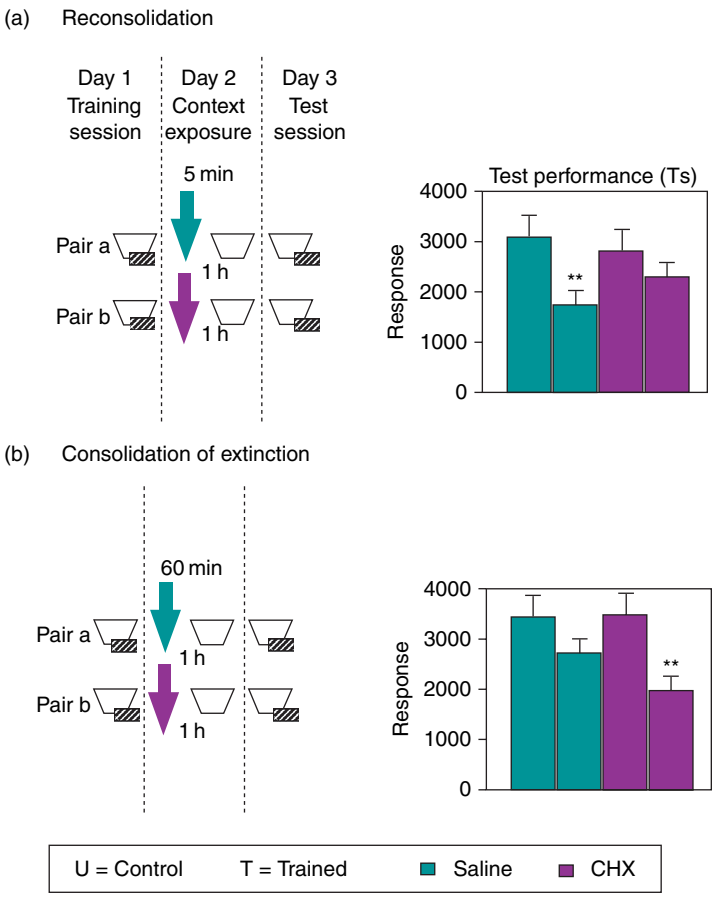

Figure 14 The crab *Chasmagnathus granulatus*: Reconsolidation and consolidation of extinction memory depend on the duration of the reexposure to the training context. Day 1: Training with 15 9-s presentations of the visual danger stimulus (striped bar), separated by 3 min; Day 2: Systemic injection (arrow) of Cycloheximid (CYX; violet arrow and bars) or saline (green arrow and bars) 1 h prior to reexposure to the training context trapeze for either 5 min (reconsolidation) or 60 min (consolidation of extinction); Day 3: Memory retention test: a single 9-s VDS presentation (striped bar). A significant difference between the untrained group (U) and the trained group (T) (U > T) at the memory retention test indicates memory retention. The trapeze stands for the container where a crab is placed during each of the experimental phases. Adapted from Figure 2 in Pedreira ME and Maldonado H (2003) Protein synthesis subserves reconsolidation or extinction depending on reminder duration. *Neuron* 38: 863–869.

that the mismatch between what is expected and what actually occurs triggers memory reconsolidation or extinction. Interestingly, a similar finding has been recently reported in an aversive paradigm in the gastropod *Helix lucorum*, namely, that the reconsolidation phenomenon is not visible when in the reminding situation (the reexposure to a context) the reinforcing stimulus (a shock) is applied in combination with a protein synthesis inhibitor (Gainutdinova et al., 2005) (see "The Terrestrial Snail *Helix lucorum*"). This is in contrast to findings in *Limax flavus* (see "The Terrestrial Slug *Limax flavus*") and in rats. In *Limax flavus* amnesia can be induced by retrieval with the CS alone or with an additional CS–US pairing followed by a cooling procedure (Sekiguchi et al., 1997). A similar result has been reported in an aversive conditioning paradigm in rats (Duvarci and Nader, 2004), namely, that the injection of anisomycin in selected brain regions after retrieval with and without reinforcement inhibits reconsolidation (Nader et al., 2000; Duvarci and Nader, 2004). The reason for this contradiction is not known. One could assume that the type of paradigm used in the different experiments is critical. In context conditioning (used in *Chasmagnathus granulatus* and *Helix lucorum*) memory retrieval that is accompanied by the reinforcement does not lead to reconsolidation. In contrast, the reconsolidation phenomenon is detectable after retrieval with or without reinforcing stimulus in cue-dependent conditioning (used in *Limax flavus* and rats).

1.27.2.4.4 CSM consolidation and reconsolidation share molecular mechanisms

Several molecules have been identified that are involved in the consolidation of the associative CSM (Romano et al., 2006). Presently it is not known if this holds true for reconsolidation and if the same molecular mechanisms underlie both the consolidation of the CSM and the reconsolidation. Growing evidence in vertebrates demonstrates that reconsolidation is not a faithful recapitulation of consolidation, but each process is mediated by distinct intracellular signaling cascades, which might overlap (Kelly et al., 2003; Lee et al., 2004). Findings in *Chasmagnathus* are in accordance with this in demonstrating that molecular mechanisms are shared by both consolidation processes, but differences between both processes have not yet been demonstrated.

Consolidation of the CSM and reconsolidation are sensitive to inhibitors of translation. In accordance with these results, a transcription factor, the nuclear factor κB (NF-κB), (*See* Chapter 4.28), has been found to be involved in the consolidation of the CSM and in reconsolidation (Freudenthal et al., 1998; Freudenthal and Romano, 2000; Merlo et al., 2002). After training, NF-κB is activated in two phases, directly and 6 h after spaced training (Freudenthal and Romano, 2000). This parallels activity of the cAMP-dependent protein-kinase A (PKA) after spaced training (Locatelli et al., 2002; Locatelli and Romano, 2005), suggesting a causal relationship between these processes, which nevertheless remains to be demonstrated. Also, reconsolidation depends on NF-κB activity during a 5-min reexposure to the trained context (Merlo et al., 2005), but it is unknown whether NF-κB is activated 6 h after memory retrieval as it is after training, and whether PKA plays a role in reconsolidation.

Are the same transmitters and receptors involved in consolidation and reconsolidation? Application of the *N*-methyl-D-aspartate (NMDA)-receptor antagonists during training up to 4 h after training inhibits the formation of CSM (Troncoso and Maldonado, 2002). This holds true for reconsolidation (Pedreira et al., 2002). Interestingly, the involvement of NMDA receptors in reconsolidation processes (and consolidation processes) has also been demonstrated in appetitive and aversive paradigms in several studies on vertebrates (Przybyslawski and Sara, 1997; Przybyslawski et al., 1999; Torras-Garcia et al., 2005; Akirav and Maroun, 2006; Lee et al., 2006). Accordingly, the involvement of the NMDA receptor might be an evolutionarily conserved feature of the reconsolidation processes.

The endogenous peptide angiotensin II, which plays a role in regulating fluid homeostasis and is present in higher amounts after water shortage in the crab brain, facilitates the consolidation of CSM (Delorenzi and Maldonado, 1999; Delorenzi et al., 2000; Frenkel et al., 2002). This memory enhancement is mediated by NF-κB that is activated by angiotensin II following water shortage (Frenkel et al., 2002). Angiotensin II is also involved in reconsolidation because its inhibition leads to retrieval-induced amnesia (Frenkel et al., 2005).

1.27.2.5 The Honeybee *Apis mellifera*

1.27.2.5.1 The appetitive, olfactory conditioning of the proboscis extension response

The honeybee is one of the oldest – if not the oldest – invertebrate models in learning and memory research. Its pronounced learning ability is used in a classical, Pavlovian conditioning paradigm in the laboratory, the olfactory conditioning of the proboscis extension response, where honeybee learning and memory formation are studied in single, restrained bees (**Figure 15(a)**) (*See also* Chapters 1.29 and 4.06).

Honeybees reflexively extend their proboscis when their antennae are touched with a drop of sucrose solution. This response to sucrose solution is called the proboscis extension response (PER) (**Figure 15(b)**). When the presentation of an odor precedes the sucrose reward (**Figure 15(c)**), honeybees learn to associate the odorant (CS) with the sucrose reward (US) (Menzel et al., 1974; Bitterman et al., 1983). After an association has formed, the odor alone elicits the proboscis extension. This reaction toward the odor is the CR. The CR can be elicited by the learned odor immediately after the acquisition and up to several days later, indicating the formation of short as well as long-lasting memories for this odor-sucrose association (Menzel, 1999; Eisenhardt, 2006).

1.27.2.5.2 A consolidated LTM is formed after three CS–US pairings

Three CS–US pairings are sufficient to induce a consolidated LTM. Two LTMs have been characterized so far by means of their sensitivity to systemically injected inhibitors. One and 2 days after three CS–US pairings, an LTM has been formed depending on translation during acquisition (Friedrich et al., 2004;

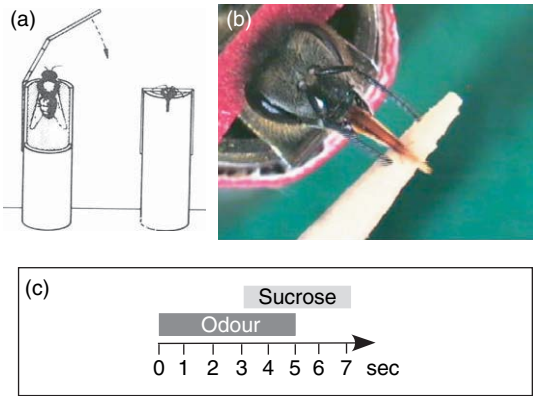

Figure 15 The honeybee *Apis mellifera*: Olfactory conditioning of the proboscis extension response. (a) Single honeybees are restrained in small tubes to condition the proboscis extension response (PER). Adapted from Bitterman ME, Menzel, R, Fietz, A, and Schäfer S (1983) Classical conditioning of proboscis extension in honeybees (*Apis mellifera*). *J. Comp. Psychol.* 97: 107–119. (b) Honeybees reflexively elicit their proboscis when the antennae and the proboscis are touched with sugar water. Here a toothpick that is moistened with sucrose solution is used to touch the honeybee's proboscis. After the PER is elicited, the honeybee licks sucrose solution from the toothpick. (c) Schematic diagram of the olfactory conditioning of the PER. An odor (conditioned stimulus) is presented for 5 s; after 3 s the PER is elicited with sucrose solution (unconditioned stimulus), and the honeybee is allowed to lick the sucrose solution for 4 s.

Stollhoff et al., 2005) (**Figure 16(a)**). A second long-lasting memory, formed 3–4 days after three CS–US pairings, depends on translation, but also on transcription. Inhibition of transcription and translation during acquisition, 1 h and 6 h after acquisition, results in an inhibition of this LTM (translation, 6 h: Eisenhardt & Stollhoff, unpublished data; Grünbaum and Müller, 1998; Wüstenberg et al., 1998; Friedrich et al., 2004). Thus, the activation of both processes for at least 6 h after acquisition is necessary for the formation of this later LTM. Interestingly, both LTMs are formed in parallel. They are induced by two different mechanisms that both depend on the cAMP-dependent protein kinase A (PKA) (Fiala et al., 1999; Müller, 2000; Friedrich et al., 2004).

1.27.2.5.3 Retrieval of a consolidated olfactory LTM

When a consolidated LTM is retrieved 1 day after training, two different consolidation processes can be induced, and the consolidation of an extinction memory and reconsolidation (Stollhoff et al., 2005). A series of experiments with one, two, and five retrieval trials that were applied 1 day after the initial training revealed that the resulting memory is dependent on the number of retrieval trials. Memory retention was

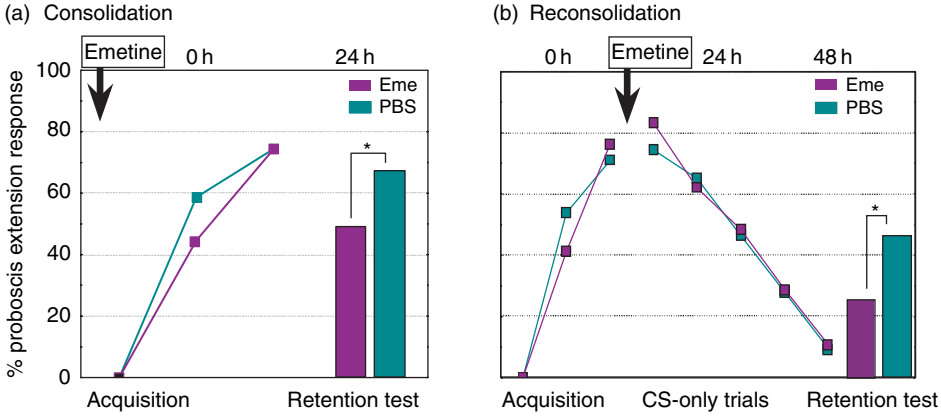

Figure 16 The honeybee *Apis mellifera*: Consolidation and reconsolidation. (a) Consolidation in the honeybee. 0 h: Emetine or PBS were systemically injected 30 min before honeybees were conditioned with three trials with an intertrial interval of 10 min (acquisition); 24 h: Memory retention was tested 1 day after acquisition by one 5-s presentation of the conditioned odor (CS). Eme: Animals that were injected with emetine; PBS: Control group; Animals that were injected with PBS. (b) Reconsolidation in the honeybee occurs after extinction. 0 h: Honeybees were conditioned with three trials with an intertrial interval of 10 min (acquisition); Emetine or PBS were systemically injected 30 min before the initial memory was retrieved with five conditioned stimulus (CS)-only trials with an intertrial interval of 10 min (CS-only trials); 48 h: memory retention was tested with one CS-only trial Eme: Emetine; PBS: Control group injected with saline. Adapted from Stollhoff N, Menzel R, and Eisenhardt D (2005) Spontaneous recovery from extinction depends on the reconsolidation of the acquisition memory in an appetitive learning paradigm in the honeybee (*Apis mellifera*). *J. Neurosci.* 25: 4485–4492.

tested 24 h after the initial memory retrieval. It turned out that one retrieval trial induced neither an extinction memory nor a reconsolidation phenomenon. Two retrieval trials led to significant extinction, and application of protein synthesis inhibitor before this memory retrieval resulted in an inhibition of the extinction memory. Five retrieval trials also induced significant extinction and spontaneous recovery of the CR (**Figure 16(b)**). After the application of the protein synthesis inhibitor, the amount of spontaneous recovery from extinction was reduced, but inhibition of the extinction memory was not observed. Hence, reconsolidation was induced after five retrieval trials (**Figure 16(b)**). Accordingly, although extinction was induced, the reconsolidation phenomenon was observed (Stollhoff et al., 2005).

These data contrast to those gathered in studies of the crab *Chasmagnathus* and in vertebrates (Eisenberg et al., 2003; Pedreira and Maldonado, 2003; Suzuki et al., 2004). Reconsolidation was induced in these studies only when extinction did not take place, and it was concluded that extinction is a boundary condition for reconsolidation (Nader, 2003).

The reason for this contradiction remains unclear, but only recently a study in vertebrates revealed a similar phenomenon, namely, the occurrence of reconsolidation after extinction (Duvarci et al., 2006). Hence extinction is not always a boundary condition for reconsolidation.

Spontaneous recovery from extinction after five retrieval trials in the honeybee is not complete (**Figure 16(b)**). From that it was concluded that after five retrieval trials, an extinction memory has been found, although spontaneous recovery occurred. Because this spontaneous recovery is based on reconsolidation, it seems likely that consolidation of the extinction memory and reconsolidation are two parallel processes (Stollhoff et al., 2005). What might be the mechanisms generating two parallel memory traces? A new hypothesis was put forward to explain the existence of these two memory traces (Eisenhardt and Menzel, 2007). This internal reinforcement hypothesis is substantially different from the original reconsolidation hypothesis (Nader, 2003) because it proposes that memory retrieval initiates new learning rather then activating and destabilizing the original CS–US memory trace. The hypothesis is based on the assumption that mechanisms underlying the reconsolidation phenomenon can be ascribed to basic neuronal mechanisms that are found in both vertebrates and invertebrates. The central tenet refers to the properties of reinforcement-predicting neurons, such as the dopamine neurons of the ventral tegmentum (Schultz, 2006) and the VUMmx1 neuron in the honeybee (Hammer, 1993). Neurons with comparable properties are assumed to exist also in the fruit fly *Drosophila melanogaster* (Riemensperger et al., 2005) and the molluscs (e.g., Aplysia et al., 1984). The internal reinforcement hypothesis proposes that two learning processes take place when memory is retrieved: one based on the lack of reinforcement (extinction learning) and one based on the internal existence of the reinforcement, which is activated by the CS (reminder learning) (Eisenhardt and Menzel, 2007). This internal existence of the reinforcement is proposed to be due to neuronal activity that is induced by memory retrieval, like the activity that can be observed in the honeybee's Vum_{mx1} neuron (Hammer, 1993). When retrieving a memory, the presentation of the CS and the activation of these neurons at the same time should then result in excitatory learning comparable to physical CS–US pairing. This form of learning should lead to a consolidation process underlying the reconsolidation phenomenon. Accordingly, reminder learning and extinction learning induce the formation of two memories that are consolidated in parallel and together constitute controlling behavior.

1.27.3 Conclusion

Several invertebrate species are currently used to study the reconsolidation phenomenon: the gastropods *Helix lucorum*, *Limax flavus*, *Lymnaea stagnalis*, the crab *Chasmagnathus granulatus*, and the honeybee, *Apis mellifera*. Findings from each of these organisms contribute to elucidate the reconsolidation phenomenon and its underlying mechanisms.

The slug *Helix lucorum* was the first invertebrate for which the reconsolidation phenomenon was demonstrated (Sekiguchi et al., 1997). In addition, the study of an odor-avoidance paradigm revealed that the age of the retrieved memory is important for the reconsolidation process to occur. It is only when fresh memories are retrieved that reconsolidation occurs. When retrieving an old memory, reconsolidation occurs only when either an additional training trial or a second-order conditioning was applied shortly before (Sekiguchi et al., 1997).

Furthermore, a study of an appetitive classical conditioning paradigm in the snail *Lymnaea stagnalis*

revealed that the age of the retrieved memory is important for the reconsolidation process. Retrieval of fresh and old memories induces a reconsolidation process that depends on protein synthesis. But only retrieval of a fresh memory induces a reconsolidation process that depends on the cAMP-dependent PKA (Kemenes et al., 2006). Accordingly, the molecular mechanisms underlying the reconsolidation processes depend on the age of the retrieved memory (*See* Chapter 4.09).

The neuronal network underlying reconsolidation in an aversive, operant conditioning paradigm has been studied in *Lymnaea stagnalis*. It has been demonstrated that only a single neuron is necessary for reconsolidation. In this paradigm, the reconsolidation phenomenon has been uncovered by cooling and using a transcription inhibitor. In accordance with this, reconsolidation is not induced when the nucleus of the relevant neuron has been ablated. Nevertheless, the nucleus is not needed to retrieve the inhibited reconsolidated memory (Sangha et al., 2003a).

In an aversive context conditioning paradigm in the snail *Helix lucorum*, the exposure to a context as a reminder elicits the reconsolidation phenomenon (Gainutdinova et al., 2005). But if the reinforcer is presented during the exposure to the reminder, reconsolidation cannot be observed.

A similar result has been found in the crab *Chasmagnathus granulatus*. Work on an aversive classical conditioning paradigm revealed that the duration of the CS presentation when retrieving a consolidated memory is critical for the induction of the reconsolidation phenomenon: Only a short exposure to the CS results in reconsolidation, whereas a long exposure leads to extinction and the consolidation of an extinction memory (Pedreira and Maldonado, 2003). Accordingly, it is only when the CS exposure is terminated without the occurrence of the US that reconsolidation and the consolidation of an extinction memory occur (Pedreira et al., 2004). In contrast to the findings in *Chasmagnathus*, a study on an appetitive classical conditioning paradigm in the honeybee demonstrates that – although extinction was induced – reconsolidation occurs after many CS presentations (Stollhoff et al., 2005). These results do not support the hypothesis of trace dominance that derives from studies in *Chasmagnathus* and vertebrates stating that extinction is a boundary condition for reconsolidation. It rather suggests that reconsolidation and the consolidation of an extinction memory are two parallel processes.

1.28 Behavioral Analysis of Learning and Memory in *Drosophila*

M. Heisenberg and B. Gerber, Universität Würzburg, Würzburg, Germany

Associative learning is supposed to come about through changes in neurons, and it is believed that memory-guided behavior relies on these changes (Lechner and Byrne, 1998; Martin et al., 2000; Cooke and Bliss, 2006). Thus, in terms of physiology, past experiences would leave traces in terms of altered properties of neuronal circuits (*See* Chapters 1.02, 1.04, 1.33, 1.34). Here, we discuss whether it is possible to assign such changes to specific cells in the brain and, in this sense, to localize those memory traces underlying conditioned behavioral modifications. What could be the criteria for an accomplished localization of such a memory trace? As argued elsewhere (Gerber et al., 2004), if a certain set of cells were said to be the site of a memory trace, one should be able to show that:

1. Neuronal plasticity occurs in these cells and is sufficient for memory.
2. The neuronal plasticity in these cells is necessary for memory.
3. Memory cannot be expressed if these cells cannot provide output during test.
4. Memory cannot be established if these cells do not receive input during training.

If these criteria are met, it must be concluded that the group of cells in question is the one and only site of the memory trace under investigation. Clearly, neither of these criteria alone is sufficient to draw this conclusion; in particular, despite claims to the contrary (e.g., Yu et al., 2004, 2005; Liu and Davis, 2007), the mere observation of altered neuronal activity after some training regime in imaging experiments, albeit indispensable for the argument, is in itself not sufficient to localize a memory trace. This is because such data allow concluding that some memory trace must be residing between the stimulation site (i.e., the sensory level in Yu et al., 2004, 2005; Liu and Davis, 2007) and the site of the measurement, but more specific conclusions cannot be drawn.

In *Drosophila*, three different learning paradigms have been used in efforts to localize memory traces according to these criteria (Zars et al., 2000a,b; Liu et al., 2006). We will go through the available evidence, restricting ourselves to short-term (3–30 min) memory throughout, unless explicitly stated otherwise. *See* Chapter 4.07 for additional information on mechanisms of olfactory memory in *Drosophila*.

1.28.1 Neural Plasticity?

Criteria (1) and (2) rely on the ability to measure the plasticity of candidate neurons during the learning

process, as well as on the manipulation of these neurons *in vivo*. In *Drosophila*, no method is available to directly measure neural plasticity *in vivo* in adult central brain neurons, despite impressive advances in physiological techniques (Fiala et al., 2002; Ng et al., 2002; Hallem et al., 2004; Wang et al., 2004; Wilson et al., 2004). In a strict sense, this makes it difficult to test for criteria (1) and (2). Actually, the only way to directly observe neural plasticity in flies to date is to study the larval neuromuscular junction (Koh et al., 2000; Schuster, 2006). Being left with inferences from larval motor neuron-to-muscle synapses to central brain neurons in adults, however, is unsatisfying. Therefore, as a second best approach, genetic intervention was used to locally manipulate molecular components underlying neural plasticity. The process of choice was the cAMP/PKA signaling cascade. It had been shown to be required for learning as well as for neuronal plasticity in various paradigms throughout the animal kingdom (Byrne et al., 1991; Davis et al., 1995; Renger et al., 2000; Davis, 2005; Hawkins et al., 2006). More specifically, *in vitro* studies in *Aplysia* suggest that the type I adenylyl cyclase (in flies encoded by the *rutabaga* gene, *rut*) might act as a timing-specific molecular coincidence detector for the stimuli to be associated (Abrams et al., 1998). Hence, by an admittedly indirect argument, one is inclined to attribute an impaired or restored capacity to learn, caused by a genetic manipulation of the cAMP cascade in specific brain regions, to impaired or restored neural plasticity in that region (Zars et al., 2000a,b; McGuire et al., 2003; Mao et al., 2004; Liu et al., 2006).

As will be discussed later, such local *rut* rescues were successful for all three learning paradigms covered here (**Figure 1**). We therefore tentatively assume that indeed a lack of *rut* impairs neuronal plasticity and that a local rescue of *rut* does rescue

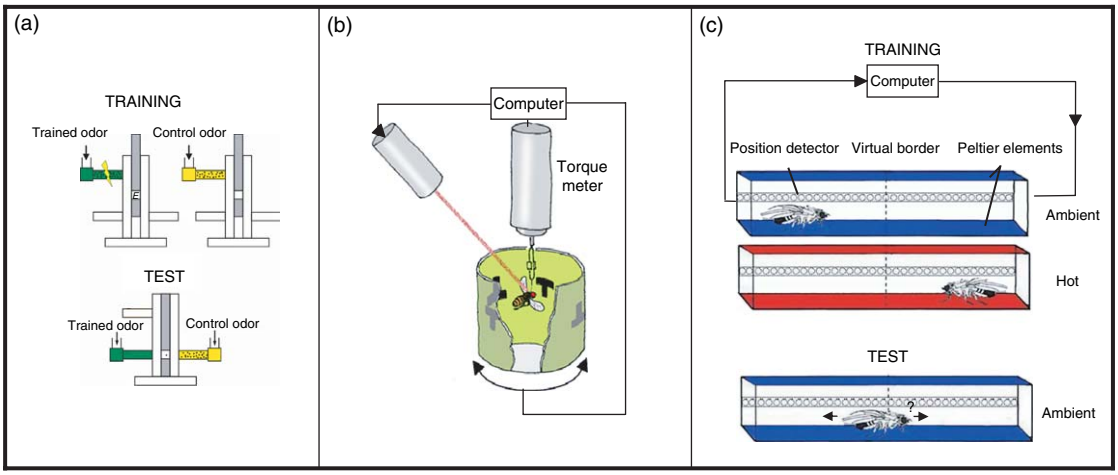

Figure 1 Behavioral procedures for measuring associative learning and memory. In all three cases flies are tested for memory by choosing between two conditions, of which they previously experienced one together with the reinforcer. In all cases, the *rutabaga* adenylyl cyclase is necessary for learning/memory, presumably via its role in synaptic plasticity. (a) Odor discrimination learning. Two experimental groups are run that undergo reciprocal training: One group of flies is exposed to odor A (green) and the reinforcer (in this case electric shock, but sucrose as appetitive reinforcer works as well). Next, the flies are exposed to odor B (yellow) without reinforcer. For testing, flies are shaken into the elevator (grey) and placed between two tubes simultaneously presenting the odors A and B; then flies on either side are counted and the difference in the number of flies on the control versus the trained side is calculated. For the other group of flies, the shock is presented with the respective other odor. Performance indices then present the mean of the odor choice scores in these reciprocally trained groups. (b) Visual pattern memory in the flight simulator. Tethered flies are suspended at a torque meter such that their yaw torque drives the angular velocity of a rotating panorama surrounding the fly. The wall of the panorama is decorated by two alternating patterns spaced by 90°. Flies can choose their direction of flight with respect to the patterns. Flies that are heated by a laser beam while heading toward one of the patterns subsequently avoid that pattern. The paradigm also uses a reciprocal training design; performance indices are calculated as in (a). (c) Heat box learning. Flies walk in a dark alley, and their position is monitored. During training they are heated if they enter one half of the chamber, some flies on the left side, some on the right side. During the memory test, flies still avoid the side where they had previously been heated. Again, the performance index is calculated as in (a).

this plasticity in the respective neurons. Clearly, the scope of conclusions thus is limited to those kinds of neuronal plasticity that involve *rut* and that are impaired in the available *rut* mutants. Still, as criteria (3) and (4) do not rely on any knowledge of the biochemistry underlying memory, they can serve to independently validate claims of localization of a memory trace.

1.28.2 Olfactory Learning

In odor discrimination learning (**Figure 1**), flies receive one odor together with an electric shock, and later another odor without shock. In a subsequent binary choice test, flies avoid the previously punished odor (Tully and Quinn, 1985). A similar paradigm can be used with sugar instead of electric shock, making flies approach the trained odor (Tempel et al., 1983; Schwaerzel et al., 2003). Within this section, however, we refer to odor-shock learning throughout unless explicitly stated otherwise.

Odors are detected (reviews by Stocker, 1994, 2001; Hallem et al., 2006) by receptor neurons, each expressing a single functional receptor gene of the *Or* gene family; receptor neurons expressing the same *Or* gene converge to one so-called glomerulus in the antennal lobe. Hence, the glomeruli represent the fly's primary odor qualities. The glomerular patterns of activity are shaped in addition by local interneurons. Projection neurons then relay the primary odor qualities to two sites, the lateral horn, a presumed premotor center, and the mushroom body calyx. Output from the mushroom bodies projects to a variety of target regions, including premotor areas. Thus, the mushroom bodies constitute a side branch of the olfactory pathway.

A memory trace underlying conditioned odor avoidance was proposed to be localized within the mushroom body neurons, also called Kenyon cells (reviews by Heisenberg, 2003; Gerber et al., 2004): Whenever the activation of a pattern of Kenyon cells elicited by a given odor coincides with a modulatory reinforcement signal impinging onto the Kenyon cells, future output from these activated Kenyon cells onto mushroom body output neurons is suggested to be strengthened. This facilitated output is thought to subsequently mediate conditioned behavior in response to the odor alone. The following data are the basis for this working model.

1.28.2.1 Sufficiency of Neuronal Plasticity in the Mushroom Bodies

In *rut* mutants, local transgenic expression of an intact *rut* cDNA can fully rescue the learning impairment (Zars et al., 2000a); notably, such rescue requires *rut* expression in the γ- and α/β-lobes of the mushroom bodies (GAL4 driver lines mb247, c772, 30y, 238y, and H24; for the GAL4/UAS technique, see Brand and Perrimon, 1993). A partial rescue is observed with the driver line 201y. In contrast, three drivers not expressing in the mushroom body γ-lobes (c232, 189y, and 17d) do not rescue (Zars et al., 2000a) (concerning H24, see also supplementary material provided with McGuire et al., 2003). The driver line mb247 also rescues sugar reward learning (Schwaerzel et al., 2003). Furthermore, Davis and colleagues (McGuire et al., 2003; Mao et al., 2004) showed that providing the *rut* cDNA during adulthood is sufficient for rescuing short-term memory. These results argue that the mushroom bodies are a site at which restoring neuronal plasticity is sufficient to restore olfactory learning, and that criterion (1) for the localization of a memory trace to the mushroom bodies is met. It needs to be emphasized that neuronal plasticity related to the *rut* adenylyl cyclase (rut-AC) can account for only about 50% of memory in conditioned odor discrimination; under the assumption that the used *rut* mutants completely lack the type I adenylate cyclase function required in this task, this would imply a distinct *rut* independent memory trace.

1.28.2.2 Necessity of Neuronal Plasticity in the Mushroom Bodies

Transgenic mushroom body expression of a dominant negative $G\alpha_s$ protein subunit ($G\alpha_s^*$), which constitutively activates the type I adenylyl cyclase, completely abolishes learning (Connolly et al., 1996) (driver lines 238y, c309, and c747). The driver line 201y that provides a partial rescue also inhibits partially (about 50%) when driving $G\alpha_s^*$ expression. Two lines with expression outside of the mushroom bodies (c232 and ok348) were normal. Under the plausible assumption that a constitutively activated cyclase prevents regulation of cAMP levels, and hence regulation of neuronal efficacy, this argues that plasticity within the mushroom body Kenyon cells is necessary for memory trace formation and that criterion (2) for the localization of a memory

trace to these cells is met. Strikingly, expression of the $G\alpha_s^*$ transgene in the mushroom bodies completely blocks 3-min memory in odor-shock learning, but *rut* mutants show only a 50% reduction, suggesting that any potentially *rut*-independent memory trace is also blocked by $G\alpha_s^*$ and is also located in the Kenyon cells.

In contrast, odor-sugar learning is only partially suppressed by $G\alpha_s^*$ expression in the mushroom bodies (A. Thum and H. Tanimoto, personal communication), suggesting that the memory trace in the Kenyon cells is not the only one underlying the odor-reward association. Indeed, a second memory trace may be located in projection neurons connecting the antennal lobe to the calyx and lateral protocerebrum (Thum, 2006). Whether these two traces are functionally redundant remains to be investigated; that is, do they differ in terms of the kinds of behavior supported, in their role during different memory phases, or the specificity of their 'content' (see Menzel, 2001 for such analyses in the honeybee; *See also* Chapter 1.29)?

1.28.2.3 Blocking Mushroom Body Output during Test

In flies it is possible to within minutes reversibly turn off the output of chemical synapses using a dominant negative, temperature-sensitive dynamin transgene, Shi^{ts} (Kitamoto, 2002). If Shi^{ts} is expressed in the mushroom bodies, flies can be trained with mushroom body output enabled, but tested with mushroom body output blocked. Three different laboratories have independently found that flies do not express odor memory if the temperature is raised to the off-condition 15 min prior to the test (driver lines c739, c747, c309, mb247, and c772) (Dubnau et al., 2001; McGuire et al., 2001; Schwaerzel et al., 2002; see Krashes et al., 2007, for a specific role of output from the $\alpha'\beta'$ lobes for stabilizing short- into longer-term memory). Apparently, criterion (3) for the localization of memory traces of odor-shock and odor-sugar learning to the Kenyon cells is met. Because the Shi^{ts} method is unspecific with regard to the biochemical mechanism(s) of memory trace formation, this supports the conclusions discussed earlier and, moreover, indicates that any *rut*-independent memory trace is unlikely to be located downstream of the Kenyon cell output synapses.

1.28.2.4 Blocking Input to the Mushroom Body during Training

Olfactory input to the mushroom bodies is carried by the uniglomerular projection neurons from the antennal lobes. If, by means of Shi^{ts} expression, synaptic output during training is blocked in approximately 60% of these projection neurons (driver line GH 146; Stocker et al., 1997), flies do not show any sign of memory during subsequent test (Schwaerzel, 2003), suggesting that criterion (4) for the localization of a memory trace to the mushroom bodies is met as well. However, the projection neurons provide input not only to the mushroom bodies but also to the lateral protocerebrum (Yasuyama et al., 2003) (and presumably even the antennal lobe; Ng et al., 2002). Therefore, this conclusion needs to be taken with caution, as we are still lacking appropriate tools to specifically block mushroom body input.

Concerning reinforcer-related input to the mushroom bodies, Riemensperger et al. (2005) showed that dopaminergic neurons, which impinge onto the mushroom body lobes, are activated by electric shock. Concerning behavior, Schwaerzel et al. (2003) found that for aversive learning dopamine (driver line TH-Gal4) but not octopamine signaling is necessary, and that in turn for appetitive learning, octopamine but not dopamine signaling is necessary. Furthermore, as shown in the *Drosophila* larva by using the 'remote control' of neuronal activation with a transgenically expressed light-gated ion channel (channelrhodopsin; Schroll et al., 2006), the respective catecholaminergic neurons also are sufficient to substitute for reinforcement in appetitive and aversive training, respectively. In the adult fly, both dopamine and octopamine signaling were shown to be specifically required during training, but not during test (Schwaerzel et al., 2003). The Kenyon cells clearly express octopamine and dopamine receptors and are targets of dopamine- and octopamine-immunoreactive neurons (Han et al., 1996, 1998; Friggi-Grelin et al., 2003; Kim et al., 2003; Strausfeld et al., 2003); notably, the antennal lobe receives strikingly little if any dopaminergic innervation (Riemensperger et al., 2005). However, whether specifically those octopaminergic and/or dopaminergic neurons that carry the reinforcing information do indeed directly impinge onto the mushroom bodies is at present unknown. Interestingly, using Ca^{++} imaging, Riemensperger et al. (2005) have reported that dopaminergic neurons innervating the mushroom

body lobes acquire increased responsiveness specifically to the learned odor, suggesting that training confers the reinforcing function of the shock to the odor. Thus, in keeping with the seminal work on reinforcement processing in bees (Hammer, 1997; Menzel, 2001; see also Schultz, 2006, for analogous results concerning dopaminergic neurons in monkeys), it seems likely that (i) also in flies (and fly larvae), signaling via aminergic neurons carries a prediction error–like internal reinforcement signal, (ii) these neurons impinge onto the mushroom bodies, and (iii) these neurons act during acquisition to induce, but not during retention to express, olfactory memory traces.

1.28.2.5 A Memory Trace Downstream of the Mushroom Bodies?

Three different laboratories found that blocking Kenyon cell output during odor-shock training (in the driver lines c739, c747, c309, mb247, and c772) leaves performance during test intact (Dubnau et al., 2001; McGuire et al., 2002; Schwaerzel et al., 2003; but see Krashes et al., 2007). Thus, for learning to occur, olfactory information needs to enter but does not need to leave the Kenyon cells. In fact, any kind of plasticity underlying learning, be it *rut* dependent or *rut* independent, thus seems to occur upstream of mushroom body output and, as argued in the previous paragraph, likely downstream of projection neuron output.

1.28.2.6 A Memory Trace in the Projection Neurons and/or Antennal Lobes?

Concerning an additional memory trace established in the projection neurons (for review of the work in honeybees, see Menzel, 2001), Yu et al. (2004) reported that two identified glomeruli (D and VA1) in the *Drosophila* antennal lobe are more strongly activated by the odor after training than before. This effect is stimulus specific, in that training with either of two different odors (3-octanol or 4-methylcyclohexanol) leads to the recruitment of either of the two glomeruli; it is also associative, as it is seen after odor-shock training, but not after a reversed order of stimulus presentation (i.e., shock-odor training); it is cell specific in that neither olfactory receptor neurons nor local antennal lobe interneurons show such recruitment; and it is specific for very short term memory, as after 7 min the effect has waned. Thus, there must be a memory trace somewhere between olfactory input and the projection neurons. As neither the olfactory sensory neurons nor the local interneurons, which are canonically acknowledged as inputs to the projection neurons, show any training-induced change, Yu et al. (2004) are inclined to conclude that a memory trace for very short term memory is located within the projection neurons themselves.

However, some caveats may warrant an alternative explanation. First, in naïve flies, neither of the odors induces excitation in either of these glomeruli (Wang et al., 2003; Yu et al., 2006); rather, olfactory sensory neurons innervating VA1 likely respond by inhibition (Hallem and Carlson, 2006), so that a specific explanation is required as to how an inhibited projection neuron could be the site of coincidence detection of odor and shock. Second, the antennal lobe is receiving little if any dopaminergic input (Riemensperger et al., 2005), so that one may need to invoke a dopamine-independent internal reinforcement signal to induce a memory trace in the antennal lobe. Third, $G\alpha_s^*$ expression in the mushroom bodies completely blocks learning (Connolly et al., 1996), and fourth, attempts to rescue aversive learning using *rut*-AC expression in the projection neurons have failed (H. Tanimoto, personal communication; A. Keene and S. Waddell, personal communication). The latter two arguments suggest that in electric shock learning any projection-neuron memory trace in itself would be insufficient for behavior control. Fifth, blocking projection neuron output during training completely abolishes learning (Schwaerzel, 2003), arguing against a cell-autonomous memory trace within the projection neurons. Finally, blocking mushroom body output during test completely blocks expression of memory (Dubnau et al., 2001; McGuire et al., 2001; Schwaerzel et al., 2002), which is difficult to reconcile with a memory trace located in the projection neurons because such a trace could be read-out directly via the lateral protocerebrum, independently of the mushroom bodies.

These caveats may prompt the question of whether the recruitment of antennal lobe glomeruli may be explained without reference to an antennal-lobe memory trace. Could it be that the two glomeruli are activated by a memory trace located elsewhere? It was shown in honeybees that mushroom body output neurons feed back onto the antennal lobe (Rybak and Menzel, 1993; loc. cit. Figure 4b, 16; Kirschner et al., 2006); thus, at the moment of test the learned odor may activate its memory trace in the mushroom body, which by virtue of this feedback loop could disinhibit antennal

lobe glomeruli to indicate the odors' behavioral relevance. Such a scenario predicts that glomerular recruitment would not be inducible if projection neuron output was blocked during training and would not be observed if it were blocked during test.

1.28.2.7 A Memory Trace in the DPM Neurons?

In a seminal discovery, Waddell et al. (2000) found that a single pair of identified, dorsal paired medial neurons (DPM neurons) are expressing the *amnesiac* gene product, the lack of which leads to an unusually fast decay of memory. That is, retention is more or less normal right after training but has completely waned already after 60 min. Restoring *amnesiac* function in these cells is sufficient to overcome this defect. However, given that output from the DPM neurons is dispensable at the moment of test (Keene et al., 2004, 2006; Yu et al., 2004). by our criteria they cannot be the site of a memory trace underlying retention (criterion [3]).

In summary, concerning short-term memory after odor-shock training, the rut^{2080}-dependent memory trace can be assigned to the Kenyon cells with reasonable confidence because this hypothesis accommodates all available experimental data.

1.28.3 Learned Visual Pattern Preference

Visual pattern learning at the flight simulator (**Figure 1**) involves an association between the heat of a laser beam and a specific visual feature of a landmark in the panorama (Ernst and Heisenberg, 1999; Tang et al., 2004). Landmark features so far have been found to fall into five classes (parameters): the height of the pattern in the panorama, its size, its color, the vertical distance between its components, and the orientation of its contour. Flies can be conditioned to discriminate landmarks according to any of these parameters if the landmarks have different values for them (how high? how big? etc.). This kind of learning, at the very least concerning pattern height, clearly is independent of the mushroom bodies, as their ablation leaves this task unaffected (Wolf et al., 1998). Until recently it had remained elusive which parts of the brain might house the corresponding memory traces.

Genetically, visual pattern recognition requires *rut* (Liu et al., 2006), allowing the application of a similar mapping strategy as in the case of olfactory memory. A total of 27 driver lines with different expression profiles were used to locally supply *rut*-AC to the brain of the rut^{2080} mutant. Seven of them restored the learning defect. What distinguishes the expression patterns in these seven lines from those of the 20 nonrescuing lines seems to be a group of about 15 neurons on either side of the protocerebrum (the so-called F5 neurons), forming a sharp horizontal layer of fibers in the upper fan-shaped body. All flies with *rut*-AC in F5 neurons were able to learn to avoid flying toward a pattern previously combined with heat. No fly without *rut*-AC in F5 neurons was able to perform this learning task (Liu et al., 2006).

In these experiments the authors used pairs of patterns that the flies could possibly distinguish only by their height in the panorama. However, *rut*-AC expression in the F5 neurons failed to restore pattern learning when the patterns were distinguishable only by their size or only by the orientation of their contours. Hence, the rescuing effect of *rut*-AC in the F5 neurons was specific for the pattern parameter 'height.' Subsequently, two driver lines were investigated that showed transgene expression in a horizontal fiber layer of the fan-shaped body that was different from that of the F5 neurons. This layer is formed by two clusters of about 10 neurons each (F1 neurons). Strikingly, expression of *rut*-AC in these cells did not rescue the memory defect for height or size but did restore the memory for contour orientation. Both rescue effects, that for height and that for contour orientation, are adult specific, as was shown by temporal and regional expression of *rut*-AC using tub-$GAL80^{ts}$ (Liu et al., 2006), a temperature-sensitive silencer of GAL4 (McGuire et al., 2003).

These results argue that by criterion (1), two further memory traces can tentatively be localized, the memory trace for the pattern parameter height in F5 neurons and that for the parameter contour orientation in F1 neurons of the fan-shaped body. Moreover, *rut*-AC also seems to be necessary in these neurons (criterion [2]), as expression of $G\alpha_s^*$ in the F5 and F1 neurons specifically interferes with the corresponding pattern memories but leaves the memories for the other pattern parameters unaffected. Thus, these memory traces appear to be the only ones for the respective tasks. Regarding criteria (3, 4), we cannot make any conclusion, as using heat as the punishing stimulus in pattern learning may

interfere with Shi^{ts} function, at present precluding this kind of experimental strategy.

1.28.4 Heat Box

Historically, the first attempt at mapping a memory trace was conducted for place memory in the so-called heat box (Zars et al., 2000b). In this paradigm, single flies walk in a small dark box that can be quickly heated and cooled between 24 °C and 37 °C (**Figure 1**). The position of the fly in the box is monitored, and the fly is heated when it is located on one side of the box but not when located on the other. Flies quickly learn to avoid being heated and retain their side preference for some minutes even after place-dependent heating has ceased. Clearly, this kind of learning is independent of the mushroom bodies (Wolf et al., 1998).

By mutant analysis, it turned out that *rut* mutant flies show reduced acquisition and memory scores, allowing for local rescue experiments. Seventeen driver lines with transgene expression in various parts of the central nervous system were used to restore the *rut*-AC in the mutant. In four lines the learning/memory defect was rescued. All four lines had substantial, potentially overlapping expression in the median bundle and more subtle overlapping expression in the antennal lobes and ventral ganglion. Of five mushroom body expressing lines that rescue olfactory learning, four do not rescue heat-box learning (30y, 238y, 201y, and H24); one line (c772) rescues in both paradigms. A refined anatomical assessment of the expression patterns in rescuing and nonrescuing lines is still pending, but neither the mushroom bodies nor the central complex seem to contribute to heat-box learning. The most likely sites thus include the median bundle and/or the antennal lobes and the ventral ganglion. So far, experiments neither using $G\alpha_s^*$ nor tub-GAL80^{ts} have been performed. Moreover, as in the case of visual pattern learning, the use of Shi^{ts} is not readily possible. In all, exactly where the memory trace for place learning is localized remains poorly resolved.

1.28.5 Selectivity of Rescue Effects

In the studies reviewed here (**Figure 2**), 33 selected lines were tested in *rut* rescue experiments, 16 of them successfully. A total of 60 rescue experiments were performed. Of these, 18 were positive. Seventeen lines were tested in more than one memory task. Only two (c772 and c271) rescued in two tasks, and none of the 11 lines that were used in all three tasks rescued in all three of them. These numbers document the high local specificity of the rescue effects by GAL4 expression.

Taking into account that the used GAL4 lines typically express the transgene in much less than 1% of the brain neurons, one might wonder why that many positive results were obtained. It is likely that, in the studies on olfactory and visual memory, the choice of driver lines was biased toward the mushroom bodies and central complex, respectively, because previous studies on HU-ablation as well as structural brain mutants in which the mushroom bodies or the central complex were affected had pointed to these structures. In any event, the amazing selectivity of the rescue effects, even for different parts of the fan-shaped body housing traces for different visual parameter memories, is independent of such bias in the choice of lines.

1.28.6 Assessing Gene Expression Patterns

The most important caveat for memory mapping – and actually for any circuit analysis in the fly brain using the GAL4/UAS approach – is that the spatial expression patterns of driver lines are difficult to reliably assess (Ito et al., 2003; Saper and Swachenko, 2003). Neither for Shi^{ts} nor $G\alpha_s^*$ are any means available to directly detect the transgenically expressed effector proteins. Regarding the *rut-AC*, the *rut* mutant used for rescue experiments (rut^{2080}) most likely is no protein-null mutant (H. Tanimoto and T. Zars, personal communication). This leaves us with inferences from the expression patterns of reporter genes like GFP. However, this again is no reliable approach. First, the expression of the reporter may alter connectivity, as was shown for *tau* (Wittmann et al., 2001); second, with the same GAL4 driver line, the expression pattern of different effectors and – even the expression pattern for the same effector construct at different insertion sites (e.g., UAS-GFP on different chromosomes; A. Jenett and M. H., unpublished) – can be different. The construction of tagged transgenes and appropriate immunocytochemistry will be a major advance in this field, in particular when it comes to arguing about levels of transgene expression. At present, using multiple GAL4 lines for answering the same question seems the best way to deal with these concerns.

Expression pattern / Learning tasks	 Mushroom body	 Projection neurons	 F5 neurons	 F1 neurons	 Median bundle
	not sufficient	n.d.	not sufficient	n.d.	sufficient
 Trained odour Control odour	sufficient, not necessary	sufficient, not necessary	n.d.	n.d.	n.d.
 Trained odour Control odour	sufficient and necessary	not sufficient	n.d.	n.d.	n.d.
 Height	not sufficient	n.d.	sufficient and necessary	not sufficient	n.d.
 Contour orientation	n.d.	n.d.	not sufficient	sufficient and necessary	n.d.

Figure 2 Locally restoring the *rutabaga* adenylyl cyclase (*rut*-AC) rescues specific memory tasks. Top row: Five different groups of neurons (yellow in columns 2–5 and black in column 6). Leftmost column: Five learning paradigms requiring *rut*-AC (see **Figure 1** for further details). The matrix shows in which of the above neuronal groups *rut*-AC is sufficient and necessary to allow for the respective task. Odor–reward learning/memory can be rescued at either of two places.

1.28.7 Memory Mapping Reveals Functional Architecture

Contemplating the sites for olfactory and visual memory traces (**Figures 2, 3**), one notices interesting parallels and deviations. In both cases the memory trace is known from the behavioral analysis to be specific for a particular learned stimulus, whereas the neurons highlighted in the rescuing lines likely contribute to processing of many stimuli from the same sensory modality. In other words, the precise set of neurons housing a particular memory trace most likely is smaller than the group of neurons genetically highlighted in a certain driver line. Searching through more driver lines one might gradually approach the minimal set. Yet, at least in the mushroom bodies, the GAL4/UAS approach may fall short of reaching the resolution of individual memory traces: GAL4 expression patterns highlight groups of Kenyon cells that are genetically defined, whereas the sets representing given odors are functionally specified.

Odor quality appears to be coded in a combinatorial way such that the primary odor qualities constitute the coordinates of one multidimensional feature space. To accommodate a memory trace for a given odor quality within this feature space, the output of a subset from one common pool of Kenyon cells is strengthened.

In contrast, visual processing is parametrical in the sense that it is subdivided into several parameters (e.g., height and contour orientation). For visual memory, the values for each of these parameters need to be stored; consequently, each of these parameters has its own feature space employing distinct sets of neurons (e.g., F1 and F5 neurons for contour orientation and height, respectively); each of these feature spaces typically has a low dimensionality tailored toward storing parameter values. In short, olfaction employs one multidimensional feature space, whereas vision

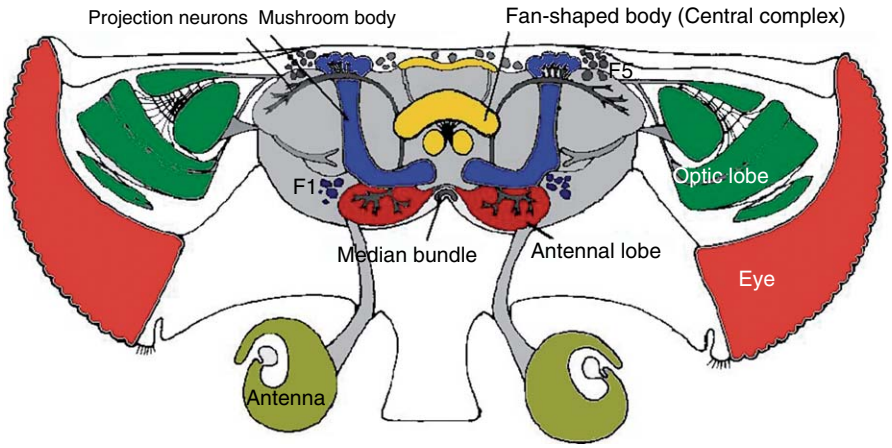

Figure 3 Schematic horizontal section of the *Drosophila* head showing some of the brain structures indicated in Figure 2. The Median bundle runs perpendicular to the plane of section. In the fan-shaped body, the horizontal strata of the F5 and F1 neurons lie about parallel to, but above and below, the plane of section.

appears to work in multiple, low-dimensional feature spaces. This example shows that beyond localizing the engram, memory mapping can elucidate the functional organization of the brain at the circuit level.

1.28.8 Conclusions

We have suggested a set of criteria for localizing a site of neuronal plasticity as the one and only trace (engram) underlying an associative memory. These criteria are that plasticity in a given group of cells be (i) sufficient and (ii) necessary for memory, and that memory be abolished if (iii) these cells could not output during test, and/or (iv) would not receive input during training. Regarding short-term memory for odor quality in aversive conditioning, the working hypothesis of the underlying memory trace being localized to Kenyon cells of the mushroom body is holding up well. Regarding visual pattern recognition, restoring the *rut*-AC is sufficient and presumably necessary in the F1 and F5 neurons of the fan-shaped body to restore memory for contour orientation and height, respectively. However, the containment of the engram in these neurons using temporally specific blockade of synaptic output has not yet been verified. For place learning in the heat box, the situation is less clear. Most likely, neither mushroom body nor central complex play a role; candidate structures are neurons in the median bundle, the antennal lobe, and the ventral ganglion.

These data altogether show that memory traces for different simple learning tasks reside in distinct parts of the brain, and that for any given learning task, the site of the underlying memory trace can be amazingly local. It should be interesting to see whether this kind of conclusion may hold up generally (i.e., also for memory traces in bees, snails, rabbits, mice, and humans). Keeping the neuronal changes of elemental memory traces locally confined may be a general operating principle of brains.

1.29 Behavioral and Neural Analysis of Associate Learning in the Honeybee

M. Giurfa, CNRS, Université Paul Sabatier, Toulouse, France

1.29.1 Introduction

French naturalist Georges-Louis Leclerc Buffon (1707–1788) became famous for the 36 volumes of his *Natural History*, an entire life's work, in which he covered subjects as diverse as the origin of the solar system, the fossilization processes, the classification of flora and fauna, and the origin of humans. Following a peculiar vision of animal intelligence, he expressed admiration for some creatures but fervently rejected others. Among the despised animals, an insect gathered his anger and devastating criticisms. It was neither an irritating mosquito nor a creeping cockroach. It was the honeybee. Buffon was impressed by the reproductive capabilities of a honeybee queen, which "produces thirty or forty thousand flies" (bees were indistinctly called bees and flies in his works), thus constituting "the largest known multiplication in the animal kingdom." This led him to conclude that "the most abject, vilest and smallest species are the most abundant ones" (Buffon, 1749a: 13–14). He went further and argued that "it is forceful to conclude that bees, taken individually, have less genius than a dog, a monkey and the vast majority of living animals; we shall also agree that they have less docility, less attachment and fewer feelings, in a word, fewer qualities relative to our own" (Buffon, 1749b: 93–94).

This animadversion contrasts with the admiration expressed by another famous scientist, who devoted his life to the study of honeybees. Karl von Frisch (1886–1982) became famous for the discovery of the honeybee dance, a ritualized behavior that allows a successful bee forager to inform other bees within the hive about the distance and direction of a profitable food source (von Frisch, 1967). This was not the only contribution made by von Frisch. He left us an amazingly rich and accurate body of evidence on honeybee behavior that spans studies on honeybee navigation, vision, olfaction, taste, and magnetic sensing, among other things (Frisch, 1967). Von Frisch liked to describe honeybees as a 'magic well' for discoveries in biology because the more that is drawn from it, the more there is to draw. Surprisingly, this fascination ended at a particular

point, in which, ironically, von Frisch could be said to approach some of Buffon's ideas. He expressed his view on the plasticity underlying honeybee behavior in the following way: "The brain of a bee is the size of a grass seed and is not made for thinking. The actions of bees are mainly governed by instinct" (Frisch, 1962, p. 78). Admittedly, von Frisch expressed this view in relation to communication behavior, but it is nevertheless striking that a tendency to dismiss the cognitive capacities of bees – and insects in general – has been perpetuated for centuries.

Despite this prolonged skepticism, in the last three decades honeybees have become a useful model for the study of learning and memory (Menzel and Erber, 1978; Menzel, 1985; Menzel et al., 1993). More recently, they have also acquired a new reputation in studies addressing higher-order cognitive capacities that have long seemed to exclusively belong to vertebrates such as monkeys, pigeons, or dolphins, which are known for their learning abilities. In this chapter, I analyze the contributions made by research on honeybee learning and memory that have facilitated this progress. I present findings and open questions that show the extent to which honeybees have increased our current understanding of cognitive processing at both the behavioral and the cellular levels, in hopes of underlining the power and potential of the honeybee in cognitive neurosciences. Chapter 4.06 provides a detailed description of the molecular mechanisms of bee learning.

1.29.2 Elemental and Nonelemental Forms of Associative Learning

Because this chapter intends to present the different levels of complexity that honeybees can reach in mastering different learning tasks, it is worth starting with operational definitions that allow discerning the simple from the complex. I focus on associative learning and introduce the distinction between elemental and nonelemental learning, which may be useful as a boundary between simple and complex forms of learning.

Associative learning is a capacity that is widespread among living animals and that allows extracting the logical structure of the world. It consists in establishing predictive relationships between contingent events in the environment so that uncertainty is reduced and adaptive behavior results from individual experience with such events. Two major forms of associative learning are usually recognized: In classical conditioning (Pavlov, 1927), animals learn to associate an originally neutral stimulus (conditioned stimulus, CS) with a biologically relevant stimulus (unconditioned stimulus, US); in operant conditioning (Skinner, 1938), they learn to associate their own behavior with a reinforcer. Both forms of learning, therefore, reliably predict reinforcement, either appetitive or aversive, and admit different levels of complexity. In their most simple version, both rely on the establishment of elemental links connecting two specific and unambiguous events in the animal's world. What has been learned for a given tone in terms of its outcome is valid for that tone but not necessarily for another stimulus, such as a light. The outcome of a given behavior, such as pressing a lever, is valid for that behavior but not for a different one such as pulling a chain (*See* Chapters 1.03, 1.07, 1.08). These forms of learning, which have been intensively studied by experimental psychologists, are also particularly interesting for neuroscientists interested in the neural bases of learning because they allow tracing to the level of neural circuits and single neurons the basis of associations underlying learning. Because these forms of learning rely on specific stimuli (e.g., a given CS and a given US), it is possible to study where and how in the central nervous system such stimuli are represented, where and how their neural pathways interact in order to facilitate association, and how experience modifies their respective neural representations. Both at the behavioral and neural level, these forms of learning have in common the univocal and unambiguous relationships established between events in the world. Because they can be characterized through specific links between unique events, simple forms of associative learning are termed elemental learning forms. Typical examples of elemental learning are absolute conditioning (A+), in which a single stimulus A is reinforced (+), and differential conditioning (A+ vs. B−), in which one stimulus, A, is reinforced (+), while another stimulus, B, is nonreinforced (−) (see **Table 1**). In the former, an animal has to learn to respond to A, which is unambiguously associated with reinforcement; in the latter, it has to learn to respond to A and not to B because both are unambiguously associated with reinforcement and with the absence of it, respectively.

However, other forms of associative learning are possible, in which unique links connecting specific events are useless because ambiguity characterizes the events under consideration (see **Table 1**). For instance, in the so-called patterning problems, animals have to learn to discriminate a stimulus

Table 1 Examples of elemental and nonelemental conditioning protocols[a]

Conditioning task	*Training*	*Processing*
Absolute conditioning	A+	Elemental
Differential conditioning	A+ vs. B−	Elemental
Feature positive discrimination	AB+ vs. B−	Elemental
Negative patterning	A+, B+ vs. AB–	Nonelemental
Biconditional discrimination	AB+, CD+ vs. AC–, BD–	Nonelemental

[a]In absolute conditioning, the subject has to learn to respond to stimulus A, which is unambiguously associated with reinforcement (+); in differential conditioning, the subject has to learn to respond to stimulus A and not to B; A is unambiguously associated with reinforcement (+), whereas B is unambiguously associated with the absence of reinforcement (−); in feature-positive discrimination, the subject has to learn to respond to the compound AB, which is reinforced (+), and not to B (−), which is nonreinforced; although B is ambiguous because it appears as often reinforced as nonreinforced, the fact that A is unambiguously associated with the reinforcement allows solving the problem. Simple links between a stimulus and reinforcement allow solving these three elemental problems. Elemental solutions cannot account for negative patterning solving, in which the subject has to learn to respond to the single stimuli A+ and B+ but not to their compound AB−, because elements are as often reinforced as nonreinforced. The same remark applies to biconditional discrimination, in which the subject has to learn to respond to the compounds AB+ and CD+ but not to AC− and BD−.

compound from its components, a task that is not necessarily trivial. Consider, for example, negative patterning, a problem in which an animal has to learn to discriminate two single components reinforced from their nonreinforced binary compound (A+, B+ vs. AB−). This situation is challenging because each element A and B appears as often reinforced as nonreinforced. Relying on elemental links between A (or B) and reinforcement (or absence of reinforcement) cannot solve this problem. Different strategies, such as treating the binary compound in a nonlinear form (i.e., as being different from the simple sum of A and B) have to be implemented to solve this kind of problem. A profuse literature has shown that some vertebrates can solve this kind of nonlinear processes and has put the accent on the nervous circuits and brain structures required for this kind of cognitive processing (Rudy and Sutherland, 1995; O'Reilly and Rudy, 2001; Bucci et al., 2002; Alvarado and Bachevalier, 2005; Moses et al., 2005; Borlikova et al., 2006; Jacobs, 2006; *See* Chapter 1.10).

Having introduced these two forms of learning, which define different levels of complexity in cognitive processing in a formalized and operational way, I present findings showing that it is possible to dissect and understand the basic mechanisms underlying these two levels of processing, using honeybees as a model system. I demonstrate that this insect exhibits elemental and nonelemental forms of learning that are relevant in its natural life and that are amenable to the laboratory, thus allowing controlled study and access to the underlying nervous system.

1.29.3 The Honeybee as a Natural Model for Studies on Learning and Memory

Several reasons warrant the use of the honeybee as a model for the study of learning abilities. In a natural context and despite their small size, honeybees exhibit an extremely rich behavioral repertoire (von Frisch, 1967). A social lifestyle is obligatory, and a single bee cannot survive very long separated from its mates. Outside of the hive, a bee travels over distances of several kilometers and visits hundreds of flowers in quick and efficient succession for gathering food (nectar and/or pollen). It also collects resin or water or roams for information-gathering purposes. Sensory capacities and motor performance are highly developed. Bees see the world in color (Menzel and Backhaus, 1991), perceive shapes and patterns (Srinivasan, 1994; Giurfa and Lehrer, 2001), and resolve movements with a high temporal resolution (Srinivasan et al., 1999). Their olfactory sense is able to distinguish a wide range of odors (Guerrieri et al., 2005b), and their mechanosensory perception is also extremely rich because of thousands of hair cells all around the body and proprioreceptors inside the body.

In a natural context, bees learn and memorize the local cues characterizing the places of interest, which are essentially the hive and the food sources (Menzel, 1985; Menzel et al., 1993). In the case of food sources, learning and memory are the very basis of floral constancy, a behavior exhibited by foragers that consists of foraging on a unique floral species as long as it offers profitable nectar and/or pollen reward (Grant,

1951). Only when such an offer becomes unprofitable will bees switch to a different species. Learning and memorizing the sensory cues of the exploited flower through their association with nectar and/or pollen reward is what allows a bee forager to track a particular species in the field. Similarly, learning abilities for landmark constellations and for celestial cues used in navigation (azimuthal position of the sun, polarized light pattern of the blue sky) ensure a safe return to the nest and enhance foraging efficiency (Collett et al., 2003).

Honeybees communicate information about important locations around the hive through ritualized body movements, called the waggle dance, a communication system that transmits information on the vector flown toward an attractive food source or nest site (von Frisch, 1967). Hive bees attending such a dance decode from the speed of dance movement the distance to the food source, and from the angle of the waggling phase relative to gravity, the flight direction relative to the sun. In this context, specific associations are built as dance followers learn to associate the odor of nectar brought by a dancer with the nectar that it regurgitates and passes them through trophallactic contacts (Farina et al., 2005, 2007; Gil and de Marco, 2005, 2006; *See* Chapter 1.25). Usually, many such dances occur in parallel within a colony. Individual and collective decision-making result from multiple and independent decisions without reference to full knowledge of all potential options available (Seeley, 1995).

The complexity and richness of the honeybee's natural life is therefore appealing in terms of the opportunities it offers for the study of natural learning and memory. Such an appeal would be, however, useless if these phenomena were not amenable to controlled laboratory conditions. However, several protocols have been developed to allow experimental access in terms of controlled training and testing conditions, thus underscoring the remarkable plasticity of this insect, which can learn even under restrictive (in terms of movement, for instance) or stressful (in terms of the aversive reinforcement experienced) conditions.

1.29.4 Experimental Access to Learning and Memory in Honeybees

Honeybees can be easily trained individually to solve different kinds of discrimination problems (von Frisch, 1967). Different from the en-masse training commonly used in other insects (e.g., *Drosophila*; Tully and Quinn, 1985), which does not always allow controlling the exact experience of the experimental subjects, different experimental protocols have been implemented to study learning and memory in honeybees at the individual level. This individual approach is important because learning and memory result from individual experience and because a neurobiological approach can then be undertaken and correlated with individual learning and memory scores only if such scores have been recorded in a precise way. Three main protocols developed to study honeybee learning and memory can be mentioned here: (1) conditioning of the approach flight toward a visual target in free-flying bees, (2) olfactory conditioning of the proboscis extension reflex in harnessed bees, and (3) olfactory conditioning of the sting extension reflex in harnessed bees. The first two protocols exploit the appetitive context of food search, as in both cases bees are rewarded with sucrose solution as an equivalent of nectar. The third protocol represents a case of aversive learning, as bees learn to associate odorants paired with the noxious reinforcement of an electric shock. In all three cases, and with different possible modifications derived from particular experimental needs, the basic experimental design comprises an acquisition or training phase in which the bees experience a particular stimulus or perform a given task that is reinforced, and a test or retrieval phase without reinforcement in which the bees are presented with the trained situation in order to assess the memory created by training. Eventually, novel stimuli can be presented in the test phase together with the trained stimulus in order to study generalization and discrimination capabilities. Transfer to novel stimuli (i.e., in absence of the trained stimulus) can also be tested to characterize the flexibility of the bee's choice (see below).

1.29.4.1 Conditioning of the Approach Flight Toward a Visual Target in Free-Flying Bees

Free-flying honeybees can be conditioned to visual stimuli such as colors, shapes and patterns, and depth and motion contrast, among others (von Frisch, 1914; Wehner, 1981; Giurfa and Menzel, 1997; Lehrer, 1997; Giurfa and Lehrer, 2001). In such a protocol, each bee is individually marked by means of a color spot on the thorax or the abdomen so that individual performance can be recorded. The marked bee is

generally displaced by the experimenter toward the training/test place, where it is rewarded with sucrose solution to promote its regular return (**Figure 1(a)**). Such pretraining is provided without presenting the training stimuli in order to avoid uncontrolled learning. When the bee starts visiting the experimental place actively (i.e., nondisplaced to it by the experimenter), the training stimuli are presented and the choice of the appropriate visual target reinforced with sucrose solution. As pointed out above, bees have to be trained and tested individually to achieve a precise control of the experience of each subject when it enters into a particular test. It is also important to control the distance at which a choice is made because orientation and choice are mediated by different visual cues at different distances or angles subtended by the target (Giurfa and Menzel, 1997; Giurfa and Lehrer, 2001). The time between visits to the experimental place is also an important variable to be recorded, because it reflects the appetitive motivation of the bee (Núñez, 1982), and thus its motivation to learn. For a food source approximately 100 m from the hive, motivated bees take between 3 and 10 min between foraging bouts. Longer intervals reflect a lower appetitive motivation and thus unreliable data.

Several behaviors can be used to quantify the bees' choice in these experiments. Touches (i.e., the flights

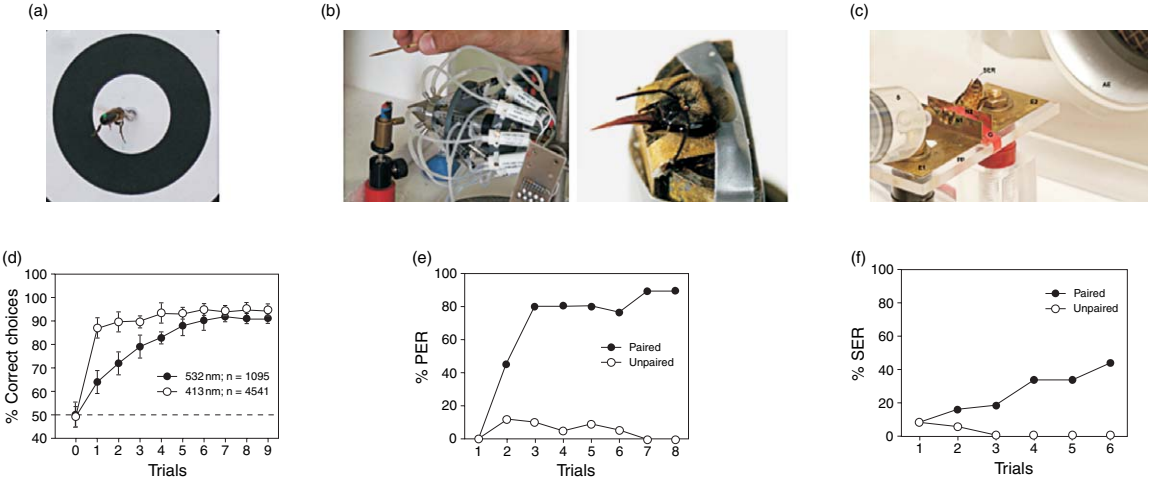

Figure 1 Experimental protocols for the study of learning and memory in honeybees. (a) Visual appetitive conditioning of free-flying bees. A bee marked with a green spot on the abdomen is trained to collect sugar solution in the middle of a ring pattern. (b) Olfactory appetitive conditioning of harnessed bees. The left panel shows a bee immobilized in a metal tube facing an olfactory stimulation device controlled by a computer. The toothpick soaked in sucrose solution held by the experimenter allows delivering reward to the antennae and mouthparts. The right panel shows the proboscis extension reflex (PER) of a trained bee to an odorant previously paired with sucrose solution. (c) Olfactory aversive conditioning of harnessed bees. A bee is immobilized by an elastic girdle (G) between two metal plates (E1, E2) on a plexiglas plate (pp) through which a mild electric shock is delivered. Odorant presentation is achieved by a syringe (S), and olfactory contamination is avoided by an air extractor (AE) placed behind the bee. Bees learn to extend the sting (sting extension reflex, SER) to the odorant aversively reinforced. (d) Acquisition curves for bees trained with colors in dual-choice experiments. Adapted from Figure 4 in Menzel R (1967) Untersuchungen zum Erlernen von Spektralfarben durch die Honigbiene (*Apis mellifica*) *Z. Vergl. Physiol.* 56: 22–62. The curves depict the percentage of correct choices along conditioning for two wavelengths, 413 nm (human violet) and 532 nm (human green). Trial 0 constitutes a spontaneous-choice test in which bees freely choose between the color that will be trained and an alternative. Although bees reached comparable levels of correct choices at the end of training, they learned 413 nm faster than 532 nm. n, number of choices recorded. (e) Acquisition curves for bees trained to associate an odorant with sucrose solution. Adapted from Figure 2 in Bitterman ME, Menzel R, Fietz A, and Schäfer S (1983) Classical conditioning of proboscis extension in honeybees (*Apis mellifera*) *J. Comp. Psychol.* 97: 107–119. The curves depict the percentage of PER along conditioning trials for two groups of bees, one trained with explicitly paired presentations of odorant and reward (paired, black dots), and another trained with explicitly unpaired presentations of odorant and reward (unpaired, white dots). Only the paired group learned the odorant–reward association, thus showing that learning has an associative basis and is not merely a result of experience with the stimuli independently of their temporal relation. (f) Acquisition curves for bees trained to associate an odorant with an electric shock. Adapted from Figure 2 in Vergoz V, Roussel E, Sandoz JC, and Giurfa M (2007a) Aversive learning in honeybees revealed by the olfactory conditioning of the sting extension reflex. *PLoS ONE* Mar 14 2: e288. The curves depict the percentage of SER along conditioning trials for two groups of bees, one paired (black dots) and another unpaired (white dots). Only the paired group learned the odorant–reward association, thus showing that learning has an associative basis.

toward a target that end with a contact of the bee's antennae or legs with the stimulus surface) and landings on a given stimulus are usually recorded to this end. The associations built in these contexts can be either operant, classical, or both; that is, they may link visual stimuli (CS) and reward (US), the response of the animal (e.g., landing) and the US, or both. The experimental framework is nevertheless mainly operant, as the bee's behavior is determinant for obtaining or not the sucrose reinforcement.

1.29.5 Olfactory Conditioning of the Proboscis Extension Reflex in Harnessed Bees

Apart from visual stimuli, honeybees can be conditioned to olfactory stimuli (Takeda, 1961; Bittermann et al., 1983). In this type of protocol, each bee is restrained in an individual harness such that it can only freely move its antennae and mouth parts (mandibles and proboscis) (**Figure 1(b)**). The antennae are the bees' main chemosensory organs. When the antennae of a hungry bee are touched with sucrose solution, the animal reflexively extends its proboscis to reach out to and suck the sucrose (proboscis extension reflex, PER). Neutral odorants blown to the antennae do not release such a reflex in naive animals. If, however, an odorant is presented immediately before sucrose solution (forward pairing), an association is formed that enables the odorant to release the PER in a following test (**Figure 1(b)**) This effect is clearly associative and constitutes a case of classical conditioning (Bittermann et al., 1983); that is, the odorant can be viewed as the conditioned stimulus (CS) and the sucrose solution as the rewarding, unconditioned stimulus (US). Within this framework, bees learn to associate the odorant with the sucrose reward.

As in any learning protocol, it is important to ensure the appropriate appetitive motivation of the experimental subjects. Immobilized bees in the laboratory therefore have to be starved prior to conditioning. A period of 2–3 h or a whole night is usually used as a starvation period in which bees have to be kept in a calm, darkened, humid environment. In olfactory PER conditioning, the response recorded is the extension of the proboscis, which is a dichotomous response (1 or 0). The duration of PER can also be recorded in order to provide a continuous, instead of a discrete, measure of acquisition (Hosler and Smith, 2000). To quantify learning, responses to the CS (the odorant) have to be measured before US delivery in each acquisition trial. In quantifying responses to the US, it is also important to control for the presence of the unconditioned reaction, and thus for the maintenance of the appetitive motivation of the bee throughout the experiment. A useful practice is to check the integrity of PER before and after the experiment by touching the antennae with sucrose solution. Animals not exhibiting PER in these control assays should not be included in the experimental analyses, as negative responses during acquisition and/or retrieval can be caused by sensory-motor deficits instead of learning and/or memory deficits.

1.29.5.1 Olfactory Conditioning of the Sting Extension Reflex in Harnessed Bees

Contrary to the previous protocols, this new form of conditioning (Vergoz et al., 2007a) offers the opportunity to study aversive instead of appetitive learning in honeybees. In this case, each bee is restrained in an individual harness such that it builds a bridge between two metallic plates through which an electric shock can be delivered (**Figure 1(c)**). Bees stimulated in this way exhibit an unconditioned, defensive reaction, which is the extension of the sting (sting extension reflex, SER) (Núñez et al., 1997). Using odorants paired with electric shocks, it is possible to condition the SER so that bees learn to extend their sting in response to the odorants previously punished (Vergoz et al., 2007a). Because no appetitive responses are involved in this protocol, true aversive learning can be characterized in this way.

As in appetitive olfactory conditioning of PER, the experimenter controls the stimulus contingency and can therefore vary the interstimulus interval and/or the intertrial interval in order to study the impact of these variations on aversive olfactory memory. Responses recorded are also dichotomous (1 or 0), but continuous measures can be obtained by recording SER duration. To quantify learning, responses to the CS (the odorant) have to be measured before shock delivery in each acquisition trial. Quantifying responses to the shock is also important to control for the presence of the unconditioned reaction, and thus for the aversive motivation of the bee throughout the experiment. As for PER conditioning, the integrity of SER has to be checked before and after the experiment to ensure the use of reliable data for the experimental analyses.

1.29.6 Accessibility of the Central Nervous System

The brain of a honeybee has a volume of approximately 1 mm^3 and contains around 960 000 neurons (Figure 2). Despite this apparent simplicity, the bee brain is capable of supporting learning and memory under simplified and restrictive conditions such as those described above. Accessing it in order to understand how neural architecture relates to cognitive processing is therefore possible, and several approaches can be employed to this end.

Although the free-flying visual conditioning protocol offers the obvious advantage of keeping the bee free, and thus allows visualizing the richness of its natural learning abilities, it is not helpful to uncover the neural bases of such abilities. Appetitive and aversive olfactory PER and SER conditioning, respectively, have the advantage of being controlled learning protocols precluding the bees' movement so that they can be easily combined with physiological approaches allowing *in vivo* the study of cellular and molecular substrates of learning and memory. This is a considerable advantage offered by bees and other invertebrate models with respect to some vertebrates, namely the possibility of an on-line access to the nervous system of a nonanesthetized animal while it learns and memorizes. It is possible to expose the bee brain through a small window cut in the cuticle of the head and to employ several invasive methods to study the bases of learning and memory. Physiological correlates of these different forms of olfactory conditioning can be found at different levels, ranging from the molecular and pharmacological levels to single identified neurons and neuronal ensembles whose activity can be visualized using electrophysiological or optophysiological techniques (Menzel, 1999, 2001). Neuropharmacological approaches based on the injection of agonists or antagonists of neurotransmitters or receptors into the brain can also be employed. Furthermore, RNAi can also be injected into the bee brain to characterize the role of certain receptor molecules functionally (Farooqui et al., 2003).

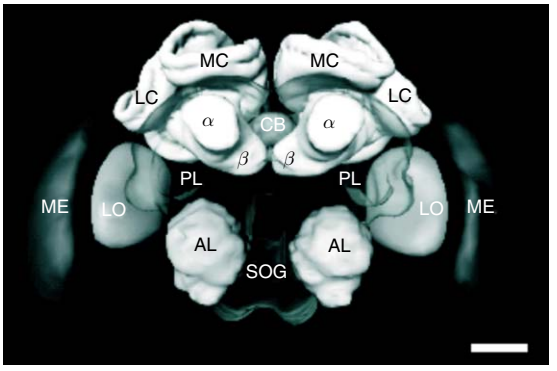

Figure 2 Three-dimensional reconstruction of a honeybee brain in frontal view based on confocal microscopy. Different neuropiles are indicated: ME, medulla, together with the lamina (not shown); LO, lobula; together with the lamina (not shown), both constitute the visual lobes in which visual processing occurs; AL, antennal lobe, the primary olfactory neuropile; PL, protocerebral lobe (lateral horn), a neuropile whose function is unclear; SOG, subesophageal ganglion, a region of the brain related to gustatory input; CB, a region of the brain related to motor responses; the two prominent, lighter symmetric structures in the middle of the brain are the mushroom bodies. Each mushroom body consists of two subunits, the calyces, lateral (LC) and median (MC) that constitute the input region of the mushroom bodies. Two lobes α and β constitute their output. Bar = 200 μm. From Malun D, Giurfa M, Galizia CG, et al. (2002) Hydroxyurea-induced partial mushroom body ablation does not affect acquisition and retention of olfactory differential conditioning in honeybees. *J. Neurobiol.* 53: 343–360.

Experimental access to the bee brain has characterized its basic architectural principles (Menzel and Giurfa, 2001). It comprises (1) dedicated neuropiles (i.e., brain regions devoted to the processing of specific sensory information [vision, olfaction, etc.]), (2) dedicated neurons (i.e., neurons that can be recurrently identified from bee to bee and within the same bee because of their unique morphology and because they accomplish specific functions in sensory-motor routines), and (3) higher-order integration centers (i.e., centers in which different sensory pathways converge such that multimodal integration takes place in them). Examples of these elements are provided when discussing the neural substrates of elemental and nonelemental learning in bees.

1.29.7 Elemental Appetitive Learning in Bees

Having described the main protocols used for the study of learning in honeybees, in this section I outline the main findings that have characterized elemental forms of learning at the behavioral and the cellular levels.

1.29.7.1 Elemental Color Learning and Memory in Free-Flying Honeybees

The first pioneering study on honeybee learning and memory that used controlled protocols for

characterizing individual acquisition and retention employed colors as rewarding stimuli (Menzel, 1967). Free-flying bees were trained to choose a rewarded monochromatic light and were then presented in dual-choice situations with the rewarded light vs. an alternative color. This study reported acquisition curves for different wavelengths and showed that bees learned all wavelengths after few (generally three) learning trials (**Figure 1(d)**). Performance was independent of the alternative, nonrewarded wavelength presented in the test. Moreover, some wavelengths, particularly 413 nm, were learned faster than others, especially after a first acquisition trial (Menzel, 1967). This result argued in favor of innate biases in color learning, probably reflecting the intrinsic biological relevance of the color signals that are learned faster (Menzel, 1985). Indeed, color-naïve honeybees in their first foraging flight prefer these colors, which experienced bees learn faster (Giurfa et al., 1995), and preliminary findings indicate that these colors could correspond to floral colors that are highly associated with a profitable nectar reward (Giurfa et al., 1995).

Menzel's (1968) experiments determined that one learning trial leads to a memory trace that fades a few days after learning if the animal is not allowed to learn anything else during this time, but three learning trials lead to a lifelong color memory. This was the very basis for discovering the existence of different memory phases in honeybees, some of which are short-term memories susceptible to interferences from additional color trials, and others are long-term memories that are resistant to such interferences. Short-term memories that allow keeping memory active during shorter periods of time are dominated by nonassociative processes such as sensitization. It was shown that at intervals of 24 h, memory formation is not protein-synthesis dependent, thus leading to the conclusion that long-term visual memories were not dependent on protein synthesis (Wittstock and Menzel, 1994). However, this conclusion is only valid for early components of long-term memory, as bees in these experiments were only tested 24 h after conditioning. Results from olfactory conditioning (see below) have shown that olfactory memories older than 4 days are indeed dependent on protein synthesis (Wüstenberg et al., 1998). A similar dependence on color memory is expected, given the parallels in dynamics between olfactory and visual memories. However, the demonstration that later components of long-term color memory do indeed depend on protein synthesis is still pending.

Color conditioning of free-flying bees was used to characterize other elemental learning phenomena such as overshadowing, the fact that after learning a color compound a bee responds significantly more to one color at the expense of the other (Couvillon and Bittermann, 1980; Couvillon et al., 1983), and blocking, the fact that after learning a single color and being then trained with a color compound made of the previously rewarded color and a new color, a bee may not learn the new color despite its close association with reward in the second training phase (Couvillon et al., 1997). Often, studies addressing these phenomena did not consider important stimulus characteristics that could bias performance, such as chromatic salience and detectability. They nevertheless had the merit of underlining that general principles of learning studied in vertebrates could be also found in honeybees.

In the 1980s and 1990s, visual learning was mainly used as a tool to answer questions on orientation close to the goal and visual perception and discrimination. The questions raised by these studies (see Lehrer, 1997; Srinivasan and Zhang, 1997, for reviews) focused on visual capabilities such as visual spatial resolution, shape discrimination, orientation detection, and movement perception and parallax, among others, and were not concerned by learning itself. Not surprisingly, none of these investigations quantified individual acquisition performance in order to present acquisition curves. This is a critical point because the visual strategies used by bees to solve a visual discrimination may be affected by the amount of accumulated experience at the moment of a test (Giurfa et al., 2003; Stach and Giurfa, 2005).

Because of obvious limitations, color learning in honeybees was never amenable at the cellular level because of the free-flying activity of the bees under study. Stages of central color processing such as color opponent neurons (Kien and Menzel, 1977; Yang et al., 2004) are known in the bee brain (Menzel and Backhaus, 1991), but there is no evidence on the possible interactions between the known neural elements of the color processing circuit and a reward-processing pathway. Recently, a protocol for color conditioning of the proboscis extension reflex has been proposed (Hori et al., 2006), based on pioneer findings by Kuwabara (1957). This protocol consists of training harnessed bees to extend the proboscis to color signals paired with sucrose solution.

1.29.7.2 Elemental Olfactory Learning and Memory in Harnessed Bees

The first study on olfactory PER conditioning was conducted by Takeda (1961) and was inspired by Kuwabara (1957), who reported PER conditioning using colors as CS. Olfactory PER conditioning was first used to assess olfactory discrimination capabilities in bees. These were typically trained with one rewarded odor and then tested for their choice of different odors, which differed from the rewarded one in structure (Vareschi, 1971). Even now, the protocol continues to serve this purpose and has provided a description of a putative olfactory space for the honeybee (Guerrieri et al., 2005b). This space was established by quantifying similarity and difference relationships between several odorants through olfactory PER conditioning. However, the protocol turned out to be the most powerful tool to characterize elemental olfactory learning after Bitterman et al. (1983) characterized it as a case of classical conditioning in which bees learn a CS (odorant)–US (sucrose solution) association. Forward (CS precedes US) but not backward (US precedes CS) pairing results in acquisition and learning of the trained odorant (**Figure 1(e)**). The memory trace initiated by a single CS–US pairing follows a biphasic memory function similar to that found for color learning of free-flying bees. The initial high response level is dominated by a nonassociative sensitization component, because a single US alone also arouses the animal for a short period of time, leading to a transient increase in response to many stimuli, including the CS.

A single learning trial results in a medium-term memory that fades away after a few days, whereas three learning trials lead to a stable long-term memory that is resistant to different forms of interference. Olfactory memory and its different phases (short-term, early and long; medium-term, early and long; and long-term, early and long; see Menzel, 1999) have been accurately described in terms of their dynamics (Menzel, 1999). The molecular bases of these phases are currently either known or being explored (Menzel, 2001), but this subject will not be reviewed here. The fact that similar dynamics underlie color and olfactory memory can be related to the natural lifestyle of the honeybee. Indeed, olfactory memory phases correspond to the temporal dynamics of foraging activities in the field (Menzel, 1999), such that early components of memory can be related to the fast succession of experiences that a bee gathers while foraging within a patch or when moving between close patches, whereas medium-term memory corresponds, because of its intrinsic dynamic, to the intervals occurring between foraging bouts. Long-term memory relates to foraging bouts that are spaced in time and that may occur in different days or after long-interrupted bouts (Menzel, 1999).

As in other classical (Pavlovian) protocols, olfactory memory acquired through PER conditioning is dependent on variables such as the kind of CS, US intensity (i.e., the amount and/or quality of sucrose solution received during conditioning), the number of conditioning trials, and the intertrial interval; Menzel et al., 2001). Trial spacing is the dominant factor for both acquisition and retention. Generally, massed trials (i.e., trials succeeding each other in a fast sequence) lead to impaired memory performance compared with spaced trials (i.e., trials separated in time). Longer-intertrial intervals lead to better acquisition and higher retention. Several studies on olfactory memory dynamics (reviewed in Menzel, 1999) showed that memories in bees pass through an early consolidation phase and that memories are fragile before consolidation is completed. Transfer from short-term memory to long-term memory via medium-term memory is not a purely sequential process but also includes parallel processes (Menzel, 1999). As in color learning, olfactory short-term memories are dominated by a nonassociative sensitization component, and long-term memory at its latest phase is protein synthesis dependent (Wüstenberg et al., 1998). The main conclusion arising from studies on honeybee olfactory memory (Menzel, 1999, 2001) is that behavioral performance reflecting memory storage and retrieval is guided by multiple and discrete memory traces rather than by a single, continuously decaying memory trace.

Olfactory conditioning of PER allowed studying associative phenomena such as overshadowing (Smith, 1998), blocking (Smith and Cobey, 1994; Gerber and Ullrich, 1999; Hosler and Smith, 2000; Guerrieri et al., 2005a), and other forms of compound conditioning (e.g., sensory preconditioning; Müller et al., 2000; backward blocking, Blaser et al., 2004) in a more controlled way. In some cases, clear effects were found (e.g., overshadowing, sensory preconditioning), whereas in others (e.g., blocking), the responses were rather inconsistent (Guerrieri et al., 2005a).

1.29.7.3 Cellular Bases of Appetitive Olfactory Proboscis Extension Reflex Conditioning

Apart from behavioral studies, the significant advance yielded by olfactory PER conditioning was

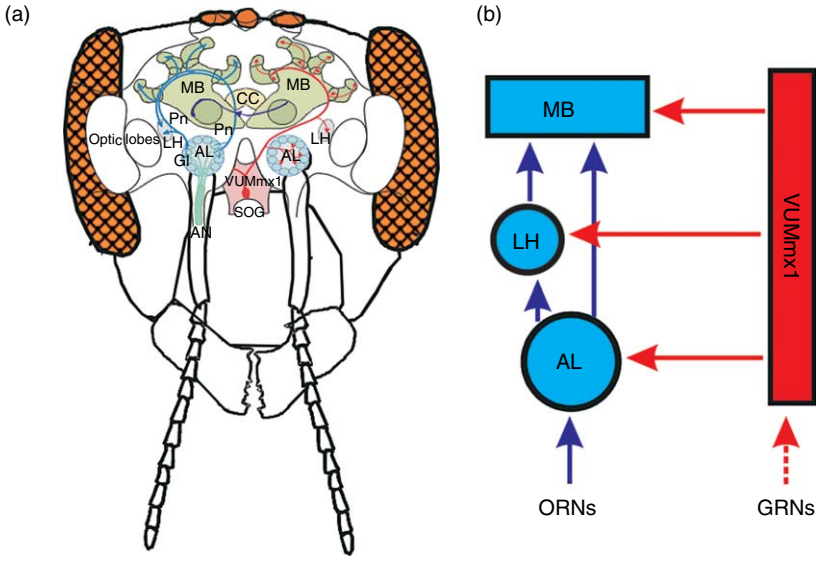

Figure 3 CS–US associations in the honeybee brain. (a) Scheme of a frontal view of the bee brain showing the olfactory (CS, in blue on the left) and gustatory (US, in red on the right) central pathways. The CS pathway: olfactory sensory neurons send information to the brain via the antennal nerve (AN). In the antennal lobe (AL), these neurons synapse at the level of glomeruli (Gl) onto local interneurons (not shown) and projection neurons (Pn) conveying the olfactory information to higher-order centers, the lateral horn (LH) and the mushroom bodies (MB). MBs are interconnected through commissural tracts (in violet).The US pathway: this circuit is partially represented by the VUMmx1 neuron, which converges with the CS pathway at three main sites: the AL, the LH, and the MB. CC, central complex, SOG, subesophageal ganglion. (b) Localization and distribution of CS–US associations in the bee brain. ORNs, olfactory receptor neurons; GRNs, gustatory receptor neurons. The dashed line between GRNs and VUMmx1 indicates that this part of the circuit is actually unknown. Adapted from a scheme provided courtesy of B. Gruenewald.

the possibility of tracing CS and US pathways in the honeybee brain and integratively studying the neural circuits underlying elemental associative learning. Odorants are processed in a neural pathway (the CS processing pathway) characterized by different processing stages (**Figure 3(a)**). Olfactory perception starts at the level of the antennae, where olfactory receptor neurons are located within specialized hairs called sensilla. Sensory neurons endowed with molecular olfactory receptors convey information on odorants to the antennal lobe. This structure is a good example of dedicated neuropile (see above), as it is the primary olfactory center of the bee brain. Antennal lobes are made up of globular structures called glomeruli, which are synaptic interaction sites between olfactory receptors, with local inhibitory interneurons connecting glomeruli laterally and projection neurons conveying processed olfactory information to higher-order centers such as the lateral horn or the mushroom bodies. The latter are higher-order integration centers, as they receive input from visual and mechanosensory pathways apart from the olfactory pathway.

Optophysiological studies based on recording calcium activity at the level of the antennal lobe following olfactory stimulation have shown that in naïve (i.e., nontrained) honeybees, odors are represented in terms of glomerular activity patterns (Joerges et al., 1997; Galizia and Menzel, 2000). Activity patterns for a given odor are symmetric between brain hemispheres and are conserved between individuals (Galizia et al., 1998, 1999). The pattern of active glomeruli tells the brain the identity of the odorant processed. When two odorants are presented in a mixture, the glomerular representation resembles the sum of the responses to the components or the response of the strongest component (Deisig et al., 2006). As more components are added, the picture changes and inhibitory interactions become apparent (Joerges et al., 1997). This across-fiber pattern coding is maintained upstream (Faber and Menzel, 2001), but there are differences in odor coding between the antennal lobes and the mushroom bodies. Indeed, odors evoke combinatorial activity patterns also at the level of the calyces, the input region of the mushroom bodies, but these are

substantially sparser (Szyszka et al., 2005). Moreover, the Kenyon cells, the neurons that constitute the mushroom bodies, exhibit a temporal sharpening of responses in response to odorants.

Although some parts of the CS pathway are still superficially characterized (e.g., the lateral horn), and although we are only starting to understand the dynamic aspects of odorant processing in several of the stages of this pathway (Szyszka et al., 2005), an integrative view of the CS circuit is already available. How does learning modify neural activity in this circuit? Faber et al. (1999) found that olfactory differential conditioning induces an increase in the intensity of the glomerular activation pattern for a rewarded odorant but not a qualitative change in its global nature. The nonrewarded odorant induced no change in glomerular activity. This conclusion has been recently challenged by experiments that showed no change in activity in a subpopulation of uniglomerular output neurons (projection neurons) after different elemental olfactory conditioning protocols (Peele et al., 2006). How olfactory representations are modified by associative learning therefore remains to be determined. In doing this, changes at the different stages of the olfactory pathway have to be studied at different intervals after conditioning. Moreover, the effect of different conditioning protocols of varying complexity should also be considered as a possible determinant of the olfactory representation achieved.

In the case of the US processing pathway, our knowledge is only partial, at least in neuroanatomical terms, as it has thus far been restricted to a unique neuron that is necessary and sufficient to substitute for the sucrose reward in the honeybee brain. This neuron, which constitutes a good example of dedicated neuron (see above), is called VUMmx1 (ventral unpaired median neuron of the maxillary neuromere 1) and responds with long-lasting spike activity to sucrose solution delivered both at the antennae and the proboscis (Hammer, 1993). The dendrites of VUMmx1 arborize symmetrically in the brain and converge with the olfactory pathway at three sites: the antennal lobes; the calyces, which are the olfactory input areas of the mushroom bodies; and the lateral horns (**Figure 3(a)**). This convergence is particularly remarkable in the case of a neuron coding for sucrose solution because it provides the structural basis for CS–US associations. That VUMmx1 indeed constitutes the neural representation of the US in olfactory PER conditioning was shown through an elegant substitution experiment conducted by Hammer (1993). He showed that behavioral learning of an olfactory stimulus can be induced by substituting the sucrose reward in PER conditioning with an artificial depolarization of VUMmx1 immediately after olfactory stimulation (forward pairing). If depolarization, and thus spike activity, precedes olfactory stimulation (backward pairing), no learning was observed. The same forward–backward effect was seen when sucrose was used as the reward under similar experimental conditions. These results showed that VUMmx1 constitutes the neural correlate of the US in associative olfactory learning.

This conclusion was reaffirmed by neuropharmacological experiments aimed at discovering the neurotransmitter acting as appetitive reinforcement in olfactory PER conditioning. As VUMmx1 belongs to a group of octopamine-immunoreactive neurons (Kreissl et al., 1994), it was hypothesized that octopamine, a biogenic amine usually associated with increased levels of arousal and behavioral facilitation in invertebrates (Libersat and Pflüger, 2004; Huber, 2005), acts as the neurotransmitter necessary and sufficient to substitute for the sucrose reward (Hammer and Menzel, 1998). Indeed, pairing an odorant with injections of octopamine as a substitute for sucrose into the mushroom bodies or the antennal lobes (but not the lateral horn lobe) produced a lasting, learning-dependent enhancement of proboscis extension (Hammer and Menzel, 1998). Thus, octopamine signaling via VUMmx1 is sufficient to substitute for sugar reinforcement in honeybees. This conclusion was confirmed by silencing octopaminergic receptor expression in the honeybee antennal lobe using double-stranded RNA (Farooqui et al., 2003). This treatment inhibited olfactory acquisition and recall but did not disrupt odorant discrimination. This result underscores that appetitive reinforcer function in the invertebrate brain is subserved by specific neurons and associated biogenic amines (here octopamine), which act as value systems in associative learning phenomena (i.e., as systems allowing ordering, prioritizing and assigning good or bad labels to odorants; Giurfa, 2006).

We still lack a more integrative view of the US pathway. Although gustatory receptor neurons tuned to sucrose have been located on specialized sensilla on the antennae, mouth parts, and tarsi (Whitehead and Larsen, 1976; Whitehead, 1978; Haupt, 2004; de Brito Sanchez et al., 2005), less is known about the circuit allowing these receptors to convey US information to the central level, and more specifically to VUMmx1. This circuit is probably localized in the subesophageal ganglion, which is the first synaptic

relay in the gustatory pathway (Altman and Kien, 1987). Despite this incomplete view of the US pathway, an important principle of classical conditioning was verified by studying VUMmx1 activity, namely, stimulus substitution. Classical conditioning relies on a CS acquiring the capacity of replacing the US as it becomes a reliable predictor of reinforcement. This was evident in recordings of VUMmx1 activity after olfactory conditioning (Hammer, 1993). After training a bee to discriminate a rewarding (CS1) from a nonrewarded odorant (CS2), it was found that VUMmx1 fired to CS1 and not to CS2 (Hammer, 1993). Thus, CS1, the odorant that reliably predicted the US, acquired the capacity of activating VUMmx1. At the same time, VUMmx1 continues to respond to the US when it is presented unexpectedly (i.e., not preceded by a predictive odorant; Menzel and Giurfa, 2001). Thus, the VUMmx1 neuron has the characteristic properties of a system that provides reinforcement prediction error information that is critical to associative learning (e.g., Schultz and Dickinson, 2000). In other words, it provides information on the discrepancy between the expected and delivered values of a reinforcing event (the prediction error), which determines the effective reinforcement value of that event (Rescorla and Wagner, 1972).

The picture emerging from these and other studies is one in which elemental, associative, olfactory learning can be accurately characterized at both the behavioral and cellular levels in order to understand the mechanisms of this simple form of learning. The honeybee offers the unique chance of dissecting elemental olfactory learning and identifying its building blocks. From this dissection, it appears that learning relies on distributed, but localized, interactions between CS and US pathways throughout the brain (**Figure 3(b)**). Distribution is reflected by the fact that interactions between these pathways occur in at least three different regions of the brain, the antennal lobes, the mushroom bodies, and the lateral horns (see **Figure 3(b)**). Localization is reflected by the fact that these interactions are spatially delimited. Redundancy could also be designated as a principle because of the repetition of synaptic interactions between CS and US pathways, but so far it remains unknown whether the interactions occurring at one of these three sites are equivalent to those occurring in another site (i.e., whether different memory contents are formed and stored in the antennal lobes, mushroom bodies, and lateral horns). Instead, it appears that these different brain structures intervene in different forms of learning (see below) so that the concept of redundancy would not be appropriated.

1.29.8 Elemental Aversive Learning in Bees

The previous sections underline that for almost a century research on honeybees has made significant contributions to our general understanding of learning and memory but that such an understanding is restricted to appetitive learning. As mentioned above, olfactory conditioning of PER has been used for 45 years (beginning in 1961; Takeda, 1961) as the only tool to access the neural and molecular bases of learning in honeybees.

Recently, aversive learning could be studied in honeybees in such a way that both behavioral and neural levels were made accessible to experimentation (Vergoz et al., 2007a). Pairing an odorant with an electric shock resulted in associative learning, in which bees learned to extend their sting (SER) in response to the odorant previously punished (**Figure 1(f)**). They were also able to learn to master appetitive and aversive associations simultaneously and exhibited the appropriate response, PER or SER, to the appropriate odorant. Moreover, neuropharmacological experiments addressed the question of modularity of appetitive and aversive learning and the possible dependency of this modularity on two different biogenic amines subserving appetitive and aversive reinforcement. Indeed, although octopamine has been shown to substitute for appetitive reinforcement (Hammer and Menzel, 1998; see above), it was found that blocking of dopaminergic, but not octopaminergic, receptors suppresses aversive olfactory learning. Thus, octopamine and dopamine subserve appetitive and aversive reinforcement in the honeybee, respectively. Again, this finding emphasizes the conclusion that dedicated biogenic amines act as value systems in the invertebrate brain and that they fulfill different reinforcing roles in different forms of learning.

This finding brought the honeybee closer to other insect models such as the fruit fly *Drosophila melanogaster* and the cricket *Gryllus bimaculatus*. In crickets, pharmacological experiments showed that octopamine and dopamine subserve the appetitive and aversive reinforcing functions, respectively (Unoki et al., 2005). In fruit flies, the same result was previously found using mutants with inactivated dopaminergic or octopaminergic neurons (Schwaerzel et al., 2003). Recently,

Schroll et al. (2006) showed that octopamine and dopamine are necessary and sufficient to substitute for appetitive and aversive reinforcement in *Drosophila* larvae. Furthermore, neurons capable of mediating and predicting aversive reinforcement have been found in the *Drosophila* brain (Riemensperger et al., 2005; *See* Chapter 1.28). These neurons may be a general feature of the insect brain, and dopamine may underlie other forms of aversive learning involving stimuli of different sensory modalities (e.g., visual stimuli associated with aversive gustatory reinforcements; Unoki et al., 2006). Interestingly, dopaminergic neurons in the fly brain exhibit the same functional principle as the VUMmx1 neuron in the bee brain, namely, stimulus substitution. Here too, dopaminergic neurons did not respond to the odorant used for aversive conditioning before conditioning and acquired this property after conditioning (Riemensperger et al., 2005). Similarly to the VUMmx1 neuron, dopaminergic neurons in the fly brain provide, therefore, reinforcement prediction error information that is critical to associative learning.

The study of aversive learning in honeybees is just starting. As this form of conditioning uses odorants as CS, it is possible to ask how odorant representations are modified by aversive experiences compared with appetitive experiences. An important goal is to identify dopaminergic neurons in the bee brain whose morphology and functional properties make them candidates for integrating the aversive US pathway. Furthermore, characterizing aversive olfactory memory at both the cellular and molecular levels is crucial for a comparative analysis of appetitive and aversive learning and memory in bees, which can now be performed. The usefulness of the aversive learning protocol has been demonstrated by the finding that green mandibular pheromone, the pheromone that is responsible for social dominance and control exerted by the queen within the hive, inhibits selectively olfactory aversive learning in young bees (Yugoz et al., 2007b). In this way, young bees, which have to stay closer to the queen are prevented from forming any aversive experience that could result from such an important bond. This fascinating result could only be accessed thanks to the aversive learning protocol, as no significant effect of the pheromone was found in the case of the appetitive olfactory learning.

1.29.9 Nonelemental Learning in Bees

Elemental appetitive and aversive learning, as discussed above, rely on the establishment of elemental associative links connecting two specific and unambiguous events in the bee's world. What has been learned for a given color in terms of its outcome is valid for that color but not for a different one. The sucrose reward that follows a given behavior, such as contacting a given surface with the left antenna, is valid for that behavior but not for a different one such as contacting the same surface with the right antenna. However, in the forms of associative learning that we discuss here, unique links connecting specific events are not useful because the events under consideration are ambiguous in terms of their outcome. A typical case introduced above is negative patterning, in which the subject needs to learn to discriminate a nonreinforced compound from its components (A+, B+, AB−). This problem does not admit elemental solutions because the animal has to learn that AB is necessarily different from the linear sum of A and B. In biconditional discrimination, the subject has to learn to respond to the compounds AB and CD and not to the compounds AC and BD (AB+, CD+, AC−, BD−). As in negative patterning, each element, A, B, C, and D, appears as often reinforced as nonreinforced, so that it is impossible to rely on the associative strength of a given stimulus to solve the task. These examples show that more elaborated computational strategies are necessary in the case of nonelemental discrimination problems.

Treating compound stimuli as entities different from the simple sum of their components (e.g., $AB = X \neq A + B$) constitutes the basis of the configural learning theory proposed to account for the solving of these nonlinear discrimination problems (Pearce, 1994). For this account, animals trained with AB can respond to A or B only to a low extent. Another theory, the unique-cue theory, proposes that a mixture is processed as the lineal sum of its components plus a stimulus (u) that is unique to the joint presentation of the elements in the mixture (e.g., $AB = A + B + u$) (Whitlow and Wagner, 1972). The unique cue is what gives a unique signature to a compound, which differentiates it from the linear sum of its components. For this account, animals trained with AB can respond to A or B to a relatively high extent.

Probably because of their inherent complexity, these problems have been rarely studied in invertebrates. However, several recent studies have addressed the issue of elemental vs. nonelemental learning in honeybees, using visual conditioning of free-flying animals and olfactory PER conditioning (Giurfa, 2003). In both experimental protocols, bees were shown to solve a biconditional discrimination (AB+, CD+, AC−, BD−). In the visual modality, free-flying

bees had to discriminate complex patterns that were arranged to fulfill the principles of this discrimination problem (Schubert et al., 2005). In the olfactory modality, olfactory compounds were used (Hellstern et al., 1995; Chandra and Smith, 1998), and bees learned to respond appropriately to each compound, independent of the ambiguity inherent to the components. This capacity demonstrates that under certain circumstances both visual and olfactory compounds are learned as entities different from the simple sum of their components.

This conclusion is underlined by studies showing that bees can solve a negative patterning discrimination (A+, B+, AB−) both in the visual (Schubert et al., 2005) and the olfactory (Deisig et al., 2001, 2002, 2003) modality. Solving this problem is possible if the compound AB is treated as being different from the simple sum of its elements. In the case of olfactory compound learning, experiments were conceived to discern between the two nonelemental theories mentioned above, the configural and the unique-cue theory. It was shown (Deisig et al., 2003) that the bees' performance was consistent with the unique-cue theory (i.e., when bees perceive an olfactory compound they detect the presence of the components in it, but they also assign a unique identity to the compound, resulting from the interaction of its components).

Another study used an original protocol, side-specific olfactory PER conditioning, which posed a nonlinear discrimination problem (Sandoz and Menzel, 2001). In this case, a thin plastic wall separated the honeybee's antennae during olfactory stimulation (**Figure 4(a)**). Bees were differentially conditioned using two odors (A and B). When odorants were delivered to one antenna, the contingency was A+ vs. B−, but it was reversed (A− vs. B+) when they were delivered to other antenna. This discrimination resembles a form of contextual learning, as the context of each antennal side (left vs. right) determines the contingency of the stimuli. Bees learned to respond appropriately to the rewarded odor and to inhibit their reaction to the nonrewarded odor on each side (Sandoz and Menzel, 2001). They thus solved this side-specific, nonelemental discrimination and remembered the contingencies learned 24 h later (**Figure 4(b)**). In this case, insight into the neural bases of this type of nonelemental problem solving was obtained by combining this protocol with *in vivo* calcium imaging recordings of glomerular activity at the level of both antennal lobes (**Figure 4(c)**). It was found that in naïve bees, odor response patterns were highly symmetrical (i.e., before conditioning, the same odorant elicited the same activation pattern in both antennal lobes). In conditioned bees, topical differences between sides were found. After side-specific conditioning, the left and right representations of the same odorant became slightly different, thus allowing differentiation between sides (Sandoz et al., 2003). Thus, this form of nonelemental learning resulted in a decorrelation of the representations of the conditioning odors between sides (**Figure 4(d)**). This result emphasizes that bees may form odor/side associations of the type AS1+/AS2− and BS1−/BS2+ (S1: side 1, S2: side 2). It is thus conceivable that structures situated upstream of the antennal lobes (e.g., the mushroom bodies or the lateral horn) are crucial for decoding differences in neural representations, such as those generated in side-specific conditioning.

Komischke et al. (2003) showed that bilateral olfactory input is required for solving a negative patterning discrimination. Given that the olfactory circuit remains practically unconnected between hemispheres to the mushroom bodies, this result suggests that the reading of a unique cue, arising from odorant interaction within the mixture, occurs upstream of the antennal lobes (i.e., at the level of the mushroom bodies). Komischke et al. (2005) used mushroom body–ablated honeybees to determine whether intact mushroom bodies are necessary to solve nonelemental olfactory discriminations. Bees were treated with hydroxyurea, which partially or totally removes the calyces (the input region to the mushroom bodies) (Malun, 1998). In previous studies, Scheiner et al. (2001) and Malun et al. (2002) showed that such ablations do not affect elemental forms of learning. Scheiner et al. (2001) showed that tactile learning, a form of elemental learning in which bees learn to associate an object within the range of one antenna with sucrose solution and discriminate it from an object presented to the opposite side, was unaffected in ablated bees. Malun et al. (2002) studied olfactory learning and showed that the presence of ablations did not impair acquisition of an elemental olfactory discrimination in which one odor was rewarded and another odor was nonrewarded (A+ vs. B−).

In the experiments of Komischke et al. (2005), bees with unilateral lesions of the mushroom bodies (a median calyx was usually absent) were trained in different olfactory discrimination problems. When odorants were delivered in a side-specific manner, bees with mushroom body lesions could not solve an

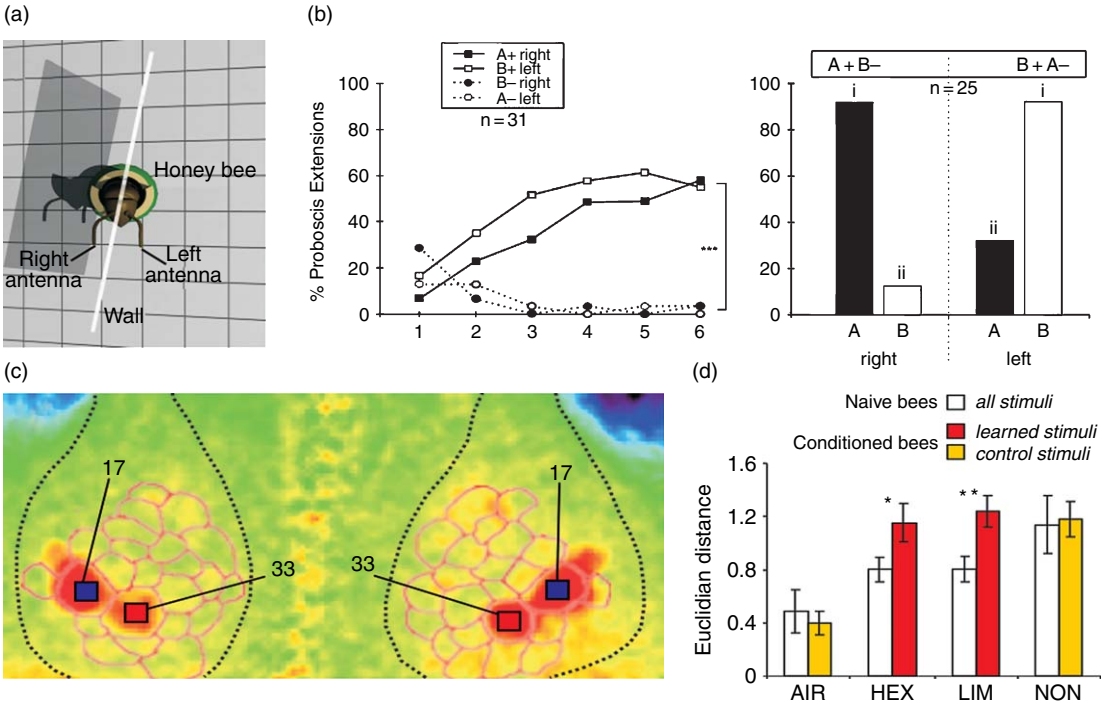

Figure 4 Side-specific olfactory conditioning of harnessed bees. (a) In this protocol, a harnessed bee is conditioned to discriminate two odorants A and B, which, depending on the presentation side (the antenna to which they are delivered), have different contingencies. To this end, the left and right antennae are separated by a thin wall glued along the bee body. Bees have to learn that when odorants are delivered to the right antenna, the contingency is A+ vs. B−, but it is A− vs. B+ if they are delivered to the left antenna. (b) Bees learn to solve this nonelemental double discrimination. The acquisition curves display the responses (% PER) to the rewarded odorants (A+ right and B+ left) and to the nonrewarded odorants (B− right and A− left). At the end of training, bees discriminate the rewarding from the nonrewarding stimuli. Twenty-four hours later, they still remember the appropriate contingencies on the appropriate side (histogram); n, number of bees trained or tested. (c) Simultaneous calcium imaging recording of both antennal lobes (delimited by the dashed lines). In this case, the response of naïve (nontrained) bees to Nonanol is shown. Glomeruli 17 and 33 are activated by this odor, and this activation is symmetric between sides. (d) The effect of side-specific conditioning on odor representation. The perceptual distance between the left and right representations of the same odorant was measured in a putative olfactory space, calculated for the honeybee. Odor representations differing perceptually are separated by a larger Euclidian distance in that space. For Hexanol and Limonene, the two odors used in the side-specific conditioning, the distance between left and right representations increased significantly as a consequence of training (red bars), thus showing that left and right representations of the same odorant became more different. For a control odorant, Nonanol, and for a clean-air control, the responses on the right and left antennal lobes were the same. Adapted from Sandoz JC and Menzel R (2001) Side-specificity of olfactory learning in the honeybee: Generalization between odors and sides. *Learn. Mem.* 8: 286–294 and Sandoz JC, Galizia CG, and Menzel R (2003) Side-specific olfactory conditioning leads to more specific odor representations between sides but not within sides in the honeybee antennal lobes. *Neuroscience* 120: 1137–1148; courtesy of J.C. Sandoz.

unambiguous double discrimination (Problem 1: A+ vs. B− on one antenna, C+ vs. D− on the other; A + B−/C + D−), even though each of the four odorants had an unambiguous outcome. When confronted with the ambiguous side-specific discrimination (Problem 2: A + vs. B− on one antenna, A− vs. B+ on the other; see above and **Figure 4**), bees were also impaired because they could only learn the discrimination proposed to their intact brain side. Nonablated bees could master both side-specific discriminations. When odorants were delivered simultaneously to both antennae (Problem 3: A + B−C + D−), ablated bees learned slower than normal bees.

Thus, in all three cases, the unilateral loss of a median calyx affected olfactory learning (Komischke et al., 2005). It was proposed that mushroom bodies are required for solving nonelemental discriminations but also elemental tasks whose complexity is enhanced by virtue of the number of stimuli involved (Problems 1 and 3: 4 stimuli). To solve an A + B−/A−B+ discrimination, information exchange between brain

hemispheres has to be inhibited such that A on the right side is not generalized to A on the left side, and vice versa. Mushroom body ablations could have an effect on this inhibition; in normal bees conditioning would result in inhibition of interhemispheric transfer. Ablations would restore the transfer from the intact side, thus creating confusion on the ablated side.

Cumulative experience seems to play a critical role for adopting elemental or nonelemental learning strategies (Giurfa et al., 2003). When free-flying bees are trained to fly into a Y-maze to collect sucrose solution on a rewarded visual target presented in one of the arms of the maze, the strategy underlying the choice of visual compounds changes along training. Bees were trained with color stimuli that were color disks violet (V), green (G), or yellow (Y), which were of equal salience for honeybees. Training followed an A+, BC+ design, followed by an AC vs. BC test. Training consisted of six (three A+ and three BC+), 20 (10 A+ and 10 BC+), or 40 (20 A+ and 20 BC+) acquisition trials, thus increasing the amount of experience on the same problem. Elemental models of compound processing predict that in the test (AC vs. BC), a preference for the nontrained stimulus AC should occur, whereas configural models predict a preference for the trained stimulus BC (Giurfa et al., 2003). After six training trials, bees favored an elemental strategy and preferred AC to BC during the tests. Increasing the number of training trials resulted in an increase of the choice of BC. Thus, short training favored processing the compound as the sum of its elements (elemental theory), whereas long training favored its processing as being different from the sum of its elements (configural theory). It was also observed that the change in stimulus processing was influenced by stimulus similarity. Color similarity favored configural processing with increasing experience (Giurfa et al., 2003), a result that was consistent with the results of honeybee olfactory compound conditioning (Deisig et al., 2002). Further factors favoring nonelemental compound processing and learning could be the spatial and temporal proximity of elements and the animals' previous experience.

There is, however, a limitation in these studies that has to be overcome in future research, namely that all compound stimuli used were of the same modality, either visual or olfactory. It would be important to verify that similar rules apply for intermodal compounds. This goal is particularly important in the context of searching for the neural substrates of nonelemental learning forms. If mushroom bodies, which are multimodal sensory integration structures, are indeed an important center for achieving nonlinear processing, affecting their normal function could have more dramatic consequences in the case of bimodal than unimodal compounds. In studying nonelemental learning with stimuli from different modalities, one should guarantee comparable salience between stimuli, because differences at this level may lead to overshadowing or blocking.

1.29.10 Positive Transfer of Learning in Honeybees

In this section, I focus on problem solving in which animals respond in an adaptive manner to novel stimuli that they have never encountered before and that do not predict a specific outcome *per se* based on the animals' past experience. Such a positive transfer of learning (Robertson, 2001) is therefore different from elemental forms of learning, which link known stimuli or actions to specific reinforcers. In the cases considered in this section, the response can attain levels in which it becomes independent of the physical nature of the stimuli presented so that it acts as a rule guiding the animal's behavior (like relational rules such as 'on top of' or 'larger than,' which can be applied irrespective of the similarity of the stimuli considered).

1.29.10.1 Categorization of Visual Stimuli

Positive transfer of learning is a distinctive characteristic of categorization performance. Categorization refers to the classification of perceptual input into defined functional groups (Harnard, 1987). It can be defined as the ability to group distinguishable objects or events on the basis of a common feature or set of features, and therefore to respond similarly to them (Troje et al., 1999; Delius et al., 2000; Zentall et al., 2002; *See* Chapter 1.08). Categorization deals, therefore, with the extraction of these defining features from objects of the subject's environment. A typical categorization experiment trains an animal to extract the basic attributes of a category and then tests it with novel stimuli that were never encountered before and that may or may not present the attributes of the category learned. If the animal chooses the novel stimuli based on these attributes, it classifies them as belonging to the category and therefore exhibits positive transfer of learning.

Using this basic design in which procedural modifications can be introduced, several studies have recently shown the ability of visual categorization in free-flying honeybees trained to discriminate different patterns and shapes. For instance, van Hateren et al. (1990) trained bees to discriminate two given gratings presented vertically and differently oriented (e.g., 45° vs. 135°) by rewarding one of these gratings with sucrose solution and not rewarding the other. Each bee was trained with a changing succession of pairs of different gratings, one of which was always rewarded, while the other was not. Despite the difference in pattern quality, all the rewarded patterns had the same edge orientation, and all the nonrewarded patterns also had a common orientation, perpendicular to the rewarded one. Under these circumstances, the bees had to extract and learn the orientation that was common to all rewarded patterns to solve the task. This was the only cue predicting reward delivery. In the tests, bees were presented with novel patterns, to which they had never been exposed, and that were all nonrewarded, but that exhibited the same stripe orientations as the rewarding and nonrewarding patterns employed during the training. In such transfer tests, bees chose the appropriate orientation despite the novelty of the structural details of the stimuli. Thus, bees could categorize visual stimuli on the basis of their global orientation.

They can also categorize visual patterns based on their bilateral symmetry. When trained with a succession of changing patterns to discriminate bilateral symmetry from asymmetry, bees learn to extract this information from very different figures and transfer it to novel symmetrical and asymmetrical patterns (Giurfa et al., 1996). Similar conclusions apply to other visual features such as radial symmetry, concentric pattern organization and pattern disruption (see Benard et al., 2006 for review), and even photographs belonging to a given class (e.g., radial flower, landscape, plant stem) (Zhang et al., 2004).

How could bees appropriately classify different photographs of radial flowers if these vary in color, size, dissection, and so on? An explanation is provided by Stach et al. (2004), who expanded the demonstration that bees can categorize visual stimuli based on their global orientation to show that different coexisting orientations can be considered at a time and integrated into a global stimulus representation that is the basis for the category (Stach et al., 2004). Thus, a radial flower would be, in fact, the conjunction of five or more radiating edges. Besides focusing on a single orientation, honeybees were shown to assemble different features to build a generic pattern representation, which could be used to respond appropriately to novel stimuli sharing this basic layout. Honeybees trained with a series of complex patterns sharing a common layout comprising four edge orientations remembered these orientations simultaneously in their appropriate positions and transferred their response to novel stimuli that preserved the trained layout (**Figure 5**). Honeybees also transferred their response to patterns with fewer correct orientations, depending on their match with the trained layout. These results show that honeybees extract regularities in their visual environment and establish correspondences among correlated features such that they generate a large set of object descriptions from a finite set of elements.

Thus, honeybees show positive transfer of learning from a trained to a novel set of stimuli, and their performance is consistent with the definition of categorization. Visual stimulus categorization is not, therefore, a prerogative of certain vertebrates. However, this result might not be surprising because it admits an elemental learning interpretation. To explain this interpretation, the possible neural mechanisms underlying categorization should be considered. If we admit that visual stimuli are categorized on the basis of specific features such as orientation, the neural implementation of category recognition could be relatively simple. The feature(s) allowing stimulus classification would activate specific neuronal detectors in the optic lobes, the visual areas of the bee brain. Examples of such feature detectors are the orientation detectors whose orientation and tuning have been already characterized by means of electrophysiological recordings in the honeybee optic lobes (Yang and Maddess, 1997). Thus, responding to different gratings with a common orientation of, say, 60° is simple because all these gratings will elicit the same neural activation in the same set of orientation detectors despite their different structural quality. In the case of category learning, the activation of an additional neural element is needed. This type of element would be a reinforcement neuron equivalent to VUMmx1 (Hammer, 1993; see above) but contacting the visual circuits at its relevant processing stages. Other VUM neurons whose function is still unknown are present in the bee brain (Schroter et al., 2006). It could be conceived that one of them (or more than one) acts as the neural basis of reinforcement in associative visual learning. Category learning could thus be reduced to the progressive reinforcement of an associative neural

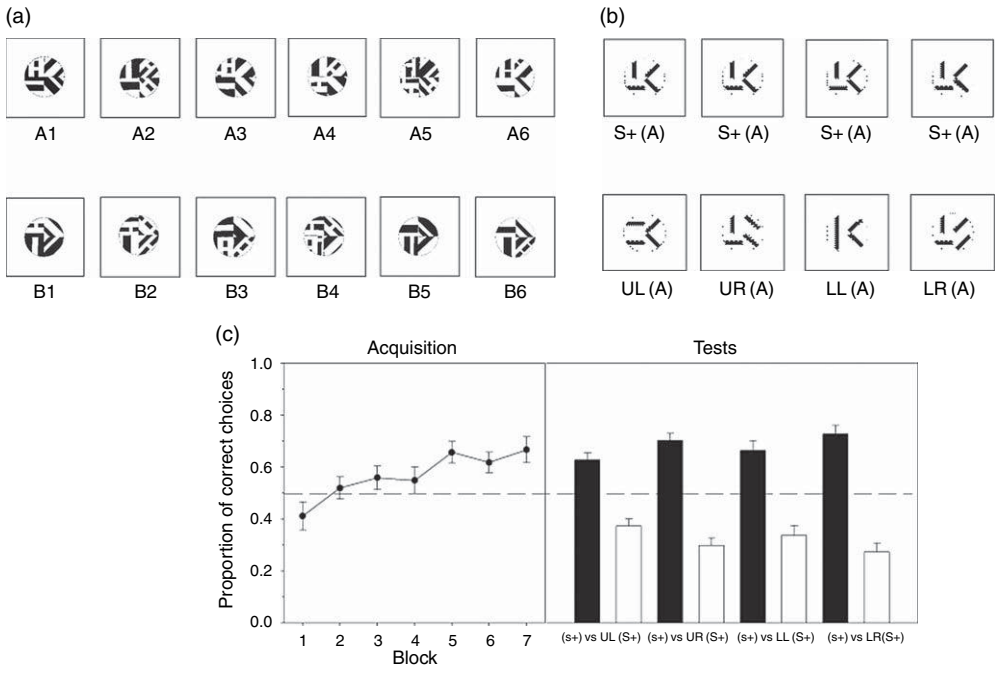

Figure 5 Categorization of visual patterns based on sets of multiple features. (a) Training stimuli used in Stach et al.'s experiments (2004). Bees were trained to discriminate A from B patterns during a random succession of A vs. B patterns. A patterns (A1–A6) differed from each other but shared a common layout defined by the spatial arrangement of orientations in the four quadrants. B patterns (B1–B6) shared a common layout perpendicular to that of A patterns. (b) Test stimuli used to determine whether or not bees extract the simplified layout of four bars from the rewarded A patterns. The four test pairs shown correspond to the honeybees trained with A patterns. Equivalent tests were performed with the honeybees trained with B patterns (not shown). S+, simplified layout of the rewarded A patterns; UL, upper-left bar rotated; UR, upper-right bar rotated; LL, lower-left bar rotated; LR, lower-right bar rotated. (c) Left panel: acquisition curve showing the pooled performance of bees rewarded on A and B patterns. The proportion of correct choices along seven blocks of six consecutive visits is shown. Bees learned to discriminate the rewarding patterns (A or B) used for the training and significantly improved their correct choices along training. Right panel: proportion of correct choices in the tests with the novel patterns. Bees always preferred the simplified layout of the training patterns previously rewarded (S+) to any variant in which one bar was rotated, thus showing that they were using the four bars in their appropriate spatial locations and orientations. Adapted from Stach S, Benard J, and Giurfa M (2004) Local-feature assembling in visual pattern recognition and generalization in honeybees. *Nature* 429: 758–761.

circuit relating visual-coding and reinforcement-coding neurons, similar to that underlying simple associative (e.g., Pavlovian) conditioning. From this perspective, even if categorization is viewed as a nonelemental learning form because it involves positive transfer of learning, it may simply rely on elemental links between CS and US.

1.29.10.2 Rule Learning

This argument is not applicable to rule learning in which positive transfer occurs independently of the physical nature of the stimuli considered. In this case, the animal learns relations between objects and not the objects themselves. Typical examples are the so-called rules of sameness and difference. These rules are demonstrated through the protocols of delayed matching to sample (DMTS) and delayed nonmatching to sample (DNMTS), respectively. In DMTS, animals are presented with a sample and then with a set of stimuli, one of which is identical to the sample and is reinforced. Since the sample is regularly changed, animals must learn the sameness rule, that is, always choose what is shown to you (the sample), independent of what else is shown to you. In DNMTS, the animal has to learn the opposite, that is, always choose the opposite of what is shown to you (the sample). Honeybees foraging in a Y-maze learn both rules (Giurfa et al., 2001). Bees were trained in a DMTS problem in which they were presented with a changing nonrewarded sample (i.e., one of two different color disks or one of two different black-and-white gratings,

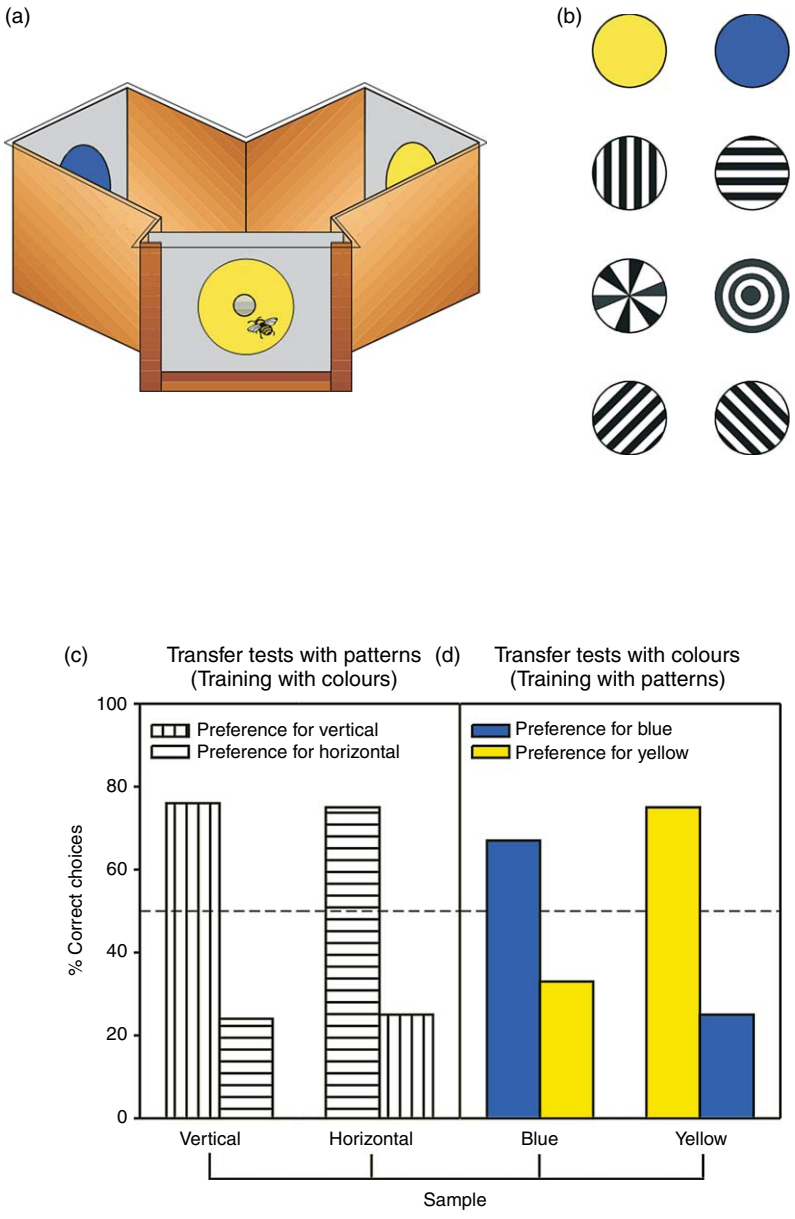

Figure 6 Rule learning in honeybees. Honeybees trained to collect sugar solution in a Y-maze (a) on a series of different patterns (b) learn a rule of sameness. Learning and transfer performance of bees in a delayed matching-to-sample task in which they were trained to colors (Experiment 1) or to black-and-white, vertical and horizontal gratings (Experiment 2). (c, d) Transfer tests with novel stimuli. (c) In Experiment 1, bees trained on the colors were tested on the gratings. (d) In Experiment 2, bees trained on the gratings were tested on the colors. In both cases, bees chose the novel stimuli corresponding to the sample, although they had no experience with such test stimuli. n denotes number of choices evaluated. Adapted from Giurfa M, Zhang S, Jenett A, Menzel R, and Srinivasan MV (2001) The concepts of 'sameness' and 'difference' in an insect. *Nature* 410: 930–933.

vertical or horizontal) at the entrance of a maze (Figure 6). The bees were rewarded only if they chose the stimulus identical to the sample once within the maze. Bees trained with colors and presented in transfer tests with black-and-white gratings that they had not experienced before solved the problem and chose the grating identical to the sample at the entrance of the maze. Similarly, bees trained with the gratings and tested with colors in transfer tests also solved the problem and chose the novel color corresponding to that of the sample grating at the maze entrance. Transfer was not limited to different kinds

of modalities (pattern vs. color) within the visual domain, but it could also operate between drastically different domains such as olfaction and vision (Giurfa et al., 2001). Furthermore, bees also mastered a DNMTS task, thus showing that they learn a rule of difference between stimuli (Giurfa et al., 2001). These results document that bees learn rules relating stimuli in their environment. The capacity of honeybees to solve a DMTS task has recently been verified and studied with respect to the working memory underlying it (Zhang et al., 2004, 2005). It was found that the working memory for the sample underlying the solving of DMTS lasts approximately 5 s (Zhang et al., 2005) and coincides with the duration of other visual and olfactory short-term memories characterized in simpler forms of associative learning in honeybees (Menzel, 1999; see above). Moreover, bees trained in a DMTS task can learn to pay attention to one of two different samples presented successively in a flight tunnel (either to the first or to the second) and can transfer the learning of this sequence weight to novel samples (Zhang et al., 2005).

Despite the honeybees' evident capacity to solve relational problems such as the DMTS or the DNMTS tasks, such capacities are not unlimited. In some cases, biological constraints may impede the solving of a particular problem for which rule extraction is necessary. It is therefore interesting to focus on a different example of rule learning that bees could not master, the transitive inference problem (Benard and Giurfa, 2004). In this problem, animals have to learn a transitive rule (i.e., A > B, B > C, then A > C). Preference for A over C in this context can be explained by two strategies: (1) deductive reasoning (Fersen et al., 1990), in which the experimental subjects construct and manipulate a unitary and linear representation of the implicit hierarchy A > B > C, or (2) responding as a function of reinforced and not reinforced experiences (Terrace and McGonigle, 1994), in which case animals choose among stimuli based on their associative strength (i.e., on the effective number of reinforced and nonreinforced experiences with the stimuli; A is always reinforced, and B is always nonreinforced).

To determine whether bees learn a transitive rule, they were trained using five different visual stimuli A, B, C, D, and E in a multiple discrimination task: A+ vs. B−, B+ vs. C−, C+ vs. D−, D+ vs. E− (Benard and Giurfa, 2004). Training involved overlapping of adjacent premise pairs (A > B, B > C, C > D, D > E), which underlie a linear hierarchy A > B > C > D > E. After training, bees were tested with B vs. D, a nonadjacent pair of stimuli that were never explicitly trained together. In theory, B and D have equivalent associative strengths because they are, in principle, equally associated with reinforcement or absence of it during training. Thus, if bees were guided by the stimulus's associative strength, they should choose randomly between B and D. If, however, bees used a transitive rule, they should prefer B to D. Honeybees learned the premise pairs as long as these were trained as uninterrupted, consecutive blocks of trials (Benard and Giurfa, 2004). But if shorter and interspersed blocks of trials were used, such that bees had to master all pairs practically simultaneously, performance collapsed, and bees did not learn the premise pairs. The bees' choice was significantly influenced by their experience with the last pair of stimuli (D+ vs. E−), such that they preferred D and avoided E. In the tests, no preference for B over D was found. Although this result agrees with an evaluation of stimuli in terms of their associative strength (see above), during training bees visited B more when it was rewarding than D, such that a preference for B should have been expected only if the associative strength were guiding the bees' choices. It was then concluded that bees do not establish transitive inferences between stimuli but, rather, guide their choices by the joint action of a recency effect (preference for the last rewarded stimulus, D) and by an evaluation of the associative strength of the stimuli (in which case preference for B should be evident). As the former supports choosing D while the latter supports choosing B, choosing B and D equally in the tests could be explained (Benard and Giurfa, 2004). At any rate, memory constraints (in this case, that simultaneous mastering of the different premise pairs was not possible and that the last excitatory memory seems to predominate over previous memories) impeded learning the transitive rule. Recently, Chen (2006) demonstrated that failure to master several consecutive visual discriminations is a result of the response competition occurring when animals are tested. This may explain why bees in the transitive inference protocol were unable to master the successive short blocks of training with different premise pairs.

1.29.11 Distributed Cognition in Honeybees

So far, we have concentrated on individual cognitive capabilities, but bees live in societies and therefore face problems that require coordination, task sharing, and collective decision making. From this perspective, it is

legitimate to ask whether collective behaviors reflect or even surpass individual plasticity, because of, for instance, the possible additive effect of individual cognitive capacities.

This question has been the subject of debate in the case of social insects in which colonies were considered superorganisms (Southwick, 1983; Seeley, 1989). It has been argued that the superorganism protects and constitutes itself from colony recognition systems based on cuticular hydrocarbons that are transferred between individuals within the colony, thus obscuring, in theory, individual identity. The metaphor of the superorganism may be in a sense misleading because an individually behaving organism is made from cells and structures that are tightly interconnected by complex neuronal, circulatory, and regulatory networks and has a central brain that commands and produces behavior. The superorganism, on the other hand, is made up of individuals that may be interconnected by complex chemical interactions but that are rather autonomous and can hardly be compared to constituent cells. The essential difference, however, is that although an insect colony produces collective behavior, it does not have a central brain to command and control such behavior. On the contrary, studies on collective decision making in social insects show that collective behavioral patterns can arise from simple interactions between individuals, without any central control and without memory (Theraulaz et al., 2003).

From this point of view, the sophisticated cognitive capacities that honeybees exhibit in individual tests are not required for the close coordination of the social group. Differences in individual thresholds for reacting to environmental sensory stimuli seem to be a critical factor for the emergence of collective behaviors based on task partitioning. This may account, for instance, for the collective behavior of nest choice by a honeybee swarm. Group decision making in honeybee swarms has been studied (see Seeley and Vischer, 2004) to determine the rules underlying collective choice. It was found that the essence of a swarm′s decision making relies on sensing a quorum (a sufficient number of scouts) at one of the nest sites rather than sensing a consensus (agreement of dancing scouts) at the swarm cluster. By this quorum-sensing hypothesis, a scout bee votes for a site by spending time at it. Somehow the scouts act and interact so that their numbers rise faster at superior sites, and somehow the bees at each site monitor their numbers there so that they know whether they have reached the threshold number (quorum) and can proceed to initiating the swarm′s move to this site. Exactly how scout bees sense a quorum remains an enigma (Seeley and Visscher, 2004). They may use visual, olfactory, or even tactile information to assess the number of fellow scouts at a site. But the complex migration pattern involving the coordinate displacement of thousands of bees does not require sophisticated mechanisms such as dance comparisons or verifying the reliability of information conveyed by a hive mate. In short, the bees appear to begin preparations for liftoff as soon as enough of the scout bees, but not all of them, have approved of one of the potential nest sites.

The interesting conclusion emerging from studies on social insect collective behavior is that individuals, who may be viewed as extremely sophisticated at the cognitive level when performing some individual tasks, appear to be automatons with limited cognitive capacities when performing collective tasks. This difference may seem puzzling and could be the result of cognitive richness being lost or at least temporally inhibited in a social context. However, a possible explanation is that in an individual and in a social context, the animal will adopt the behavioral strategies leading to adaptive solutions, either boosting or sacrificing what researchers would view as cognitive sophistication. Whenever simple behaviors can lead to adaptive solutions, they are adopted. When, on the contrary, cognitive abilities are required, they are used. The critical question in this context is therefore what determines the adoption of one or the other level of cognitive complexity? Which factors are responsible for the fact that an ant or a bee that can learn and memorize several cues while foraging, solve complex discriminations, and generate novel behaviors leading to adaptive solutions behaves like an automaton following a reduced set of repetitive patterns and simple rules in a social context? Which physiological changes, if any, determine the passage from one state to the other? Do social regulation pheromones intervene in the expression or inhibition of behavioral autonomy in a social context by acting on neurotransmitter levels in the insect nervous system? Do social pheromones determine changes in immediate early gene (IEG) expression in the brain affecting cognitive processing? So far, we have no answers to these questions, but they can be approached experimentally. Studying whether or not individual learning and memory are modified by exposure to social pheromones or by chemosensory cues within a group and whether or not biogenic amine and neurotransmitter levels and IEG expression are changed in the presence of a group of cospecifics are just some of the questions that need to be considered.

1.29.12 Conclusion

This chapter underlines the enormous richness of experience-dependent behavior in honeybees, its high flexibility, and the fact that it is possible to formalize and characterize in controlled laboratory protocols some forms of cognitive processing. Adopting rigorous definitions from elemental and nonelemental learning is useful to determine the extent to which honeybees can go beyond simple forms of associative learning. This type of experimental approach is possible, as illustrated by the numerous examples reviewed here, which have made it possible to appreciate the sophistication of cognitive processing in a honeybee, which, as most insects, was traditionally considered as being limited in terms of its cognitive capabilities.

Contrary to simple forms of associative learning for which specific neural circuits have been identified, more work is needed to relate complex problem solving to neural structures of the honeybee brain. The existing evidence points toward the mushroom bodies, a central structure in the insect brain that has been repeatedly associated with learning and memory capabilities (Menzel, 1999). It has been shown that some elemental discriminations can be achieved without the mushroom bodies (Malun et al., 2002), but this does not seem to be so obvious in the case of nonelemental discriminations. Although specific substrates or circuits for complex problem solving in the bee brain are still unknown, it is possible to be optimistic with respect to their future identification. In this case, what is delaying our understanding of cognitive brain processing is not the technical level but, rather, that up to now researchers have not dared to raise questions on complex cognitive processing in an insect.

What are the specific limitations of the bee brain when compared with larger brains, and what might the structural/functional basis be? To address this question, one would need to know more about its deficiencies, an area that has so far been investigated very little (but see Benard and Giurfa, 2004). Because of obvious limitation in space, we have not discussed the role of different forms of learning in natural contexts such as navigation and communication. These contexts also offer promising frameworks for the study of cognitive processing. Questions such as the nature of space representation and the flexibility of communication strategies are important to characterize the potential of the bee brain. They need to be related, when possible, to underlying neural circuits and structures, a task that has been impossible until now.

Studies on honeybee behavior allow researchers to be optimistic in view of these questions. Moreover, as learning in honeybees can be compared to that of vertebrates in many senses, the honeybee may serve as a model system for understanding intermediate levels of complexity of cognitive functions and their neural substrates.

1.30 Behavioral and Circuit Analysis of Learning and Memory in Mollusks

P. R. Benjamin and G. Kemenes, University of Sussex, East Sussex, UK

1.30.1 Introduction

The major advantage of using gastropod mollusks for investigating neural mechanisms underlying learning and memory is that behavioral studies can be linked to circuit analysis by taking advantage of the ability to identify individual neurons with known electrical properties and synaptic connectivity (Benjamin et al., 2005). Simple forms of associative learning such as classical and operant conditioning and nonassociative forms such as habituation and sensitization have been extensively investigated. The use of a wide variety of learning paradigms in a number of different gastropod species allows comparisons to be made of underlying neural mechanisms involved in memory formation in different types of learning (e.g., associative versus nonassociative, classical versus operant conditioning). Important progress has been made in understanding the mechanisms of synaptic plasticity in gastropod memory formation, but nonsynaptic (cellular) mechanisms such as changes in excitability also have been increasingly recognized as contributing to memory formation. These data on gastropod molluscs are of general importance in understanding the mechanisms of memory formation in the brain.

1.30.2 Model Circuits

A brief review of the four molluscan circuits most useful for learning and memory studies will be given next because the synaptic and cellular changes that underlie memory formation are located within these

circuits. Two general types of circuit will be described: defensive reflexes in *Aplysia* and *Hermissenda* and the more complex central pattern generator (CPG)-mediated feeding and respiratory circuits of *Lymnaea*.

1.30.2.1 *Aplysia* Gill-Siphon Defensive Withdrawal Reflex

A brief tactile stimulus applied to the siphon of *Aplysia* elicits gill and siphon withdrawal into the protective mantle cavity (**Figure 1(ai)**). The withdrawal responses in these two organs are mediated by identified sensory and motor neurons located in the abdominal ganglia (**Figure 1(aii)**), and because the strength of these responses is modified by experience, they have been extensively used to study the mechanisms underlying both associative and nonassociative forms of learning (Hawkins et al., 2006). Early studies of habituation focused on gill withdrawal plasticity, but the ease of identifying siphon responses in the live animal and the identification of a distinct set of siphon motor neurons (the LFS cells, **Figure 1(aii)**) has meant that the siphon circuit has been used mainly for more recent studies of sensitization and classical conditioning (Antonov et al., 2003). A variety of centrally located siphon sensory neurons and excitatory and inhibitory interneurons provide synaptic input to the LFS motor neurons but the direct LE mechanosensory to LFS monosynaptic pathway (**Figure 1(aii)**) has been the main focus of attention for learning studies, although sensorimotor synapses in the pleural and pedal ganglia also have been used. Monosynaptic excitatory connections from the LE to LFS motor neurons have been estimated to mediate about one-third of the siphon reflex response that corresponds to siphon flaring in the intact animal. The remainder of the response is mediated by peripheral motor neurons (Hawkins et al., 2006).

For habituation studies, sequences of weak touch stimuli are applied to the siphon, and the strength of the gill/siphon withdrawal reflex is measured either mechanically or by using a photocell to record displacement. Electrical shocks are applied to the tail or neck for sensitization of the siphon reflex, and repeated shocks (unconditioned stimulus, US) are paired with siphon touch (conditioned stimulus, CS) for behavioral studies of aversive classical conditioning. The detailed pathway by which the electrical stimuli influence the gill-siphon circuitry is not known for certain, although it may recruit the serotonergic cerebral CB1 neurons that have projections to the abdominal ganglion (Mackey et al., 1989).

1.30.2.2 *Hermissenda* Statocyst-Mediated Behaviors

High-speed rotation or orbital shaking elicits two types of behavioral response in *Hermissenda:* foot shortening (**Figure 1(bi)**) and inhibition of the normally positive phototactic response, indicated by a reduced forward locomotion toward light (Crow, 2004). The type of stimuli used to elicit this response in the laboratory mimics the natural response to mechanical turbulence caused by wave action that results in the animal clinging to the substrate for protection. The sensory response is mediated by a pair of gravity detector organs called the statocysts that have hair cell receptors analogous in function to the vestibular hair cells of vertebrates. In *Hermissenda*, depolarization of the hair cells by rotation generates responses in interneurons in the central ganglia that excite foot motor neurons responsible for foot shortening and inhibit ciliary motor neurons to inhibit forward locomotion (**Figure 1(bii)**). The interneurons involved in the two behavioral responses are different, giving independent pathways for the control of the two unconditioned responses.

Rotation of the body is used as the aversive US in behavioral associative conditioning studies, and a light flash is used as the CS. Repeated pairing of these two stimuli over several days leads to a reduction of the phototactic response to the CS and foot shortening similar to the previously described response to the US. Photoreceptors in the eye respond to the light CS, and these cells have a variety of excitatory and inhibitory synaptic connections with sensory receptors and interneurons of the US statocyst pathway. However, these synaptic connections are ineffective in eliciting unconditioned responses in naive animals (Crow, 2004).

1.30.2.3 *Lymnaea* Feeding

Feeding in *Lymnaea* consists of a sequence of repetitive movements called rasps. During each rasp, the mouth opens (**Figure 1(ci)**), and a toothed radula is scraped forward over the food substrate (protraction phase). Food is then lifted into the mouth (retraction phase), which closes while the food is being swallowed (swallow phase), and the sequence is repeated. Rhythmic

movements of the feeding muscles are driven by a network of motor neurons (B1 to B10) that, in turn, are driven by synaptic inputs from a feeding CPG network of interneurons (**Figure 1(cii)**). Each phase of the feeding rhythm is generated by one of three main types of CPG interneurons, N1 (protraction), N2 (retraction), N3 (swallow), providing sequences of excitatory and inhibitory synaptic inputs to motor neurons active in different phases of the feeding rhythm (Benjamin and Elliott, 1989). CPG-driven rhythmic electrical activity can be recorded in the feeding network even in the absence of feeding muscles, and this is called fictive feeding. Activity in the motor neurons and CPG neurons is modulated by identified higher-order interneurons (**Figure 1(cii)**), such as the cerebral giant cells (CGCs) and cerebral ventral 1 cells (CV1s). These higher-order neurons have been the major focus of learning and memory studies (Benjamin et al., 2000). The CGCs act as gating neurons in the feeding circuit. Increased CGC spiking activity during feeding facilitates feeding responses to food. The CV1 cells are members of a larger population of neurons called the cerebrobuccal interneurons (CBIs) (**Figure 1(cii)**) that are commandlike neurons involved in the activation of feeding.

Sucrose is an effective chemical stimulus for feeding and is therefore used as the US for reward conditioning. At the cellular level, sucrose applied to the lips in semi-intact preparations induces fictive feeding in motor neurons and interneurons of the feeding network. The CPG neurons are activated in the sucrose-driven fictive feeding rhythm, along with the modulatory CGC and CV1 cells.

The CS used for reward conditioning in *Lymnaea* is either a chemical (amyl acetate) or a tactile stimulus (a gentle brushstroke applied to the lips). The chemical CS was previously thought to have no effect on feeding ('neutral stimulus'), either at the behavioral or electrophysiological levels, but has recently been shown to have stimulatory or inhibitory effects in naive animals, depending on concentration (Straub et al., 2006). Touch to the lips, monitored either at the behavioral or the electrophysiological level, cannot initiate or maintain feeding, but nevertheless touch produced a complex sequence of inhibitory and excitatory synaptic inputs on all neurons of the feeding network (Staras et al., 1999b).

1.30.2.4 *Lymnaea* Respiration

The aquatic pulmonate snail *Lymnaea* can breathe either through the skin or through a simple lung. As their name implies, *Lymnaea stagnalis* populations often live in stagnant water, and when the environment becomes hypoxic, the snails float to the surface and perform rhythmic opening and closing movements of their pulmonary opening, the pneumostome (**Figure 1(di)**). This aerial respiration behavior is controlled by a respiratory CPG, the three main components of which are the right pedal dorsal 1 (RPeD1), input 3 (IP3), and visceral dorsal 4 (VD4) interneurons (**Figure 1(dii)**). These components provide synaptic inputs to identified motor neurons (I and J, opener, and K, closer) innervating pneumostome opener and closer muscles (**Figure 1(dii)**). The chemosensory stimulus (hypoxia) that triggers pneumostome opening first activates sensory cells in the pneumostome–osphradial area, which in turn provides excitatory afferent inputs to RPeD1. Through its synaptic connections with the other members of the CPG network, activation of RPeD1 initiates CPG activity, which underlies the respiratory rhythm. Tactile stimulation of the pneumostome area evokes pneumostome closure and stops aerial respiratory behavior. This type of tactile stimulation is used as the positive punishment in behavioral operant conditioning studies (Lukowiak et al., 2003).

1.30.3 Nonassociative Learning: Habituation and Sensitization in the Gill-Siphon Withdrawal Reflex

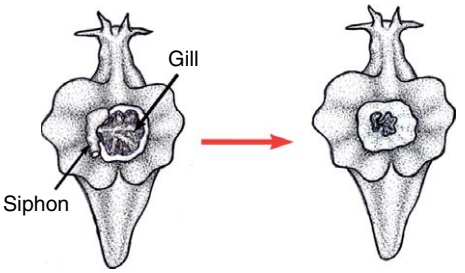
The gill-siphon withdrawal reflex of *Aplysia* shows both habituation and sensitization (Kandel, 1976). When a weak touch (usually by a calibrated water jet) is applied repeatedly to the siphon or adjacent mantle skin at intervals of between 30 s and 3 min, the gill withdrawal response habituates (decrements) to about 30% of control values after 10–15 trials. This short-term habituation lasts for several hours, but if these trials (10 per day) are repeated over 4 days then a long-term habituation of the gill withdrawal response is induced that lasts for up to 3 weeks. If, prior to touch, a single strong noxious stimulus, such as an electric shock, is applied to the tail or neck, the subsequent touch-evoked response is enhanced or sensitized for a few hours. Long-term sensitization can be induced by the application of multiple shocks. Applying four shocks a day to the head for 4 days significantly increased the duration of withdrawal so that it was greater than in controls up to 1 week after training. Both of

these nonassociative phenomena are central processes that involve changes in synaptic strength at the sensory level to motor synapses that mediate the normal gill-siphon withdrawal reflex.

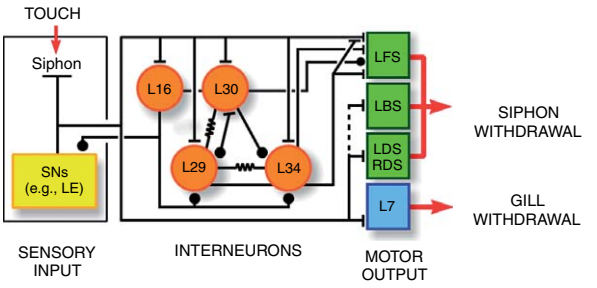
1.30.3.1 Habituation

Behavioral habituation was found to be paralleled by suppression of neurotransmitter release from the presynaptic terminals of the touch-sensitive

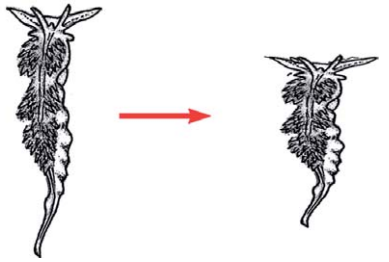
(ai) *Aplysia* defensive reflexes



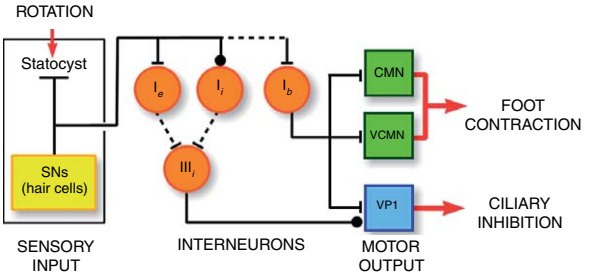
(aii) *Aplysia* siphon and gill withdrawal networks



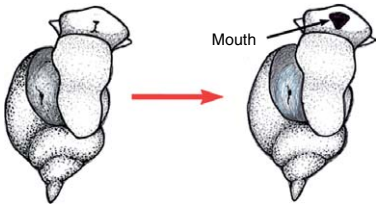
(bi) *Hermissenda* defensive reflexes



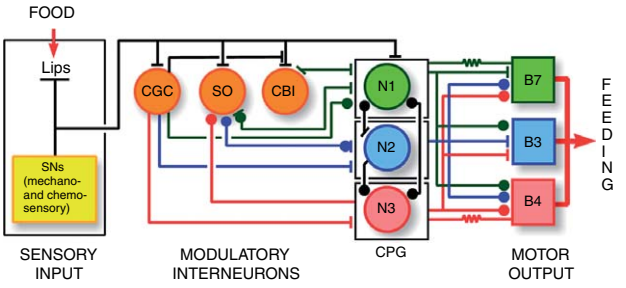
(bii) *Hermissenda* foot contraction and ciliary inhibition networks



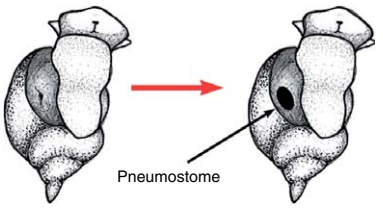
(ci) *Lymnaea* feeding behavior



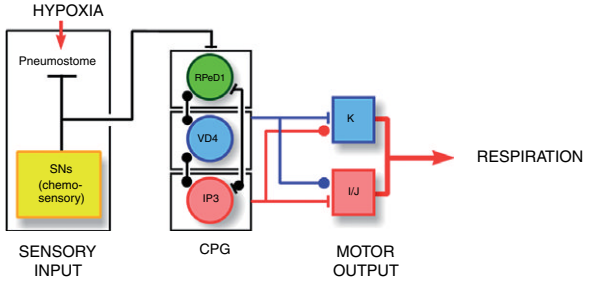
(cii) *Lymnaea* feeding network



(di) *Lymnaea* aerial respiration



(dii) *Lymnaea* respiratory network



mechanosensory neurons resulting in homosynaptic depression (HSD). A consequent reduction in the size of the motor neuron excitatory postsynaptic potential (EPSP) is followed by a reduction in the activation of the motor neurons, which consequently fires less. Both calcium-dependent and -independent mechanisms have been suggested to underlie HSD, the cellular mechanism of habituation.

There appears to be a consensus that short-term habituation (STH) involved purely presynaptic mechanisms (Armitage and Siegelbaum, 1998; Ezzeddine and Glanzman, 2003), but recent work by Ezzeddine and Glanzman (2003) suggests that long-term habituation (LTH) may involve postsynaptic mechanisms as well. In a behavioral preparation, these authors showed that induction of LTH depended on the activation of specific types of glutamate receptors presumed to be located on the postsynaptic motor neurons. LTH was blocked either in the presence of the *N*-methyl-D-aspartate (NMDA) antagonist 2-amino-5-phosphonopentanoic acid (APV) or the alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) antagonist 6,7-dinitroquinoxaline-2,3-dione (DNQX) (Ezzeddine and Glanzman, 2003). DNQX had no effects on STH, as shown in earlier experiments (Armitage and Siegelbaum, 1998).

1.30.3.2 Sensitization

Sensitizing stimuli have the opposite effect of habituation, causing an increase in transmitter release (reviewed in Carew and Sahley, 1986). Sensitizing stimuli cause the release of the transmitter serotonin (5-hydroxytryptamine, 5-HT) from facilitatory interneurons onto the sensory neuron terminals of the mechanosensory neurons, and this transmitter acts presynaptically to facilitate synaptic transmission at the sensorimotor junction. This causes the motor neurons to fire more after sensitization, thereby increasing the strength of the withdrawal reflex. This type of heterosynaptic facilitation can be mimicked in reduced preparations and in a simplified cell culture system if tail shock is replaced by brief applications of 5-HT to the sensory neurons. The mechanisms underlying presynaptic facilitation involve two types of synaptic mechanisms that result in an increase in transmitter release (reviewed in Hawkins et al., 2006). The first synaptic mechanism involves an increase in the duration of the spike in the sensory neuron. A second synaptic mechanism is independent of spike broadening and is thought to involve vesicle mobilization. A nonsynaptic mechanism increases the excitability of the sensory neurons, making it more likely that the

Figure 1 Molluscan behaviors and underlying neural circuitries most widely used in studies of the cellular mechanisms of learning and memory. (ai) Touch-evoked withdrawal reflex of the gill and siphon in *Aplysia californica* (drawing by Dr. I. Kemenes). (aii) Sensory neurons (SNs, yellow square) activated by touch to the siphon provide direct excitatory synaptic inputs to motor neurons innervating the gill and siphon (green and blue squares, respectively). In addition, there are indirect excitatory and inhibitory connections from the sensory to the motor neurons, which are mediated by a set of interneurons (orange circles) interconnected by both chemical and electrical synapses. Touch can normally only evoke a weak contraction of the siphon and gill, but the reflex becomes stronger after sensitization and classical conditioning (see **Figure 2**). (bi) Foot contraction and ciliary inhibition evoked by rotation in *Hermissenda crassicornis* (drawing by Dr. I. Kemenes). (bii) Sensory cells activated by rotation provide polysynaptic excitatory and inhibitory inputs to motor neurons responsible for foot contraction (green squares) and ciliary inhibition (blue square). Dashed lines represent polysynaptic connections with potential interneurons not yet identified. When a visual input is repeatedly paired with rotation, it will become effective in evoking both foot contraction and ciliary inhibition (see **Figure 3**). (ci) Feeding behavior in *Lymnaea stagnalis* (drawing by Dr. I. Kemenes). (cii) Chemosensory neurons located in the lip structures detect the presence of food or chemostimulants, such as sucrose. Excitatory inputs from the sensory pathways are distributed in parallel to modulatory interneurons (orange circles) and also to central pattern generators (CPG) neurons (green, blue, and pink circles). The cerebral giant cells (CGCs) may presynaptically modulate certain types of chemosensory inputs to the cerebrobuccal interneurons (CBIs) (see **Figure 4**). The complex synaptic connectivity between the modulatory and N1 interneurons leads to activation of the whole CPG, with the protraction (N1), rasp (N2), and swallow (N3) phases of the feeding cycle following in sequence due to the synaptic connectivity within the CPG and their intrinsic properties. Several subtypes of each of the N cells have been characterized, but because of the complexity of their synaptic connections with modulatory interneurons and motor neurons, only a generalized representative of each N-type is shown. The rhythmic pattern generated by the CPG drives protraction, rasp, and swallow phase motor neurons, such as B7 (green squares), B3 (blue squares), and B4 (pink squares), leading to sequences of muscular activity and feeding movements executed by the mouth (shown in drawing), the radula, and the buccal mass. Reward classical conditioning leads to an enhanced activation of the feeding network by tactile or chemically (see **Figure 4**) conditioned stimuli. (di) Hypoxia-evoked opening of the pneumostome in *Lymnaea stagnalis* (drawing by Dr. I. Kemenes). (dii) The motor neurons are excited or inhibited by a three-neuron CPG network activated by chemosensory inputs. Operant conditioning leads to the suppression of pneumostome opening and aerial respiration (see text). Dots indicate inhibitory chemical synapses, bars excitatory chemical synaptic connections, and resistor symbols electrotonic (electrical) synapses.

sensory neurons will respond to siphon touch after sensitization. These types of presynaptic mechanisms are produced by single brief applications of 5-HT (1 min) or single shocks to the tail, and they are believed to underlie behavioral short-term sensitization or short-term facilitation (STF) of synaptic transmission seen in reduced preparations and in cell culture.

Long term-facilitation (LTF) of synaptic responses in culture is induced by repeated and spaced application of 5-HT and lasts for as long as the cells survive in culture. Its behavioral equivalent, long-term sensitization, lasting for days or weeks, requires repetitive sensitizing stimuli lasting for 1 to 1.5 h. Recently, an intermediate-term memory (ITM) for sensitization and correlated intermediate-term synaptic facilitation (ITF) have been identified, lasting for up to 85 minutes (Ghirardi et al., 1995; Sutton and Carew, 2000).

There is a consensus that short-term sensitization and STF are due to purely presynaptic mechanisms (Glanzman, 2006; Hawkins et al., 2006) and until recently this was also thought to be the case for other forms of sensitization, such as ITM. However, important work by the Glanzman laboratory in culture and in reduced preparations (e.g., Lin and Glanzman, 1994; Li et al., 2005) and now confirmed by simultaneous behavioral and electrophysiological investigations by Antonov et al. in a more intact preparation (reviewed in Hawkins et al., 2006) have clearly shown that postsynaptic mechanisms are also involved in ITF.

A 10-minute application of serotonin in culture induced synaptic ITF, after a delay of about 5 minutes, and facilitated synaptic transmission for at least 50 minutes without decrement (reviewed in Glanzman, 2006). This ITF induced by serotonin application was found to depend on the activation of AMPA-like glutamate receptors in the motor neurons because it was blocked by DNQX. Prior injection of exocytotic inhibitors into the motor neurons blocked this facilitation, suggesting that 5-HT might stimulate the insertion of AMPA receptors into the motor neuron membrane. This trafficking of AMPA receptors is known to involve calcium/calmodulin-dependent protein kinase II (CaMKII) in vertebrate systems, so it is interesting that injecting inhibitors of this kinase into *Aplysia* motor neurons reduced synaptic ITF (see Hawkins et al., 2006). ITF also depends on the elevation of calcium levels in the motor neurons. Injection of BAPTA (1,2-bis(o-aminophenoxy)ethane-N,N,N′,N′-tetraacetic acid), a rapid chelator of intracellular calcium, blocked the delayed facilitation of the sensorimotor synapse *in vitro* (Li et al., 2005), induced by a 10-min application of 5-HT. 5-HT causes a release of intracellular calcium, mediated by both IP3 and ryanodine receptors (Li et al., 2005). ITF produced by 10-min applications of 5-HT also involves presynaptic mechanisms because injection of protein kinase C (PKC) inhibitors into the sensory neurons in culture also reduces the facilitatory effects of 5-HT on synaptic transmission (Hawkins et al., 2006).

In summary, ITF of sensorimotor synapses, a mechanism thought to underlie behavioral sensitization, involves both presynaptic (PKC-dependent) and postsynaptic (calcium- and CaMKII-dependent) mechanisms with CaMKII suggested to be linked to insertion of AMPA receptors in the postsynaptic membrane. Short-term sensitization involves only presynaptic mechanisms, mainly involving a cyclic adenosine monophosphate (cAMP)-dependent protein kinase A (PKA) pathway.

Long-term sensitization has also been investigated for changes in postsynaptic mechanisms. In a pioneering study, Cleary et al. (1998) showed that the biophysical properties of tail motor neurons were changed after behavioral long-term sensitization, resulting in hyperpolarization of the resting membrane potential and a decrease in spike threshold. This suggests that these postsynaptic neurons are a locus for memory and provides evidence for the importance of postsynaptic mechanisms in both long-term and intermediate-term sensitization (*See* Chapters 4.03 and 4.38 for additional details on the molecular mechanisms of short-, intermediate-, and long-term sensitization).

1.30.4 Associative Learning

1.30.4.1 Aversive Classical Conditioning of the *Aplysia* Gill-Siphon Withdrawal Reflex

Carew and colleagues (see Carew and Sahley, 1986) showed that the gill and siphon withdrawal reflex is subject to aversive classical conditioning as well as habituation and sensitization. In their associative conditioning paradigm, they paired a weak tactile stimulus (the CS) to the siphon with a strong electric shock to the tail (the US). After 15 trials, the CS came to elicit a stronger gill withdrawal than controls; the effect lasted for several days. Later they showed that differential classical conditioning also worked. A weak tactile stimulus applied to the siphon or mantle shelf was either paired with shock (CS+) or not paired (CS–) in the

same animal. Differences between the effects on gill withdrawal at the two sites were enhanced, even after a single trial. Cellular analysis of differential conditioning, using a reduced preparation, showed that the mechanism underlying classical conditioning of the gill withdrawal response was the elaboration of presynaptic facilitation that was previously shown to underlie sensitization, except that the effect of the pairing of CS and US produced an even greater facilitation of the withdrawal response. This effect was called activity-dependent presynaptic facilitation (ADPF) (Hawkins et al., 1983). Evidence for this mechanism was obtained in a reduced preparation where the effects of touch were mimicked by stimulation of two different sensory neurons that made excitatory synaptic connections with siphonal motor neurons. Differential conditioning produced a significantly greater enhancement of the sensorimotor synapse if weak sensory neuron spike activation (by current injection) was followed by the tail shock (CS+) than if the sensory neuron stimulation was unpaired (CS–) or if shock occurred alone (sensitization). This result supported the notion of ADPF because of its dependence on temporal pairing. Like sensitization, this mechanism was shown to be presynaptic and could also be mimicked by the application of serotonin. With a larger number of pairings, a longer-term form of synaptic plasticity is induced underpinned by changes in gene regulation and synaptic remodeling (*See* Chapter 4.10).

As was the case with sensitization, the early model for aversive classical conditioning was entirely presynaptic, but the discovery that sensorimotor synapses in culture or in reduced preparations exhibit NMDA-dependent long-term potentiation (LTP) (Glanzman, 1995; Roberts and Glanzman, 2003) led to the now generally accepted hypothesis that associative learning involves postsynaptic processes utilizing Hebbian-type LTP as well as presynaptic ADPF (**Figure 2(a)**). Use of the more intact preparation by Antonov et al. (2003) allowed classical conditioning of the behavioral siphonal withdrawal reflex to be correlated with synaptic plasticity. Pairing siphonal touch with tail shock induced a parallel associative enhancement of siphonal withdrawal and synaptic strength. Application of the NMDA receptor blocker APV to the ganglion or injection of the calcium chelator BAPTA into the siphonal motor neurons blocked conditioning, providing direct evidence that Hebbian LTP is part of the mechanism for behavioral classical conditioning. To compare the role of pre- and postsynaptic mechanisms in synaptic plasticity, Antonov et al. (2003) injected the peptide inhibitor of PKA (PKAi) into LE sensory neurons and BAPTA into LFS siphonal motor neurons. Both procedures reduced the pairing specific facilitation of

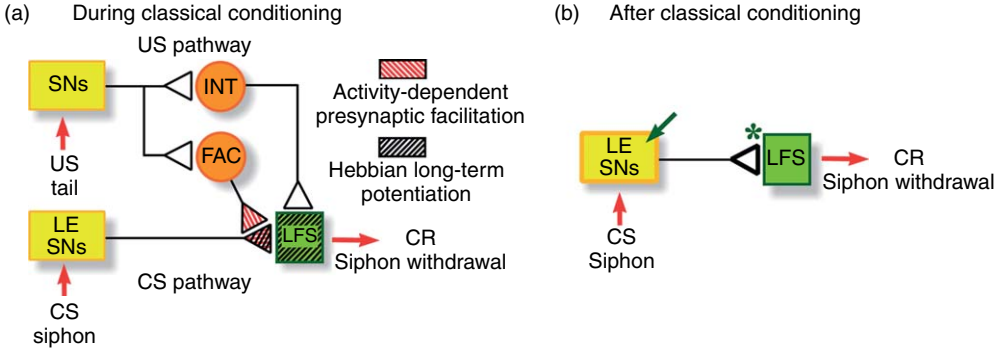


Figure 2 Aversive classical conditioning of the siphon withdrawal reflex in *Aplysia.* (a) During aversive classical conditioning, the conditioned stimulus (CS, touch to the siphon) weakly activates LE sensory neurons (SNs), which make monosynaptic connections onto LFS motor neurons. The unconditioned stimulus (US, electric shock to the tail) strongly activates tail sensory neurons. These sensory neurons excite both facilitatory interneurons (FAC) that produce presynaptic facilitation at the LE-to-LFS synapse and other types of interneurons (INT) that postsynaptically excite the LFS motor neurons. Thus, both the sensory neurons and the motor neurons are sites of CS and US pathway convergence and can act as coincidence detectors. The shading indicates neuronal elements that must be activated conjointly for the induction of either activity-dependent presynaptic facilitation (red) or Hebbian LTP (black) at the LE-LFS synapses (from Antonov I, Antonova I, Kandel ER, and Hawkins RD (2003) Activity-dependent presynaptic facilitation and hebbian LTP are both required and interact during classical conditioning in *Aplysia*. *Neuron* 37: 135–147; used with permission from Elsevier). (b) After aversive classical conditioning the synaptic connections of the LE sensory neurons with the LFS motor neurons are strengthened (synaptic plasticity, green asterisk and bold outline) and the excitability of the LE sensory neurons is increased (cellular plasticity, green arrow and bold outline). These changes lead to an increased siphon withdrawal response to the touch CS.

postsynaptic potentials (PSPs) in the motor neurons during conditioning. Thus pre- and postsynaptic mechanisms appear to be contributing (**Figure 2(a)**) to the plastic changes in synaptic strength between the sensory neurons and the motor neurons (**Figure 2(b)**). There also appears to be a retrograde signal involved, as well as orthograde, because injecting BAPTA into the motor neurons blocks the changes in the cellular membrane properties of the sensory neurons (increase in membrane resistance), so some of the changes occurring in the two sides of synapse following conditioning are coordinated. The nature of the retrograde signal is unknown, but it could be the diffusible gas nitric oxide (NO), as injecting the NO scavenger myoglobin into the sensory neuron blocks the facilitation of the PSP during conditioning (Hawkins et al., 2006). Whether both presynaptic and postsynaptic mechanisms are active together at all phases of synaptic facilitation is still an open question. On the basis of experiments where 5-HT is used to mimic classical conditioning, Roberts and Glanzman (2003) have speculated that the rapid-onset ADPF mechanism is responsible for short-term synaptic facilitation. Hebbian LTP has a longer onset and leads to more persistent synaptic plasticity for medium-term and perhaps long-term synaptic facilitation.

1.30.4.2 Aversive Classical Conditioning of *Hermissenda* Phototactic Behavior

Behavioral training in *Hermissenda* involves the pairing of the CS, a light flash, with the US, a mechanical perturbance such as rotation. This induces a short-term memory that can last for a few minutes (e.g., single trial) or long-term memory lasting for days and weeks, depending on the number of trials (e.g., 150 trials per day over 3 days gives a week-long memory). Neural correlates can be studied in semi-isolated central nervous system (CNS) preparations made from behaviorally trained animals, or single-trial *in vitro* conditioning can be induced by pairing a light flash with CNS application of 5-HT, a key transmitter in the US pathway. Conditioning in the *Hermissenda* system involves the development of two different behavioral responses to the CS, foot contraction and inhibition of ciliary locomotion (Crow, 2004). Both these conditioned responses are thought to develop independently due to the involvement of different components of the central circuit involved in the two behaviors (see earlier discussion). Functionally, there is a learning-induced 'transfer' of the ability to activate these circuits from the US to the CS. We will focus on the part of the circuit that underlies the conditioned inhibition of ciliary motor neurons, responsible for the cessation of forward locomotion in the intact animal, because most is known about how conditioning changes this circuit. After conditioning, the CS is able to activate the same interneuronal pathway that normally mediates the inhibition of ciliary motor neurons by the mechanical US in naive animals. Earlier, it was proposed that changes in the cellular properties of photoreceptor cells and the strength of synaptic connections between the two classes of photoreceptors' synaptic connections solely could account for the changes underlying behavioral conditioning (Goh and Alkon, 1984), but more recent identification of elements of the interneuronal circuit that forms an intermediate level of processing between sensory and ciliary motor neurons (Crow and Tian, 2002) has identified further sites of synaptic and nonsynaptic plasticity that are also involved in the conditioned response so that a more complex multisite model for associative conditioning in *Hermissenda* has emerged (Crow, 2004; Crow and Tian, 2006).

The electrical changes following conditioning are thought to be due to interactions between convergent CS (photic) and US (mechanical) synaptically mediated pathways that exist at various levels in the ciliary control network (**Figure 3(a)**). There are two types of synaptic connections between the CS and US pathways at the level of the sensory receptors. Reciprocal inhibitory monosynaptic connections occur between the statocyst hair cells and the B-type photoreceptors in the eye, and another unidirectional excitatory polysynaptic pathway, mediated by 5-HT, exists between the hair cells and the photoreceptors (**Figure 3(a)**). The presence of this US excitatory pathway mediated by 5-HT is of particular significance because this chemical is thought to underlie the ability of the US to induce changes in the CS photoreceptor pathway following conditioning. Conditioning induces cellular changes in both the type A and type B photoreceptors, which increase the firing of the cells in response to the CS. The CS evokes a larger receptor potential and an enhanced excitability in the B cells as tested by the response to a standard applied depolarizing pulse. An increase in membrane resistance contributes to this increase in spike activity, and a decrease in spike accommodation is also important in producing a sustained response to receptor depolarization in response to the CS. Conditioning reduces the peak amplitude of several types of potassium conductances in the B-type photoreceptors, including calcium-dependent and voltage-dependent types.

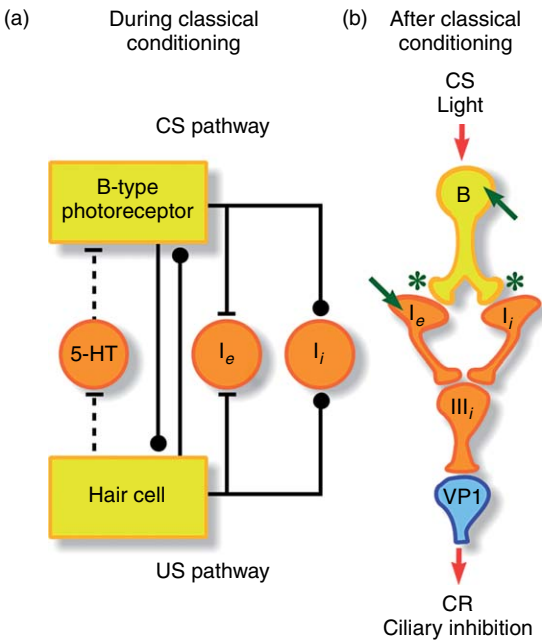

Figure 3 Aversive classical conditioning of the phototactic response in *Hermissenda*. (a) Sites of convergence between identified components of the CS and US pathways. Statocyst hair cells project have indirect excitatory synaptic connections with B-type photoreceptors through a proposed 5-HT-mediated interneuronal pathway. Hair cells and photoreceptors also have reciprocal inhibitory monosynaptic connections. Both hair cells and B-type photoreceptors form monosynaptic connections with both type I_e and type I_i interneurons (see also **Figure 1(b)**), which are therefore further sites of synaptic interactions between the CS and the US pathway (from Crow, 2004). Dots indicate inhibitory chemical synaptic connections and bar excitatory synaptic connections. (b) Components of the CS pathway involved in ciliary inhibition after classical conditioning. Changes in both cellular excitability (bold outlines, green arrow) and synaptic efficacy (bold outline, green asterisk) contribute to CS-elicited inhibition of ciliary locomotion. The net effect of cellular and synaptic plasticity is to increase the spike activity of type III_i inhibitory interneurons (see **Figure 1(b)**), during which light produces an inhibition of VP1 ciliary activating motor neurons (see **Figure 1(b)**) in conditioned animals. From Crow T (2004) Pavlovian conditioning of *Hermissenda*: Current cellular, molecular, and circuit perspectives. *Learn. Mem.* 11: 229–238; used with permission from Cold Spring Harbor Laboratory Press.

Importantly, these conductance changes can be mimicked by the application of 5-HT, providing evidence that the increased release of this transmitter via the hair cell polysynaptic pathway might be responsible for the changes in the intrinsic properties of the photoreceptors following conditioning. The molecular mechanisms underlying the effects of 5-HT on long-term memory are reviewed elsewhere (*See* Chapter 4.08).

The role of these convergent inputs in conditioning is best understood at the level of the primary sensory neurons, but convergent interactions may also be important at the level of the cerebropleural interneurons known as the I_e and I_i cells. Both cell types receive conjoint synaptic input from the photoreceptors and statocyst hair cells (**Figure 3(a)**). Photoreceptors and statocysts form monosynaptic excitatory connections with the I_e interneurons and monosynaptic inhibitory connections with the I_i interneurons.

Both I-cell types receive larger compound synaptic inputs in response to the CS in conditioned animals compared with controls (Crow and Tian, 2002). Larger EPSPs in the I_e cells increase spike activity, and larger inhibitory postsynaptic potentials (IPSPs) in the I_i cells reduce ongoing spike activity. This increase in the amplitude of the PSPs in the I-cells is due not only to increased CS-induced spike activity in the photoreceptors following conditioning but also to an increase in the strength of the B photoreceptor monosynaptic connections to both I-cell types (**Figure 3(b)**). In addition, the intrinsic excitability of the I_e interneurons also appears to be increased after conditioning, a third mechanism leading to the increased spike response of the I_e cells to the CS (**Figure 3(b)**). The mechanism increasing the excitability of the I_e cells has yet to be investigated.

Recording the VP1 ciliary motor neurons shows that light inhibits the tonic spike activity in conditioned animals compared with controls. Reduction of VP1 spiking reduces foot ciliary activity and inhibits forward locomotion. Facilitation of the synaptic connection between the B-type photoreceptors and type I_e interneurons in conjunction with intrinsic enhanced excitability in type B photoreceptors and type I_e interneurons would result in an increase in spike activity in the type III_i inhibitory interneurons and inhibition of the VP1 ciliary interneurons via the III_i-to-VP1 monosynaptic connection (**Figure 3(b)**). Thus, this combined set of synaptic and cellular changes located within the ciliary control circuit can elegantly account for the light-elicited inhibition of locomotion following associative conditioning. In the *Hermissenda* system, conditioning increases both the strength of already existing synapses by presynaptic mechanisms and postsynaptically by increasing the excitability of neurons in the circuit (Crow, 2004).

1.30.4.3 Aversive and Appetitive Conditioning of Chemosensory Responses in Terrestrial Slugs and Snails

Terrestrial slugs and snails show striking changes in the preference for food odors as a result of experience. Simply allowing the land snail *Achatina* to feed on a specific food, such as carrot, for 48 h leads to a preferential orientation of the snails toward odors of these foods, compared with the odors of a novel food, for up to 21 days after exposure to the food (Croll and Chase, 1980). Formation of food preferences depended on the consumption of food and does not occur by exposure to food odors alone, so an associative memory trace appears to have been formed between the odors and the consumption of the food, perhaps its nutritional value. Odor preferences have also been extensively investigated in the slug, *Limax*, but the emphasis in this mollusk has been on aversive classical conditioning. Slugs are attracted by odor to locomote toward a food source, such as carrot or potato, and when the food is located, they will evert their lips to taste the food and then consume the food with rhythmic feeding movements. If the food odors are paired with the bitter taste of quinidine, then the slug learns to avoid the food odor when compared with naive and unpaired groups of slugs that show no change in their food preference (Sahley et al., 1981a). A single pairing of a CS odor (carrot or potato) and the aversive US can reduce the time spent near the CS form by 80% in control groups to 20% for conditioned animals. The association of the food odor (CS) with the bitter taste (US) is an example of first-order classical conditioning, but the paradigm can also be extended to demonstrate second-order conditioning in the slug (Sahley et al., 1981b). Slugs are first presented with carrot/quinidine (phase 1) and then given the same number of pairings of two odors, potato and carrot (phase 2). To ensure that changes in the slug's preference for potato depended on it receiving both the phase 1 and phase 2 pairings, control groups were included. One control group received paired presentations of odor and quinidine in phase 1, but during phase 2, potato and carrot were unpaired. The other control group received unpaired carrot odor and quinidine in phase 1 but paired carrot and potato odor in phase 2. Slugs that received pairings during both phases of training displayed a reduced preference for potato odor when presented alone compared with slugs from the two control groups, indicating that second-order conditioning had occurred.

Another type of higher-order conditioning behavior shown by slugs is known as 'blocking' (*See* Chapter 1.18). Sahley et al. (1981b) showed that prior conditioning to one stimulus, carrot odor, reduced or blocked learning to a second stimulus, potato odor, when a compound odor consisting of both carrot and potato odors was subsequently paired with quinidine. In contrast, control groups of slugs without prior training to carrot learned to avoid both carrot odor and potato odor when the compound presentation of both odors was paired with quinidine.

As might be expected from such complex chemosensory behavior, *Limax* has an elaborate olfactory system for processing odor signals and the elaboration of memory traces. *Limax* and other terrestrial slugs and snails have two pairs of chemosensory tentacles located on the head, the 'superior' being responsible for sensing airborne odorous signals (Chase, 2002). At the tip of the tentacles is a large tentacle ganglion organized in glomeruli, and these structures contain primary olfactory neurons that are thought to code the airborne odor stimuli. These primary olfactory neurons project to a large CNS processing center, the procerebrum (PC), which is involved in odor discrimination as well as odor learning. Gelperin and Tank (1990) demonstrated the existence of synchronized neuronal oscillations in the PC of *Limax* that could be recorded as a local oscillatory field potential (LFP) with a frequency of about 0.7 Hz. This LFP is modulated by odor stimuli applied to the tentacle. As well as local potentials, waves of hyperpolarization and depolarization can be recorded that propagate continuously at 1 mm/s across the whole PC structure from the apical end of the PC to the basal end. The oscillatory activity is thought to be due to the bursting properties and inhibitory synaptic connections of the two types of neurons that form the PC (reviewed in Gelperin, 1999).

Evidence that the PC is involved on odor memories came from experiments where the fluorescent dye Lucifer yellow (LY) was used as a measure of neuronal activity (Kimura et al., 1998a). When LY was injected into the body cavity of intact *Limax* just after conditioning, many cells of the PC were stained. This was not observed in unpaired controls, so the incorporation of the dye was specific to the odor conditioning. The dye-stained clusters of neurons formed a characteristic beltlike structure transverse to the axis of wave propagation. If two different odors were used as the CS for aversive conditioning, then different clusters of cells showed dye labeling,

suggesting that memory traces for different odors were stored in distinct populations of PC cells. In related experiments (Kimura et al., 1998b), electrical activity in the PC was recorded following aversive odor conditioning using voltage-sensitive dyes. Presentation of an aversively conditioned odor to the tentacle modulated the spontaneous oscillatory activity. Initially a depolarization of the basal level of oscillation occurred in specific belt-shaped regions of the PC (cf. LY staining), and then a later phase of hyperpolarization occurred that covered a wider area. Different odors produced different patterns of spatial modulation of oscillatory activity. Spatial and temporal modulation was not observed when unpaired control odors were tested, suggesting that the electrical changes were specific to conditioning. It appears from this work that olfactory memories are stored as spatial and temporal activity patterns of oscillators that form a coherent network.

In more recent work an *in vitro* version of odor conditioning has been developed where it is possible to stimulate the olfactory organs with odors and record motor output (Inoue et al., 2006). In this preparation it was also possible to record a behavioral correlate of PC oscillation. After odor-aversion conditioning, shortening of mantle muscles was recorded *in vitro* that form part of the conditioned response in the whole animal. This was accompanied by increased activity in the parietal motor nerves that innervate the mantle. In a differential conditioning paradigm two attractive odors (carrot and cucumber) were used as CSs; one was paired with the US (CS+), and the other was applied alone (CS–). The US was an electrical stimulus applied to pedal and lip sensory nerves. Before conditioning, neither CS caused activity in the motor nerves innervating the mantle. After one pairing, the CS+ increased larger-amplitude discharges in the motor nerve but the CS– did not. In addition, LFPs were recorded from the PC during conditioning. Before conditioning, attractive odors caused little change in the PC oscillations, but after conditioning, the PC oscillation frequency doubled with increases in activity in the motor nerves. Only the aversively conditioned CS+ increased the frequency of PC oscillation with no effect from application of the CS–. Whether the changes in PC oscillation are due purely to learning-related events is still an open question, because natively aversive odors (say onion or garlic) also cause increases in PC oscillation in naive animals (Inoue et al., 2006) similar to those produced by the CS+ odors (say, cucumber) that are made aversive by conditioning.

1.30.4.4 Reward Classical Conditioning of *Lymnaea* and *Aplysia* Feeding Behavior

In the original successful formulation of chemical reward conditioning in *Lymnaea*, snails were subjected to a multi-trial chemical conditioning protocol (15 trials, 5 trials per day for 3 days) using amyl acetate as a neutral CS and sucrose as the US (Audesirk et al., 1982). Following training, the explicitly paired (CS-US) experimental group showed significantly greater feeding responses to amyl acetate over their own naive responses and all the standard control groups (random, explicitly unpaired, CS alone, US alone). As might be predicted for appetitive conditioning, both age and motivational state (hunger versus satiety) influenced learning. Both hungry and sated young snails could acquire the conditioned response, but in the latter group, its expression was only apparent when the animals were starved before testing. On the other hand, old snails could only acquire the conditioned response if they were maintained in a hungry state during training (Audesirk et al., 1982). The significance of motivational state became even more apparent when it was realized that if snails were starved long enough (for 5 days) before and throughout the experiment, even a single pairing of amyl acetate and sucrose resulted in long-term memory (LTM), which lasted for at least 19 days (Alexander et al., 1984). This is a remarkable example of single-trial learning, which is used now for analyses of the time course of the mechanisms underlying LTM formation.

An electrophysiological correlate of the conditioned response to amyl acetate was recorded as changes in the fictive feeding responses in motor neurons (Kemenes et al., 2002), but electrical activity following conditioning has also been recorded in other parts of the feeding system in attempts to localize sites of plasticity. The cell bodies of chemosensory neurons are located in lip epithelial tissue and project to the cerebral ganglia via the lip nerves, where they synapse with cerebral ganglion neurons like the CBIs (Straub et al., 2004). Extracellularly recorded spike responses to both the CS and US can be recorded in the lip nerves from naive animals, and these responses do not change after conditioning. In contrast, neuronal output from the cerebral

ganglia is significantly enhanced in response to the CS after conditioning (Straub et al., 2004). This indicates that chemical conditioning affects central but not peripheral processing of chemosensory information, with the cerebral ganglia being an important site of plasticity. The fibers that were recorded extracellularly to indicate cerebral plasticity were originating from the CBI interneurons, so their activation is particularly significant. Confirmation that the CBIs do increase their activity after conditioning was obtained by showing increases in feeding patterns to the CS in CV1 neurons, a specific CBI cell type. From this work, it is suggested that the synapses between the primary chemosensory neurons and the CBIs are increased in strength. Two other CS pathways are present in naive animals, but these are not affected by conditioning (Straub et al., 2006).

The current network model for chemical conditioning (**Figure 4(a), (b)**) includes nonsynaptic plasticity. The CGCs are persistently depolarized by about 10 mV after behavioral conditioning. This indirectly increases the strength of postsynaptic responses to CGC stimulation by a process that involves an increase in intracellular calcium concentration (Kemenes et al., 2006). The local target for CGC depolarization is the CBI cells, and artificial depolarization of the CGCs in naive snails increases the response of the CBI cells to the CS, mimicking the effects of behavioral conditioning. It appears that the CGCs are increasing the strength of the CS-to-CBI synapse by presynaptic facilitation (**Figure 4(b)**). The onset of the CGC depolarization is between 16–24 h after training, and it persists for at least 14 days, as long as the behavioral memory trace is present. There is an early behavioral memory trace from 2 h after conditioning, so the CGCs cannot be involved in memory expression immediately after training. It is more likely that the CGCs are involved in the maintenance of the LTM after the trace has already been consolidated and encode information that is important for memory recall. Interestingly, the CV1 cells that show a persistent change in membrane potential after tactile conditioning (see later discussion) show no change after chemical conditioning. A variety of molecular pathways are involved in chemical conditioning in *Lymnaea*, and these are reviewed elsewhere (*See* Chapter 4.09).

Lymnaea can also be classically conditioned to a lip touch CS by repeatedly pairing a touch to the lip with food (5–15 trials over 3 days). This type of reward learning shares important characteristics with associative conditioning in vertebrates, such as

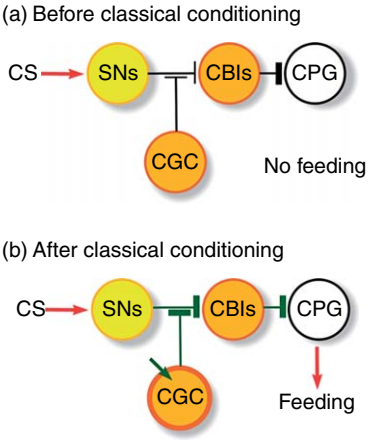

Figure 4 A cellular model for long-term memory after chemical classical conditioning in *Lymnaea*. (a) In naive animals, the excitatory connections between the sensory neurons (SNs) and the command-like cerebrobuccal interneurons (CBIs) are weak, and the chemical CS (amyl acetate) cannot activate feeding. The cerebral giant cells (CGCs) are at normal membrane potential (~65 mV), and the presynaptic modulatory input from the CGCs to the SNs is inactive or weak. (b) In conditioned animals, the CGC soma is depolarized by ~10 mV compared to naive animals, and this leads to an enhancement of the CGC presynaptic modulatory inputs to SNs and a strengthening of the SN-to-CBI excitatory synapse, which results in a feeding response to the CS. Black lines, inactive connections; green lines, active connections. Thin bars, weak chemical excitatory synapses; thicker bars, stronger/enhanced excitatory synapses. The thicker outline of the CGC and the green arrow in (b) indicate learning-induced nonsynaptic plasticity (membrane depolarization), which increases the strength of CGC-to-SN synaptic connections. CPG, central pattern generator.

stimulus generalization and discriminative learning, classical-operant interactions, and strong dependence on both external and internal background variables (Kemenes and Benjamin, 1989a,b, 1994).

Two approaches have been used to investigate the neural basis of tactile reward classical conditioning in *Lymnaea*. One approach was based on the development of an *in vitro* preparation where electrophysiological manipulation of neuronal pathways aims to mimic the behavioral conditioning paradigm (Kemenes et al., 1997). In this study a lip touch stimulus was paired with intracellular activation of the modulatory slow oscillator neuron, which can drive fictive feeding. After 6–10 pairings, presentation of the touch stimulus could activate a robust fictive feeding rhythm in feeding motor neurons.

A second approach used behavioral conditioning followed by electrophysiological analysis to record

changes in electrical activity that follows LTM formation. Using the lip touch behavioral training protocol, snails were subjected to 15 training trials over 3 days, and then these and control animals were dissected for electrophysiological analysis, starting on the day after the last training trial. Touching the lips of the intact snails from the experimental group after training induced a pattern of feeding movements significantly greater than controls. Similar significant differences were seen between experimental and control animals at the level of the electrophysiologically recorded fictive feeding pattern in motor neurons made from the same snails (Staras et al., 1998, 1999a).

The CPG-driven activity in the motor neurons depends ultimately on activity of neurons at all levels of the feeding network, so the conditioned fictive feeding recorded in the motor neurons is a systems level 'readout' of the memory trace in the whole feeding system. However, more detailed changes can also be recorded in different parts of the network (Staras et al., 1999a). One of these is the early EPSP that occurs in the B3 motor neuron before the onset of the fictive feeding pattern. The amplitude, but not the latency and duration of the EPSP, was significantly enhanced after conditioning. In sated snails the conditioned fictive feeding response to touch was lost, but the increase in the EPSP amplitude persisted. This suggests that there is unlikely to be a causal link between increases in amplitude in B3 and generation of the fictive feeding pattern.

Electrical correlates of tactile conditioning were also recorded at other levels within the feeding circuit, and these could all be potential sites of plasticity. That sites quite early in the CS pathway could be involved in conditioning was revealed by extracellularly recording mechanosensory fibers located in the connective between the cerebral and buccal ganglia. Tactile responses could be recorded in these fibers, and following conditioning, the number of spikes occurring early in this response increased, compared with controls (Staras et al., 1999a).

Interestingly, a correlate of tactile conditioning could also be recorded in the CPG network. A long-lasting sequence of inhibitory synaptic inputs that occurs in the N1 CPG interneurons in response to lip touch in naive animals changes to a strong sustained depolarizing synaptic input after *in vitro* conditioning, and this drives a sustained plateauing pattern in the N1 cell (Kemenes et al., 1997). This is an example of synaptic plasticity affecting an important CPG component of the feeding network.

One candidate for initiating CPG activity following conditioning is the CBI cell type known as CV1. This neuron is capable of driving a fictive feeding pattern via its connections with the N1M cells of the CPG network, and activity in these cells normally accompanies unconditioned feeding patterns stimulated by sucrose (Kemenes et al., 2001). After conditioning, the CV1 cells are significantly more active following touch in conditioned snails compared with controls, and they show the typical patterned activity seen with sucrose (US) application (Jones et al., 2003). More detailed experiments on the role of CV1 cells in tactile conditioning have revealed that nonsynaptic electrical changes play a role in memory (Jones et al., 2003). A long-lasting membrane depolarization of 11 mV on average was recorded in CV1s from conditioned compared with control snails that persisted for as long as the electrophysiological and behavioral memory trace. The depolarization makes the cells more responsive to the CS and can account for the activation of the feeding response after conditioning via the CV1 cell's strong excitatory synaptic connection with the CPG. The importance of this result is emphasized by experiments in which the membrane potential of the CV1 cells is manipulated to either reverse the effect of behavioral conditioning or to mimic the effects of conditioning in naive snails. These experiments showed that the persistent depolarization of the CV1 cells was both sufficient and necessary for the conditioned tactile response in the feeding network.

Like *Lymnaea*, the *Aplysia* feeding system has also been subjected to behavioral and electrophysiological analysis of reward conditioning using lip touch as the CS and food reinforcement (seaweed) as the US. An *in vitro* electrophysiological analogue of classical conditioning employed electrical stimulation of nerves to activate the CS and US pathways. Lesions of the En (esophageal nerve) blocked classical conditioning and suggested that this nerve mediates the effects of the US (Lechner et al., 2000). This nerve also contains dopamine (DA) immunofluorescent fibers, so it was interesting that the DA antagonist, methylergonovine, blocked the acquisition of the *in vitro* analogue of reward conditioning. Thus the behavioral, immunostaining, and pharmacological data are consistent with the hypothesis that DA located within nerve fibers in the En nerve mediates the actions of the US during conditioning.

Individual neurons of the *Aplysia* feeding circuit have been analyzed for changes occurring during conditioning. Buccal neurons B31/32 play a key

role in initiating buccal motor programs, and these neurons were significantly more depolarized by the CS after conditioning, although their intrinsic properties were unaffected. This suggests that there is greater excitation of the B31/B32 neurons after conditioning due to an enhancement of the CS pathway. Another neuron that plays a key role in expression of the buccal feeding program is B51. In preparations made from behaviorally trained animals, this cell type showed a greater number of plateau potentials compared with controls, and it was depolarized more by the CS. Neither the input resistance nor resting potential of the B51 was affected by conditioning, but another intrinsic property, the threshold for plateau initiation, was increased. This would make the cell less responsive to excitatory synaptic input, but nevertheless, the cell still showed more plateau potentials after conditioning, so some other unknown factor must overcome this diminished excitability (Baxter and Byrne, 2006). Similar results were obtained in both *in vivo* and *in vitro* conditioning. Recently, the CBI-2 cell type has been examined after *in vitro* conditioning and shown to increase its activity after conditioning. CBI-2 has the ability to initiate ingestive feeding motor programs, and this may contribute to the increased activation of the buccal B31/32 interneurons after conditioning (Mozzachiodi et al., 2003). No changes in the nonsynaptic cellular properties of the CBIs was reported, which contrasts with the results from *Lymnaea*, where the homologs of the CBIs, the CV1a cells, were shown to be persistently depolarized after tactile reward conditioning (Jones et al., 2003, see earlier discussion).

1.30.4.5 Reward Operant Conditioning of *Aplysia* Feeding Behavior

Brembs et al. (2002) developed a behavioral paradigm for operant conditioning using the consummatory (ingestive) phase of the feeding cycle as the operant. Contingent electrical stimulation of the En nerve that carries the US pathway from the esophagus, using implanted electrodes, was used to positively reinforce spontaneous extracellular recorded feeding bursts of activity monitored on the same nerve in freely moving animals. These extracellularly recorded bursts occurred at the same time as feeding ingestion movements and so acted as a direct monitor of the behavior. The number of spontaneous feeding bursts was increased compared with nonstimulated or yoked controls after 10 min of training immediately after the training period and when measured 24 h later. This indicates that operant conditioning was successful in producing both short-term and long-term memory. A cellular correlate of operant conditioning was monitored by intracellularly recording the B51 feeding interneuron in isolated buccal ganglia made from behaviorally trained animals. Cells from the contingent group showed a significant decrease in threshold for plateau formation and a significant increase in input resistance compared with cells from yoked controls. To test whether this was due to an intrinsic change in the B51 cell rather than changes in input originating from outside the cell, an analogue of conditioning was developed where B51 was grown in culture and electrically triggered burst of spikes paired with 6-s puffs of DA applied close to the isolated cell over a 10-min training period. Contingent application of these two stimuli produced a significant reduction in plateau threshold and a significant increase in input resistance compared with unpaired controls similar to that occurring in the previous intact buccal ganglion preparation (Brembs et al., 2002). These results indicate that intrinsic changes are induced in B51 by operant conditioning. How these changes in B51 contribute to the network and behavioral expression of the conditioned response are yet to be determined. Some of the molecular changes involving the effects of DA have been elucidated (reviewed in Baxter and Byrne, 2006).

1.30.4.6 Aversive Operant Conditioning of *Lymnaea* Breathing Behavior

The aerial respiratory behavior of *Lymnaea stagnalis* has been used to investigate the behavioral and neuronal mechanisms of operant conditioning (Lukowiak et al., 2003). Hypoxia triggers pneumostome opening, and this was used as the operant for behavioral conditioning. Tactile stimulation of the pneumostome area evokes pneumostome closure and stops aerial respiratory behavior. Animals were tested and trained in an artificially created hypoxic N_2-rich environment to increase the level of respiratory behavior. In the operantly trained group a tactile stimulus was applied to the pneumostome area each time aerial respiration was attempted by the animal. Suitable yoked and hypoxic control groups were also used. The number of openings, latency to first opening, and total breath durations were recorded in pre- and posttraining periods. Only the operantly

conditioned group showed significant changes between the pre- and posttraining behaviors, with significant reductions in openings and total breathing time and significant increases in the latency to first breath. It has since been demonstrated that a memory for this conditioned response could persist for at least 4 weeks when a spaced training procedure was used. Both intermediate memory (ITM) and LTM have been described based not only partly on the length of time the memory persists but also on the sensitivity to protein and mRNA synthesis blockers. Anisomycin prevents the formation of both ITM and LTM, whereas actinomycin-D only prevents LTM. Both reconsolidation and extinction have been studied following operant conditioning, and both have been shown to be dependent on new RNA and protein synthesis (Sangha et al., 2003a,b; *See* Chapters 1.24, 1.27). Extinction is viewed as a new type of associative memory that 'covers up' but does not replace the original memory. Thus, following extinction trials, a loss of memory at 2 h is followed by full 'spontaneous recovery' at 24 h (Sanga et al., 2003b).

Neural changes associated with this learned behavior have been identified in the isolated CNS derived from operantly conditioned animals. Specifically, spontaneous patterned activity in the IP3 interneuron, which is involved in pneumostome opening (see **Figure 1(dii)**), showed a significant reduction compared to activity in the IP3 neurons of brains derived from yoked controls. Furthermore, a higher percentage of RPeD1 CPG interneurons, which are important in the onset of the respiratory cycle, were silent in conditioned versus control preparations (Spencer et al., 1999). A reduction in the ability of the RPeD1 cells to induce IP3 activity was also observed. More direct evidence for the role of RPeD1 in memory formation came from somal ablation experiments. Removal of the soma 2 h prior to conditioning prevented LTM but had no effect on ITM, without affecting the ability of the snail to carry out respiratory behavior, suggesting that the RPeD1 soma was necessary for LTM formation (Scheibenstock et al., 2002). Removal of the RPeD1 soma 1 h after conditioning had no effect on LTM, indicating that the effects of soma ablation were not related to memory access or retrieval. Interestingly, both extinction and reconsolidation also require the presence of the soma of RPeD1, indicating that RPeD1 is involved in the formation of more than one type of memory trace (Sangha et al., 2003a,b).

1.30.5 Discussion

1.30.5.1 The Complexity of Molluscan Learning

Molluscan studies are focused on implicit forms of memory such as classical/operant conditioning and sensitization. Initially, simple forms of associative and nonassociative learning behavior were investigated. However, gastropod mollusks are capable of showing more complex types of associative learning behavior with features that are similar to those found in vertebrates (*See* Chapters 1.18, 1.36). For instance, differential conditioning has been described in a number of mollusks (Hawkins et al., 1983; Kemenes et al., 1989a; Jones et al., 2001; Inoue et al., 2006). In addition, second-order conditioning and blocking of aversive-odor conditioning has been demonstrated in *Limax* (Sahley et al., 1981b), and stimulus generalization, goal tracking, and context dependence (increased learning in a novel environment) were found in *Lymnaea* tactile conditioning (Kemenes and Benjamin, 1989a,b, 1994). The circuits underlying these behaviors are more complicated than those originally used for the study of reflexive defensive withdrawal responses and require the understanding of CPG and other interneuronal circuits mediating multimodality sensory responses. A key finding in these studies is that conditioning-induced synaptic and nonsynaptic changes occur at several sites within the same network (Benjamin et al., 2000; Crow, 2004; Baxter and Byrne, 2006; Kemenes et al., 2006; Straub et al., 2006). These include sensory neurons, modulatory and pattern-generating interneurons, and motor neurons. A future task will require us to understand how these various changes may be integrated to generate the final behavioral output.

1.30.5.2 Comparison of Nonsynaptic Electrical Mechanisms in Different Types of Molluscan Learning

It has long been recognized that changes in synaptic plasticity play a major role in molluscan learning and memory, but an increasing number of examples of nonsynaptic plasticity have been discovered that are known to be involved in circuits underlying behavioral learning. These include changes in input resistance, membrane potential, and threshold for plateau initiation. Examples of input resistance increases induced by conditioning occur in the B-type photoreceptor cells of *Hermissenda* (Crow, 2004). This leads to an increase in excitability of

the photoreceptors so that they fire more in response to the light CS. Similar input resistance increases have been described in the LE mechanoreceptors of the gill-siphon reflex of *Aplysia* following sensitization and classical conditioning (Hawkins et al., 2006). In both examples, a reduction in the size of intrinsic potassium channel conductances appears to be involved.

Persistent changes in membrane potential occur in whole body withdrawal interneurons in *Helix* (Gainutdinov et al., 1998) and in feeding command-like CV1 interneurons in *Lymnaea* (Jones et al., 2003). In both snails, the cells are depolarized following conditioning, and this lowers the threshold for firing in response to the CS, thus allowing the command cells to directly activate the motor circuits. The CGCs in *Lymnaea* also show persistent changes in membrane potential (Kemenes et al., 2006) after conditioning, but this does not lead to an increase in spiking responses to the CS. Instead, the 10-mV depolarization facilitates CS responses in the chemosensory pathway by increasing presynaptic release of transmitter at the sensory-to-command-neuron synapse. The CGCs are extrinsic to the feeding circuit, and so the change of membrane potential activates feeding responses indirectly by affecting command interneurons intrinsic to the circuit. Interestingly, the CGC's changes occur in chemically conditioned snails but not those subjected to tactile conditioning. For tactile conditioning the CV1 cells are depolarized but not the CGCs. The reason for this difference in the two types of classical reward conditioning is unclear but is probably linked to differences in the neural pathways activated by sucrose versus lip touch.

Changes in the threshold for plateau formation in the pattern generation occurs in the same *Aplysia* interneuron (B51) in both classical and operant conditioning of feeding, allowing comparisons to be made of the intrinsic changes occurring in B51 in the two different types of learning (Lorenzetti et al., 2006). The two types of conditioning have the opposite types of effect – increasing the plateau membrane potential threshold in classical conditioning and decreasing it in operant conditioning. This is despite the increase in overall plateauing frequency in both types of conditioning in the intact network. B51 is thought to have some type of 'decision-making role' in the feeding circuit but how the differential effects of conditioning on plateauing translate to differences in the type of conditioning used is unclear.

1.30.5.3 Comparison of Synaptic Mechanisms

Changes in synaptic strength have been described in several molluscan systems following training. In *Aplysia*, the gill-siphon withdrawal response is present in naive animals and is enhanced by learning (Hawkins et al., 2006). In contrast, *Hermissenda* phototactic conditioning causes a different response to the CS in naive animals compared with after conditioning, and so a new response has to be learned (Crow, 2004). There are weak synaptic responses to the photic CS-conditioned response in *Hermissenda*, but they are too ineffective in naive animals to generate a network inhibitory response in the ciliary motor neurons. It might have been expected that there might be formation of novel synapses or activation of 'silent synapses' in the circumstances where there is no behavioral response prior to conditioning, but this does not appear to be the case. In *Lymnaea* there are two alternative CS pathways, one excitatory and one inhibitory, that can be activated by the chemical CS in naive animals (Straub et al., 2006). At high concentrations the inhibitory effect is predominant on feeding behavior. Following reward conditioning, the CS becomes overall excitatory on feeding responses to high CS concentrations, but this is not due to any change in the preexisting pathways, but a previously ineffective excitatory pathway becomes predominant over the inhibitory pathway. These results from *Hermissenda* and *Lymnaea* make it clear that there are no simple rules so far elucidated that can predict whether new synapses will be formed or already-existing synapses strengthened following associative conditioning.

1.31 Behavioral Analysis of Learning and Memory in Cephalopods

L. Borrelli and G. Fiorito, Stazione Zoologica A. Dohrn, Naples, Italy

1.31.1 An Historical Overview

The ancient civilizations of the Mediterranean, whose lives were closely linked to the sea, were clearly aware of the existence and beauty of cephalopods. Exquisite motifs and sketches of marine creatures were recurrent in the well-known Middle and Late Minoan pottery (approximately 2000–1000 BC) and also in the probably less famous Chiriquian art, typical of northwest Panama (approximately 300 BC). Both made extensive use of lozenge-shaped figures from which eight waving arms emerged. Independent of their realistic or stylized rendering, common characters such as dots, spots, and circles of various shades and colors convinced archeologists, anthropologists, and art historians that the figures were artistic representations of the same peculiar marine creature: the octopus.

This brings our attention to the fact that, among living organisms, cephalopods have been familiar to man since antiquity. In his *Historia Animalium*, Aristotle (fourth century BC) described the difference in occurrence between the inking response of cuttlefishes (concealment and fear) and that of squids and octopuses (fear only), together with the changing of the patterns of their skin to match the background and disguise themselves from predators and prey. He also mentioned the octopus's strong curiosity (or stupidity, to put it in his words), which made it an easy catch since a hand shaking under the water surface was sufficient to elicit its exploratory drive (Aristotle, 1910). Cephalopods' behavior even intrigued Darwin, who gave a detailed account of his observations of octopuses and cuttlefishes in the waters of the islands of Cape Verde (Darwin, 1870).

Many other anecdotal and popular reports are known from the classic literature (review in Cousteau and Diolé, 1973; see also Borrelli et al., 2006).

1.31.1.1 The Role of the Zoological Stations in Cephalopod Research

It is without doubt, however, that the scientific and systematic analysis of cephalopods' anatomy, physiology, and behavior started near the beginning of the twentieth century, mainly from initiatives of the Zoological Station of Naples (Stazione Zoologica di Napoli) and its outstanding guests.

The Stazione, with its strategic position on the seafront, fleet of fishing boats, and professional personnel, gave foreign scientists the unique opportunity to combine leisure and work as temporary guests of the institute. Since its foundation, octopuses were among its favorite research models; moreover, they figured as a symbol of the Stazione, as is clear from the decorations on the wrought-iron gates of the main entrance to the institute (**Figure 1**) and from the numerous old postcards of the Naples Aquarium, which often depicted them. This stemmed mainly from the the long-standing tradition of Neapolitan fishermen to catch live cephalopods, always considered a prime delicacy (for review, see Lo Bianco, 1909; Lane, 1960).

Figure 1 The gate of the main entrance to the Stazione Zoologica A. Dohrn, built during the final phase of the construction of the institute (1905–1910). It is embellished with motifs of traditional fishing tools, such as the fishing net (bottom) and the row of spears and tridents (top), the latter being a symbol of the Greek sea god Poseidon. Marine creatures, such as crabs and octopuses (detail on right), are carefully depicted by Neapolitan craftsmen.

During this period, the outstanding studies of Giuseppe Jatta (1896) and Adolf Naef (1923, 1928) on the anatomy, systematics, and ontogeny of cephalopods, conducted and published at the Stazione, formed the groundwork for further studies. In addition, the first observations of cephalopods living in captive conditions (in tanks at the Naples Aquarium) gave an idea of the complexity of their behavior and learning capabilities (e.g., Piéron, 1911; for review see Boycott, 1954). Dr. Ariane Droescher referred to a description by Anton Dohrn, who tried to avoid octopuses feeding on lobsters kept in adjacent tanks. Solid cement walls, raised several centimeters above the water surface, separated the aquarium's tanks. However, his attempts proved to be unsuccessful. In fact, as observed by Dohrn, the "same day, one of [the octopuses] climbed over the wall, attacked the unsuspecting crayfish and, after a short battle, tore him into two pieces! … The octopus [could] have seen that the crab [was] set by the keeper into the neighbouring tank, or he [could have] smelled the prey in the circulating water of the tanks. Anyhow, the event shows that the octopus [was] able to deduce from a sensual impression that there [was] a prey that he did not see, to conclude and, finally, to perform an air-jump in the right direction" (Salvini-Plawen, 1979, pp. 218–219).

Research on the biology and behavior of cephalopods was not confined to the Stazione but attracted the attention of and flourished in many other marine laboratories, both in Europe and the United States. As an example, a thorough description of the chromatic changes and behavioral repertoire of *Octopus vulgaris* was carried out by Cowdry (1911) at the Bermuda Biological Station for Research. Similar studies were conducted on *Loligo pealeii* by Williams (1909) at the Marine Biological Laboratory (Woods Hole, MA, USA) and by Stevenson (1934) at the Biological Station of St. Andrews (Scotland). Finally, the behavior and complexity of body patterning of *Sepia officinalis* was described by Bert (1867) at Arcachon (France), by Tinbergen (1939) at the Aquarium of the Zoological Station of Der Helder (The Netherlands), and finally by Holmes (1940) and Sanders and Young (1940), who carried out their studies at the Marine Biological Laboratory in Plymouth (UK).

1.31.1.2 A Research Effort Lasting Over a Century

In order to evaluate the research on cephalopods from the pioneering studies to the present day, we counted the number of publications cited in the Zoological

Record on a yearly basis for over a century, from 1900 to 2006 (**Figure 2**). Only publications concerning the anatomy and physiology of the central nervous system, the behavioral responses to learning paradigms, or living habits of cephalopods were considered pertinent and were accounted for. The number and distribution of papers over years clearly shows the prominent role achieved by the octopus in the study of learning and memory in cephalopods in the 15 years spanning from 1955 to 1970 (**Figure 2**).

1.31.1.2.1 The contribution of J. Z. Young

After the Second World War, the insight into the octopus rose mainly by the initiative of the British anatomist and zoologist John Zachary Young. On a yearly basis, JZ (as he was commonly called), together with a plethora of students and co-workers, was hosted by the Stazione Zoologica, where he systematically studied the anatomy and physiology of cephalopods' nervous system, increasing the knowledge on the behavior and learning capabilities of these animals. Many people were involved in these and related physiological studies: Brian B. Boycott, Francesco Ghiretti, Pasquale Graziadei, Nicolas J. Mackintosh, Hector Maldonado, John B. Messenger, William R.A. Muntz, Andrew Packard, Geoffrey D. Sanders, Norman S. Sutherland, and Martin J. Wells are but a few names.

The impressive bulk of knowledge gained over these years at the Stazione and in other laboratories around the world has confirmed the old view of cephalopod preparations as marine guinea pigs (A. Droescher, personal communication) or as primates of the sea (Kerstitch, 1988). In fact, Young became more and more conscious of the fact that the "brain of the octopus has already abundantly proved its value for the study of behaviour. It is perhaps the type most divergent from that of mammals that is really suitable for study of the learning process" (Young, 1971: p. vii).

Apart from a few other contributions (for review, see Boycott, 1954), when J. Z. Young and Brian

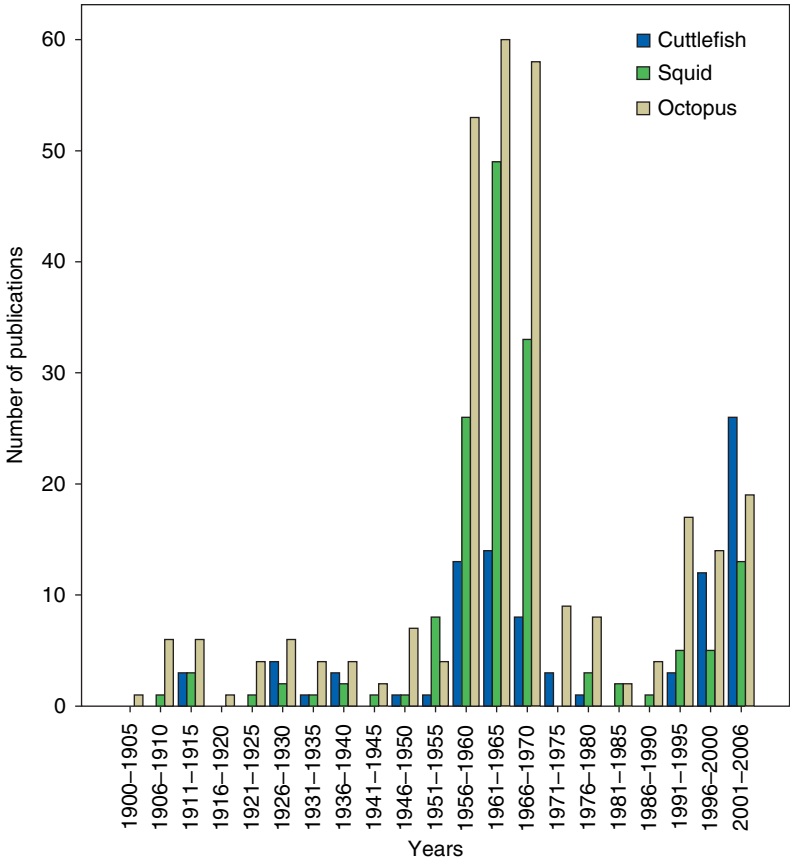

Figure 2 Number of publications per quinquennium on behavior, learning, and memory in cephalopods (cuttlefish, squid, and octopus) indexed in the Zoological Record from 1900 to 2006.

Boycott started their adventure with *Octopus vulgaris* at the Stazione Zoologica, two major works were available to them: a comprehensive overview of the brains of different cephalopod species (*Sepia officinalis*, *Sepiola robusta*, *Loligo vulgaris*, *Illex coindetii*, *Argonauta argo*, *O. vulgaris*, *Eledone moschata*, *Ocythoe tuberculata*; Thore, 1939) and an experimental study on the effects of the removal of certain lobes of the brain of *S. officinalis* on the behavior and learning of the cuttlefish (Sanders and Young, 1940).

Their aim was to study the learning capabilities of these animals by combining behavioral observations and lesions of the neural centers in order to disclose the functional organization of the cephalopod brain involved in the control of different behaviors; essentially, the predatory response.

O. vulgaris appeared to them as the ideal candidate for a series of reasons. First, because it was easy to maintain in aquaria. A tank of relatively reduced space ($30 \times 100 \times 40$ cm) with running seawater and a pair of bricks as shelter was (and still is) sufficient to make an octopus happy and at home. In this type of experimental setting, an initially scared, hiding, and pale octopus, as it commonly appears on the day it is captured becomes a tame, pet-like animal with time (Buytendijk, 1933; Hochner et al., 2006). Second, because of its natural curiosity. A few days in captivity are normally enough for the octopus to show its intrinsic attitude to attend to any object placed in its aquaria, which is largely a result of its voracity and exploratory drive toward natural (or artificial) objects. Third, because of its resilience to recover from massive brain surgery, contrary to what Young and coworkers experienced with *S. officinalis* (Sanders and Young, 1940).

The advantage of the octopus preparation became clear when Boycott introduced an efficient training technique. *O. vulgaris*'s hunting behavior was utilized as biological drive to teach animals to discriminate between stimuli that were positively and negatively reinforced. In the first experiments, octopuses were presented with crabs alone or associated with a white square; every attack on the latter was negatively reinforced (6–12 V AC). Several dozen trials were enough for the animals to learn the task and to respond correctly in quite a stable and predictive way.

In a series of subsequent experiments, it was demonstrated that octopuses were able to distinguish between different shapes by successive presentation of the two objects. The octopus was allowed to eat the crab when it attacked the positive figure, but an electric shock was delivered to the animal by a probe when it attacked the negative stimulus (Boycott and Young, 1956; for review, see Sanders, 1975; Hanlon and Messenger, 1996). Following this initial set of experiments, the protocol was improved by giving the animal a piece of anchovy as positive reinforcement instead of crabs, which could reduce the octopuses' predatory response because of satiety (Young, 1961).

1.31.1.3 The Breadth of the Studies on Octopus and Other Cephalopods

The versatility of this training protocol allowed a rapid growth of the field up to the 1960s (see also **Figure 2**). In fact, different research directions emerged from the original study by Boycott and Young (for review, see also Wells, 1965b).

For example, the first were centered on the study of the different sensorial capabilities (orientation in space, vision, chemotaxis, touch, and proprioception) and of the structures devoted to their control using different approaches (e.g., behavioral, ablation, and stimulation). Subsequent attention was focused on disclosing the role of the lobes of the brain (essentially the vertical and the peduncle lobes) in the learning and behavioral responses and in the motor coordination.

All these studies allowed Young and coworkers to produce a model of the brain of a learning (and behaving) octopus (Young, 1964; Clymer, 1973). In addition, these studies demonstrated that the animals were capable of sensitization, habituation, associative learning (passive avoidance, visual and tactile discrimination), and spatial learning (for a review, see Young, 1961; Sanders, 1975; Wells, 1978; Boyle, 1986; Boal, 1996; Hanlon and Messenger, 1996; Hochner et al., 2006). As clearly stated by Wells, "Octopuses can be taught to make a wide variety of tactile and visual discriminations. They learn rapidly under conditions that would lead to learning by mammals, and they achieve similar standards of accuracy of performance. This places them in a different category from many invertebrates, where research has tended to concentrate on demonstrating that the animals can learn at all. In the case of *Octopus* there is now no doubt that the species can learn, whatever definition of learning one cares to employ. One is free to pass on to considerations of *what* these animals can detect and learn about the world around them and what *we* can learn about the organisation of the cephalopod brain from their successes and failures" (Wells, 1965a, p. 115).

The analysis of the literature clearly shows what cephalopod workers (and modern neuroscientists) know well: The octopus, as a model, was almost (and suddenly) abandoned by the end of the 1960s (**Figure 2**).

This was mainly a result of:

- The relatively poor control by experimenters of the behavioral training procedures (Bitterman, 1966, 1975);
- The lack of appropriate tools to explore the neurophysiological properties of cells within certain lobes of the brain (e.g., amacrine cells in the vertical lobe; Young, 1985); and
- The inability of octopuses to pick up kinesthetic cues and the lack of proprioceptive feedback of the higher centers of the octopus brain (review in Wells, 1978).

Controlled handling, maintenance, and training procedures (Walker et al., 1970) and the thorough knowledge of the behavior and learning capabilities of cephalopods (Maldonado, 1963a; Packard, 1963; Messenger, 1968, 1977; Packard and Sanders, 1969, 1971; Packard and Hochberg, 1977; Hanlon, 1978; Hanlon and Messenger, 1988) have allowed subsequent workers to cope with the difficulties implicit in the training protocols and to produce renovated experimental approaches to the study of the behavioral biology of learning in these animals. This has led to a growing number of publications over the last 20 years (**Figure 2**) that are not necessarily focused on the octopus model but on different cephalopod species.

1.31.2 The Cephalopod Brain and Its Learning Capabilities

Dramatic evolutionary changes in the body plan and in the gross morphology of the nervous system (and of its relative organization) led to the origin and diversification of the phylum Mollusca (Kandel, 1979; Lee et al., 2003).

The nervous system, in particular, varies greatly in complexity and in the number of neurons among taxa (Bullock, 1965a,b,c,d). However, it is in cephalopods that this complexity reaches its highest degree within the phylum – a complexity that can be recognized at three levels. First, the brain size (relative to body weight) is comparable to that of vertebrate brains and positions cephalopods just below higher vertebrates (i.e., birds and mammals; Packard, 1972). Second, an average-sized octopus presents roughly 500 million neurons. More than one-third (roughly 200 million cells) are recruited to form its central nervous system (Young, 1963), a number that appears to be from 200 to 10 000 times higher when compared with the brains of other invertebrates (*Apis* and *Aplysia*, respectively). Finally, the degree of complexity of the nervous system is not only limited to the relative size and number of neurons within the brain but also stems from its neuroanatomical organization (for review, see Young, 1971; Budelmann, 1995; Williamson and Chrachri, 2004).

1.31.2.1 General Organization of the Brain

In cephalopods, the ganglia recruited to form the central nervous system may be considered homologous to the labial, buccal, cerebral, pedal, pleural, and visceral ganglia of gastropod mollusks. Contrary to what occurs in the typical molluscan design, in a cephalopod the ganglia are fused together and clustered around the most anterior part of the esophagus (for a review, see Bullock, 1965b; Budelmann, 1995). The agglomeration of the ganglia, which happened by the shortening of the connectives and commissures, form three almost distinct parts: the supra- and the subesophageal masses, and a pair of optic lobes that emerge laterally from the supraesophageal mass (one for each side positioned just behind the eyes).

The supraesophageal mass originated from the ancestral labial, buccal, and cerebral ganglia. The main lobes constituting it are the inferior, superior, and posterior buccal; the inferior frontal, subfrontal, and superior frontal; the vertical; and the basal lobes (**Figure 3**). Moreover, certain lobes of the supraesophageal mass (e.g., the optic and olfactory lobes) are of more recent neural formation. The subesophageal mass, instead, essentially derived from the paired pedal, pleural, and visceral ganglia that fused together to a different extent within and between cephalopod species (Nixon and Young, 2003). Again, neural masses of more recent origin were added to the ganglia listed above to form the brachial ganglion, mainly devoted to the control of the actions of arms and suckers.

Altogether, this provides cephalopods with the highest degree of centralization compared with any other mollusk and with the vast majority of other invertebrate phyla. Nevertheless, the nervous system keeps the basic invertebrate organization with layers of cell bodies distributed externally and with an inner neuropil.

A thorough description of the gross morphology, neuroanatomy, and organization of the cephalopod brain is known for *O. vulgaris* (Young, 1971) and for decapods (Young, 1974, 1976, 1977, 1979; Messenger, 1979). (Reviews on this topic are available in Bullock, 1965b; Budelmann, 1995; Nixon and Young, 2003; but see also Budelmann et al., 1997). In addition, quantitative data on the relative size of the different brain lobes of various species of cephalopods is also available following the contributions of Wirz (1959) and Maddock and Young (1987). Information on the relative size of the lobes in hatchlings has been determined for several Mediterranean species by Frösch (1971; for review see also Nixon and Young, 2003).

Taken as a whole, these studies have shown that the Cephalopoda present a marked diversification of cerebrotypes that should correspond to differences in the habitats occupied within the marine environment (Nixon and Young, 2003; Borrelli, 2007). For example, the brachial and inferior frontal lobes are highly diverse between octopods and decapods, with those in the former being considerably larger than in the latter as a consequence of their benthic lifestyle (and tactile sensorial modality). On the other hand, the vertical lobe (as integrative center, see Sections 1.31.2.2, 1.31.2.3) shows greater variability among species both in relative size and gross morphology (Young, 1979; Maddock and Young, 1987; for a review, see Nixon and Young, 2003).

Finally, as mentioned above, the arms of an octopus contain about two-thirds of the some 500 million neurons in total. The arms can thus work rather autonomously (following a hierarchical functional control of the higher motor centers), as they can generate highly stereotyped movements (Altman, 1971; Sumbre et al., 2001, 2005, 2006).

Moreover, we now know the possible function of roughly 40 lobes within the cephalopod brain by stimulation experiments carried out in *S. officinalis* (Boycott, 1961) and *O. vulgaris* (Boycott and Young, unpublished data: cited in Young, 1963, 1971).

These studies have shown that the supraesophageal mass is responsible for sensory processing and analysis and control of behavior, and it also provides motor commands and coordination to the higher motor centers (i.e., basal lobes). The subesophageal mass, instead, provides the control of particular sets of effectors via intermediate and lower motor centers.

1.31.2.2 Neural Substrates of Behavior

The analysis of hundreds of lesion experiments conducted on octopuses (mostly), squids, and cuttlefishes (review in Sanders, 1975; Boyle, 1986) and of several dozen serial histological sections of cephalopod brains allowed Young and coworkers not only to describe the anatomy of the nervous system of these animals (for a review, see Nixon and Young, 2003) but also to unravel the circuit leading to their visual and tactile learning capabilities (**Figure 3**). In Young's view, learning and memory are achieved in cephalopods by "a series of matrices of intersecting axes, which find associations between the signals of input events and their consequences" (Young, 1991: p. 200).

1.31.2.2.1 Tactile information

During tactile processing (and learning), the decision to grasp or reject an object by an octopus is made on the basis of the interaction of a network made up by the following eight matrices:

- Lateral inferior frontal lobes
- Median inferior frontal lobe
- Subfrontal lobe
- Posterior buccal lobes
- Lateral superior frontal lobes
- Median superior frontal lobe
- Vertical lobe
- Subvertical lobe

The system, which corresponds to roughly six lobes of the supraesophageal mass, is tuned to take any object touched (i.e., tactile exploratory drive) unless pain signals are conveyed.

Figure 3 A schematic representation of the neural pathways for the visual (blue) and tactile (red) sensorimotor systems in the brains of *Sepia officinalis* (a) and *Octopus vulgaris* (b). Possible integrations (or shared pathways) between the two systems are indicated in green. In the supraesophageal mass, several matrices of the two systems overlap, particularly in *Octopus* (see text for details). The optic lobes (bottom) are depicted from horizontal sections. The reciprocal positions and sizes are not in scale. The supra- and subesophageal masses of the two species are drawn or photographed from a sagittal section: (*Sepia* (a) after Sanders FK and Young JZ (1940). Learning and other functions of the higher nervous centres of *Sepia*. *J. Neurophysiol.* 3: 501–526. *Octopus* (b); after Young JZ (1991) Computation in the learning system of cephalopods. *Biol. Bull.* 180: 200–208). Esophagus (es); plexiform zone (plex).

The interaction between the inferior frontal (positive signals) and the subfrontal (negative signals) plays the major role in decision making (i.e., take/reject) by the animal.

Finally, the inferior frontal system (in decapods, the posterior buccal and the lateral inferior frontal lobes; in octopods, the posterior buccal, the lateral and median inferior frontal, and the subfrontal lobes) is qualified as the main site of the long-term memory storage for tactile information, as roughly 60% of the total tactile learning capacity is thought to reside in this brain region (Young, 1983). The remaining quota is distributed between the superior frontal and vertical lobes (approximately 25%) and, to a limited extent, in areas of the subesophageal mass (the remaining 15%; Young, 1983; see also Budelmann and Young, 1985; for a review, see Wells, 1978; Young, 1991, 1995; Williamson, 1995; Williamson and Chrachri, 2004).

In decapods, the so-called inferior frontal lobe is more comparable to the posterior buccal lobe of *Octopus* than to the inferior frontal lobe *sensu stricto* (Young, 1971, 1979), which is lacking in cuttlefishes and squids. However, the distribution and interchange of fibers originating from the arms make the inferior frontal lobe of decapods appear close to the median inferior frontal lobe of *O. vulgaris* (see p. 350 and p. 314 of Young, 1971, 1979, respectively).

From a functional point of view, the fact that cuttlefishes and squids detect their prey visually and capture it with the arms or by ejection of the tentacles (depending on the prey species; see a review in Hanlon and Messenger, 1996) makes us assume that they have only a limited need and capacity for learning tactile information. Manipulatory activities related to feeding are considered largely programmed and based on reflexes (but see Halm et al., 2000, 2002, 2003), with some inhibitory pathways (i.e., reciprocal inhibition) from the small amacrine cells that are distributed among the large motor neurons of the buccal and subesophageal centers (Young, 1976, 1991), in close resemblance to the spinal cord of mammals (Young, 1995).

1.31.2.2.2 Visual information

Like the tactile learning system, visual stimuli are classified and processed behaviorally by a network composed of the following four matrices:

- Lateral superior frontal lobes
- Median superior frontal lobe
- Vertical lobe
- Subvertical lobe

The optic lobe also plays a major role in the visual learning system but was excluded by Young from the assemblage of matrices because of its location outside of the supraesophageal mass.

Again, like before, the system of matrices is tuned to promote the animal to attack the stimulus unless unpleasant feelings are perceived. At the level of the optic lobes, the cells from the retina reach the outer plexiform zone, where they make contact with a large number of cells (second-order visual cells; see **Figure 3**) that act as feature detectors. They constitute dendritic fields of various shapes and extensions that allow the recognition of "the relevant features of objects and scenes" (Young, 1995, p. 434) encountered by the animals during their everyday life (see also Deutsch, 1960; Sutherland, 1960; for a review, see Sanders, 1975; Hanlon and Messenger, 1996). The axons of the second-order cells "form columns proceeding to the center of the [optic] lobe, where they interact in an interweaving matrix of cells and fibers" (Young, 1991, p. 205).

Outputs of the neurons of the optic lobe proceed toward various areas of the brain (**Figure 3**). Some go directly to the magnocellular lobe, which is considered to act in situations where rapid escape reactions are needed (Young, 1971, 1973, 1991, 1995). Other fibers proceed to the peduncle and basal lobes, thus serving to regulate movements, and finally the third pathway goes toward the core of the visual matrices. It is at this level that the interaction between the lateral superior frontal (promoting the attack) and the median superior frontal and vertical lobes (inhibiting the attack) regulates the animal's behavior. Finally, according to Young, memory formation for visual experiences and their outcome take place within the optic lobes, with active participation of the supraesophageal centers (Young, 1991, 1995).

As is shown in **Figure 3**, the neural organization of the visual system of decapods has close affinities to that of octopods (Cajal, 1917; Sanders and Young, 1940; Young, 1973; for a review, see Nixon and Young, 2003; Williamson and Chrachri, 2004). Perhaps the system works in a similar way in cuttlefishes and squids, although it has not yet been extensively studied in the learning context, as has been done for octopuses (see a review in Young, 1991; Agin et al., 2006a).

1.31.2.3 How Computation in the Learning System Is Achieved

The idea promoted by Young and colleagues on the existence of multiple matrices in the central nervous

system, working in the control of behavioral responses, found its roots in the pioneering studies of Cajal (1917) and Sanders and Young (1940). The model proposed by Young was deduced essentially on the basis of morphological and experimental evidence (see the review in Young, 1961).

Following Young, the two systems work on similar principles. The information is processed through a series of matrices that allow signals of different types (and meanings) to interact to some extent with each other and to regulate subsequent behavior for attack/take and retreat/reject responses (**Figure 3**). In addition, the modulation between promotion and inhibition is tuned in order to facilitate exploratory behavior. According to Young, the systems are designed with a close similarity with complex nervous systems such as the mammalian hippocampus and neocortical centers (Young, 1995). This system seems to be limited in that a complete integration (transfer) between visual and tactile information is relegated only at the level of the effectors (Allen et al., 1986), although limited cross-modality has been shown in *O. digueti* at higher neural levels (Michels et al., 1987). Similar findings are reported for *O. vulgaris* by Robertson and Young (in preparation, cited by Michels et al., 1987) but unfortunately are unpublished as far as we know.

Wells (1978) published an alternative hypothesis worthy of mention based on the response of animals to an associative learning context. In his opinion, the sensorial inputs (visual system) reach the vertical lobe, where they are modulated on the basis of the effects of positive or negative signals (tactile system). Here the system is tuned to sensitize by raising or lowering the level of response on the basis of previous experiences. In this way, new information is added to the long-term cumulative experience, allowing short-term fluctuations and flexible and adaptive behavior (Wells, 1978).

The hierarchical control of motor patterns (described earlier) with lower (i.e., arms), intermediate (i.e., subesophageal), and higher (i.e., supraesophageal) motor centers (Boycott, 1961; Young, 1971, 1991) has been updated by experimental evidence (Plän, 1987). According to this view, different motor areas work in consensus, contributing to a more democratic concept of neuronal assembly. In other words, parallel central sensorimotor pathways cooperate synaptically to produce a given motor pattern (i.e., behavior; Plän, 1987), which appears to be similar to what has been shown in other invertebrates (for a review, see Getting, 1989; Leonard and Edstrom, 2004; Calabrese, 2007).

These models should be validated (hierarchical vs. democratic) in view of modern experimental approaches.

The compartmentalization (or certain modularity of the system) achieved by the multiple matrices may correspond well to the lifestyle adaptations of cephalopod species in different environments and niches (Nixon and Young 2003; **Figure 4**), as recently tested by combining ecological and neuroanatomical data (Borrelli, 2007).

As solicited in several occasions by Young himself (1985, 1995), a physiological investigation of the responses of the cells within the various regions of the brain is necessary to disclose the functional characteristics of the system. It is only relatively recently that attention has been focused on studies of this kind, starting from the pioneering studies on *S. officinalis* (Bullock and Budelmann, 1991) and *O. vulgaris* (Williamson and Budelmann, 1991) up to the latest findings of Hochner and coworkers (2003, 2006).

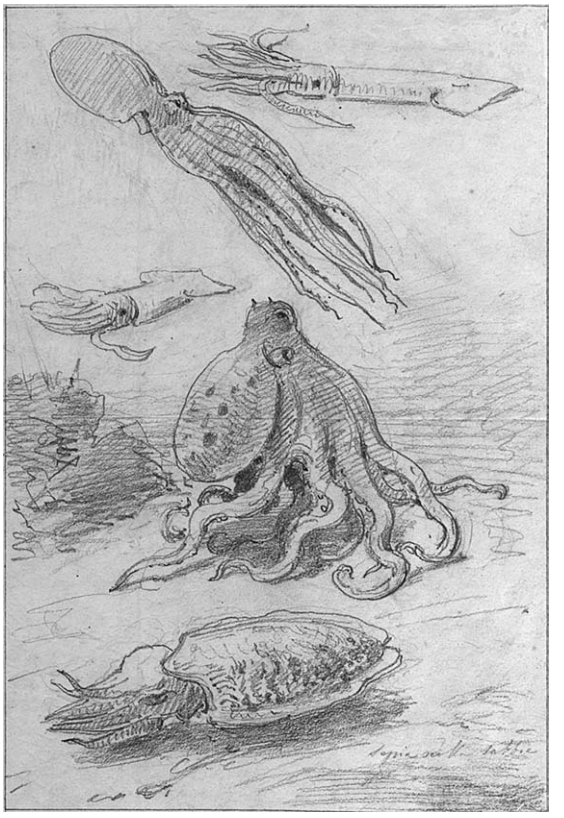

Figure 4 Old drawing by Comingio Merculiano (188?, unpublished) of octopuses (*Octopus vulgaris*), squids (probably *Loligo vulgaris*), and cuttlefishes (*Sepia officinalis*) expressing their different behavioral adaptations. Stazione Zoologica Archives, ASZN: Ua.I.506.

The most recent electrophysiological studies in the octopus confirm the view that convergent evolution has led to the selection of similar networks and synaptic plasticity in remote taxa (i.e., cephalopods and higher vertebrates), contributing to the production of complex behavior and learning capabilities (for review, see Hochner et al., 2006). A similar architecture and physiological connectivity of the vertical lobe system (i.e., median superior frontal and vertical lobes) of the octopus with the mammalian hippocampus, together with the large number of small neurons acting as interneurons, suggest a typical structure with high redundancy of connections working with en passant innervations. This makes it possible to create large-capacity memory associations (Hochner et al., 2003, 2006). However, the analogy between the octopus and mammalian systems is not complete, the major differences being in the morphological organization and biophysical characteristics (see a review in Bullock, 1965b; Williamson and Chrachri, 2004; Hochner et al., 2006).

Finally, it is important to underline that a system similar to *Octopus* has been found in *S. officinalis*, but with differences emerging at various levels (morphological, physiological, and behavioral; Agin et al., 2006a; Graindorge et al. 2006; B. Hochner, personal communication). The present results, although promising, must be taken with caution since they are preliminary at this stage.

Last, it is worth mentioning that a computer simulation model of the predatory response of *O. vulgaris* (attack behavior *sensu*: Maldonado, 1963a; Packard, 1963; for a review, see also Borrelli et al., 2006) has been developed (Clymer, 1973).

In the model, a mnemon (i.e., a visual feature with associated memory value resulting from experience; Young, 1965) is activated by a given visual input to a specific set of classifying cells and switched on/off on the basis of other inputs that depend on the taste–pain circuits. The output of these units (i.e., attack command) is summed up to produce an overall attack strength, in contrast to the opposite units (retreat command) that in a similar way build an overall retreat strength. These values (or strengths) are combined in the model and determine the final attack/retreat response (Clymer, 1973).

The model proposed by Clymer was based on the knowledge of *O. vulgaris*'s predatory behavior (also as a result of the discrimination experiments) as deduced by Young (1964, 1965) and Maldonado (1963b). Interestingly, the results produced from the model are comparable to those obtained from proper experiments with live animals, including the responses resulting from short- and long-term changes in behavior and interference on learning performance when spacing between trials is reduced in time (Clymer, 1973). In addition, the model has been recently reviewed and modified on the basis of the most advanced findings on neural networks and learning in simulated environments (Myers, 1992).

1.31.3 Learning in Cephalopods

Many reviews centered on the biology and learning capabilities of cephalopods have been published during the course of the last 50 years. An analysis of the literature indexed in both the Zoological Record and the Web of Science (from 1950 to 2007) selected roughly 100 reviews regarding the topic. Several other reference works (e.g., *The Mollusca* by Wilbur, 1983–1988) with chapters relevant to the subject must also be taken into consideration.

Over the last few decades, different workers have attempted to synthesize the knowledge on the behavioral biology of cephalopods and its flexibility (Packard and Hochberg, 1977; Hanlon, 1988; Mather, 1995, 2007; Boal, 1996; Messenger, 1996, 2001; Williamson and Chrachri, 2004; Borrelli et al., 2006; Hochner et al., 2006, to cite just a few). The most significant and comprehensive reviews published on cephalopod biology, learning, and memory are those by Young (1961), Sanders (1975), Wells (1978), Boyle (1986), and Hanlon and Messenger (1996).

In this chapter, we are deliberately not summarizing the information provided by the papers listed above, as this would necessarily result in redundancy. Our aim is simply to offer the reader with a general overview of what is known on the subject, which phenomena/mechanisms have been described and analyzed in detail, and which cephalopod species have been chosen as models for studies on the learning and memory capabilities of this taxon (**Table 1**). In the following pages, we focus our attention on the results and directions of the most recent advancements on the behavioral biology of learning and memory in cephalopods.

As thoroughly reviewed by Hanlon and Messenger (1996), various forms of learning (**Table 1**) have been demonstrated in cephalopods, from simple sensitization, to associative learning and problem solving, to more complex forms such as spatial and social learning and tool use. In essence, a large number of the entities proposed by Moore (2004) in his cladogram of learning processes have been shown in some of the 780 cephalopod species known to date. It is a pity that

Table 1 Breadth of the learning paradigms shown in cephalopods, by species[a]

Enteroctopus dofleini			√						
Eledone moschata			√		√				

[a]Data are arranged following Hanlon RT and Messenger JB (1996) *Cephalopod Behaviour*. Cambridge: Cambridge University Press. The learning capabilities (√) by species are deduced from reviews (Sanders GD [1975] The cephalopods. In: Corning WC, Dyal JA, and Willows AOD [eds.] *Invertebrate Learning. Cephalopods and Echinoderms*, pp. 1–101. New York: Plenum Press, and Hanlon RT and Messenger JB [1996] *Cephalopod Behaviour*. Cambridge: Cambridge University Press), with the exception of more recent findings (X) that are also described in the text. It is important to underline that certain paradigms, such as discrimination learning, are here classified as classical conditioning, although they could also be considered as cases of operant (or Thorndikian) conditioning (see Moore, 2004).

learning (and behavior) studies are still restricted to a limited number of representatives (**Table 1**). In fact, a detailed description of the behavioral repertoire is available for only roughly 30 species (review in Hanlon and Messenger, 1996; Borrelli et al., 2006). Another problem inherent to the cephalopod literature is that some phenomena have been relegated to anecdotal accounts (e.g., tool use: Power, 1857; Pliny the Elder, 1961) and that experimentally controlled observations on such capabilities remain to be done.

1.31.3.1 Sensitization

Following our everyday practice with octopuses, the daily presentation of food increases the chance of the animal attacking, so that its predatory performance (measured as the time to attack the prey from its appearance in the tank) improves with time. This is a clear case of sensitization, similar to what was tested empirically in the past by Wells and coworkers, who showed that food could enhance the probability to attack the stimuli (as much as shock depressed it; Wells, 1967a, cited in Hanlon and Messenger, 1996), or as was demonstrated in conditions where chemotactic behavior was studied (Chase and Wells, 1986).

This phenomenon has recently been confirmed in our laboratory for *O. vulgaris* following the classic acclimatization phase to the experimental setting. The continuous administration of a reward (food) over days improves the predatory performance that reaches a steady-state level during consecutive attacks. However, it is difficult to rule out whether different speeds in the attack curves (when interindividual variability is evaluated) may be related to food preferences, novelty, or familiarity toward food items, or to individual differences in the capability to cope with contextual learning processes, and so on (see also Section 1.31.4.1).

Finally, it could be extremely interesting to explore whether the relative length of time in the laboratory has an effect on octopuses' performance in a learning paradigm, say, for example, on the individual preferences in a simultaneous visual discrimination task. This concept should not be underestimated, also considering that as the positive learning process (see Section 1.31.4.1) proceeds with time, differences between individuals may be reduced to a few clear-cut responses and other characteristics of the subjects may emerge. Such processes may be easily extended to other cephalopods, although significant differences between species are expected as a result of different lifestyles and adaptive capabilities (for a review, see Packard, 1972; Nixon and Young, 2003).

1.31.3.2 Various Forms of Associative Learning

A new set of learning protocols (or variations on the theme) has recently been developed successfully in cephalopods. We provide a few examples below.

Painting quinine on the carapax of prey items (crabs, shrimps) was sufficient to show simple and rapid taste aversion learning in *S. officinalis* (Darmaillacq et al., 2004). This produced significant shifts in prey choice that were retained over the long term (for at least 3 days; Darmaillacq et al., 2004).

Calvé (2005) showed that the cutout of a bird (predator) gliding over individual cuttlefishes elicited startling reactions of different intensities. The startling stimulus significantly affected the cuttlefishes' hunting behavior, although evidence suggests that the animals habituated to it (Calvé, 2005).

Plastic spheres were utilized in successive visual discrimination tasks in order to test whether classical conditioning could change the species-specific predatory (or hunting) behavior; the results suggest that autoshaping occurs in *S. officinalis* (Cole and Adamo, 2005).

All the cases mentioned above represent innovations in the practice of learning studies with *Sepia* and clear additions to the classic prawn-in-the-tube training procedure pioneered by Sanders and Young (1940) and modified by successive authors (Wells, 1962; Messenger, 1973; see also Chichery and Chichery, 1992a,b; **Figure 5**). Notwithstanding, this procedure promoted a large number of studies on associative learning in the cuttlefish and on the biological machinery involved (e.g., Agin et al., 2000, 2001, 2003; Bellanger et al., 1997, 1998, 2003, 2005; Halm et al., 2003). Recent findings in *S. officinalis* strongly support the view that learning not to attack prey trapped in a transparent tube (inhibitory learning) corresponds to associative learning (Agin et al., 2006b; Purdy et al., 2006).

The number of training protocols available for *Octopus* is traditionally greater than for other species, mainly as a result of the animal's behavioral flexibility and feasibility of experimental studies with this species (see also **Table 1**). Moreover, recent protocols such as passive avoidance, additional problem-solving tasks (e.g., jars with multiple openings, black boxes; Borrelli, 2007), and even habituation tests have extended the repertoire of training paradigms that may be utilized to find answers to the fundamental question of how and to what extent *O. vulgaris* is capable of learning to modify its behavioral response.

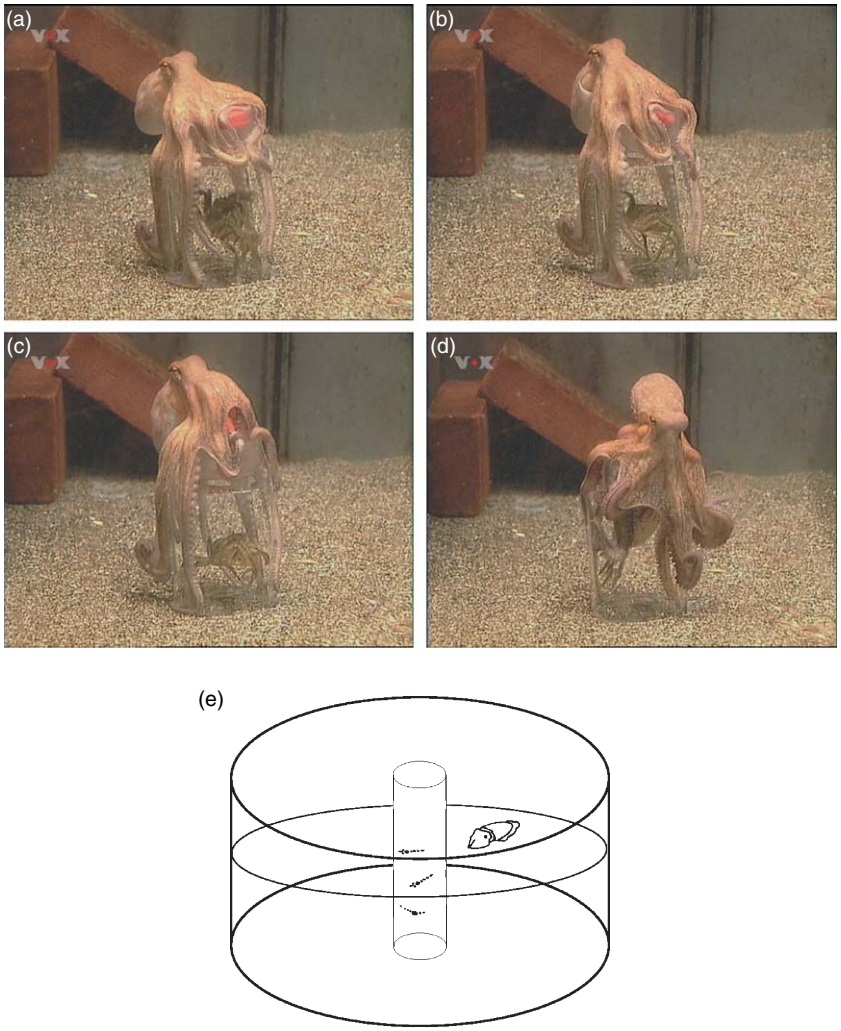

Figure 5 Two examples of classic tasks utilized to study learning and memory recall in *Octopus* and *Sepia*. (a)–(d) A sequence of frames taken from video recordings of the problem-solving experiment in *O. vulgaris* (classic jar). Courtesy of Mr. M. Schumacher, RS-Film. (e) A sketch of the prawn-in-the-tube protocol utilized with *S. officinalis* (after Wells MJ (1962) Early learning in *Sepia*. *Symp. Zool. Soc. Lond.* 8: 149–169).

1.31.3.3 Development of the Learning Capabilities

The prawn-in-the-tube protocol, which was and is still utilized to study associative learning in *S. officinalis*, disclosed important details on how cuttlefishes' behavioral plasticity changes during ontogeny. The analysis of this phenomenon made it possible to find significant correlations with the development (and maturation) of the neural circuitry, considered to play a role in the processing of behavioral responses and learned changes (Wells, 1962; Messenger, 1973; Chichery and Chichery, 1992a,b; Dickel et al., 1997, 1998, 2001; Agin et al., 2006a,c; for review see also Dickel et al., 2006).

In a similar way, the predatory efficiency of *Loligo* spp. on copepod swarms is reported to improve with age. It was found that the mastery of copepod capture develops progressively from the initial basic attack type up to more specialized strategies that effectively extend the range of capture to both longer and shorter distances, culminating in the adult-like prey capture behavior (Chen et al., 1996).

Similar changes of behavior with experience have also been described for octopuses; the optimization of the site and number of holes drilled in bivalve preys, for example, distinguishes juvenile from adult performance (see a review in Mather, 1995, 2007).

1.31.3.4 Spatial Learning

Spatial learning was originally tested in cephalopods using mazes, which led to a heated debate as to whether octopuses were capable or not of learning a detour (Bierens de Haan, 1926; Buytendijk, 1933; Schiller, 1949; Boycott, 1954; Wells, 1965a; but see Walker et al., 1970; Moriyama and Gunji, 1997).

During the last few decades, studies on the problem-solving abilities of these animals have been frequently confused and erroneously attributed to spatial learning processes (Piéron, 1911; Fiorito et al., 1990, 1998b; but for critiques, see Mather, 1995; Hanlon and Messenger, 1996).

Nevertheless, spatial learning *sensu stricto* has been shown in several species over the last few years. Apart from the pioneering studies of Mather (1991) on *O. vulgaris*, learning to orient and navigate in space is reported for *O. bimaculoides* (Boal et al., 2000a) and *S. officinalis* (Karson, 2003; Karson et al., 2003; Graindorge et al., 2006; Alves et al., 2007). However, our knowledge is probably underestimated relative to the large number of cephalopods that are known to cover short and/or long distances in space (e.g., Shevtsov, 1996; Sims et al., 2001; Arkhipkin and Middleton, 2002; Oosthuizen and Smale, 2003; Arkhipkin et al., 2004, 2006; Olyott et al., 2006; Smith et al., 2006; Watanabe et al., 2006; for a review, see also Hanlon and Messenger, 1996).

Such studies should be encouraged to increase our knowledge on the differences in the spatial capabilities among cephalopod species. In addition, this new avenue of research could facilitate comparative analysis to answer questions relative to the neural structures (i.e., the hippocampus and possibly the vertical lobe system; Graindorge et al., 2006) involved in the processing of such a sophisticated ability, as recently found in other animals (Jacobs, 2003; Frost and Mouritsen, 2006).

1.31.3.5 Other Learning Capabilities

Problem solving and social learning have mostly been studied in *O. vulgaris*. These learning paradigms have often been debated and criticized for not providing clear evidence of learning in these animals (Mather, 1995, 2007; Hanlon and Messenger, 1996; but see also Biederman and Davey, 1993; Suboski et al., 1993).

1.31.3.5.1 Problem solving

The task traditionally utilized to test the problem-solving capabilities of *O. vulgaris* (Fiorito et al., 1990), derived from the pioneering experiments by Piéron (1911), uses the well-known skills of octopuses with jars (Cousteau and Diolé, 1973). In the classic experiment, the animal is faced with a transparent glass jar, closed with a plug, containing a live prey. The octopus generally attacks the object at first glance, with the attack elicited by visual cues (the sight of the prey). The physical contact with the jar makes the animal switch to the tactile-driven exploration of the stimulus (**Figure 5**). While manipulating the jar, the octopus must solve two problems: the operandum (i.e., removing the plug by pulling), and the detour (i.e., the blind exploration of the inside of the jar with the arms to reach for the prey).

It was shown that octopuses spent significantly less time on the two motor components of the task with trials, thus suggesting that learning is involved in solving the problem (Fiorito et al., 1990, 1998b).

The switch between the two modalities (from visual to tactile) that controls and determines the octopus' performance in the task is not automatic and occurs at different instances in different animals. This further supports the view that learning of the task is required in order to sort out the motor programs (probably species specific) that are necessary to solve the paradigm. In fact, the pulling action, which is required by an animal dealing with the operandum, is already present in the species' behavioral repertoire, as the same technique is adopted by octopuses preying upon bivalves (McQuaid, 1994; Fiorito and Gherardi, 1999; Steer and Semmens, 2003). Moreover, the detour may be compared to the so-called speculative pounce (e.g., Yarnall, 1969), a common foraging strategy in which animals mostly use a tactile-driven manipulation and blind exploration of the sea bottom in search of edible items hidden under rocks or in crevices (for a review, see Hanlon and Messenger, 1996; Borrelli et al., 2006).

Different tasks (e.g., jars with multiple openings and boxes with drawers) have recently been designed to further explore *O. vulgaris*' problem-solving capabilities.

Similar objects could be used with other octopod species, facilitating comparative analysis of the taxon's behavioral flexibility. In addition, such tasks may provide more general information on the biological correlates involved in the two modalities (visual and tactile) that govern such behavioral responses.

1.31.3.5.2 Social learning

Fiorito and Scotto (1992) provided experimental evidence of social learning in *O. vulgaris*. They showed that naïve animals were able to discriminate and choose between two stimuli following observation

of trained conspecifics. The observer octopuses appeared to follow the model witnessed, and their choice seemed to be stable over time. The original work was replicated to test the role of the neural circuit considered to be involved in social learning (Fiorito and Chichery, 1995) and to study the attention and memory retrieval capabilities of this kind of learning after a pharmacological interference (Fiorito et al., 1998a).

The results of social learning in *O. vulgaris* were debated and criticized in a number of publications (e.g., Biederman and Davey, 1993; Hanlon and Messenger, 1996).

Future studies are required to reply to the many questions that remain open on this peculiar learning capability, since it is possible that certain other factors may act in favor of or against the outcome of the observation of the conspecific's behavior by naïve observers (e.g., reproductive drive, social dominance, territoriality; for review, see also Boal, 2006). This, at least, appears to be the case in *S. officinalis*, where social experience promotes (Warnke, 1994) or inhibits (Boal et al., 2000b) social facilitation in the feeding behavior of cuttlefishes, probably depending on the relative age of the animals.

1.31.4 Neglected Issues in the Study of Cephalopod Learning

As amply discussed above, most of our knowledge on the learning capabilities and memory recall in cephalopods derives from experiments conducted in the laboratory, the sole exception being the field studies on *O. vulgaris* carried out in the waters of Bermuda (Mather, 1991; Mather and O'Dor, 1991). Mather and colleagues demonstrated that octopuses acquire information and keep memories of their surroundings to navigate during foraging trips (i.e., spatial learning; Mather, 1991; see also Hanlon and Messenger, 1996; Forsythe and Hanlon, 1997). Moreover, *O. vulgaris* is capable of behavioral plasticity in lifestyle resulting from changes in foraging needs and predation pressure (Mather and O'Dor, 1991).

Despite the growing number of publications on the habits and adaptive responses of cephalopods in the wild (e.g., Smale and Buchan, 1981; Moynihan and Rodaniche, 1982; Roper and Hochberg, 1988; Mather and Mather, 1994; Hanlon et al., 1999), our inference on learning in cephalopods is still largely biased by laboratory evidence. Whether this is the result of the behavioral flexibility (neural and behavioral) of the cephalopod system to the new context (captive situation), or whether it corresponds to the animals' real needs in the wild, still remains an open question.

1.31.4.1 Effect of Acclimatization: Contextual Learning

Following capture, the animals are generally immediately brought by the fishermen to the laboratory, where they are exposed to the experimental setting (i.e., a novel environment). In the case of an octopus, the animal is thus constrained to a tank that represents a foraging area about 300 times smaller than that required by the animal in natural conditions. In addition, the scenery to which the animal is exposed is somewhat dull and uniform, independent of whether it is designed to provide an enriched or an impoverished environment (e.g., Dickel et al., 2000; Anderson and Wood, 2001; Poirier et al., 2004). We may therefore hypothesize that the new context has only a poor resemblance to the seascape the cephalopod had experienced until then.

This is true not only for octopuses but also for other cephalopod species. A rough analysis of the literature on cephalopods published over the last 10 years has provided exhaustive examples and confirms this view.

The animal must adapt to this novel environment, which is achieved in a variable amount of time and is generally referred as acclimatization. During the acclimatization phase, a common practice is to expose cephalopods to live prey (for exceptions, see, e.g., Boletzky and Hanlon, 1983; Boal, 1993; Koueta et al., 2006), not only to maintain the animals in captivity but also to test their recovery in motivation to attack (i.e., well-being; for a review, see Boyle, 1991). In addition, the animals are exposed to experiments that study their predatory behavior (attack/not attack or take/reject responses). Thus, they must be able to face the task and plastically adapt their species-specific predatory behavior to the new context. As already mentioned above, this phase takes a variable length of time and depends (from species to species) on the animals' previous experience, the individual variability resulting from biological and possibly ecological factors (differences in age, sex, maturity, etc.), and the common practice of experimenters, to cite a few examples.

It has been recently demonstrated that during the acclimatization phase, the animal is exposed to a positive learning process, which is a form of contextual learning. As described by Maldonado (1963a,b, 1964), at the beginning of acclimatization (or

training), the time spent by an octopus to attack the stimulus is relatively long, and the behavior (in terms of types of attack) is highly variable. However, as the animal becomes more and more accustomed to the experimental setting (or paradigm), its attacks on the stimulus become faster and faster, a process known as the positive learning process. Moreover, this reduces the types of attack curves to nearly a stereotype, that is, the full attack in the octopus (Maldonado, 1963a; Packard, 1963) and the tentacle attack in decapods (e.g., *S. officinalis*: Messenger, 1968; *Loligo vulgaris*: Neill and Cullen, 1974; *L. pealeii* and *L. plei*: Kier, 1982; *Illex illecebrosus*: Foyle and O'Dor, 1988).

In sum, during the positive learning process (*sensu* Maldonado, 1963a), behavioral syndromes are generally reduced to a few broad types representing populational differences (within a species). These differences are recognized to play important ecological and evolutionary roles, mainly during the adaptation to environmental changes (Sih et al., 2004a,b).

In addition, there is evidence in *O. vulgaris* that this phenomenon is directly linked to a more general form of contextual learning, as recently shown in other invertebrates (e.g., Tomsic et al., 1998; Liu et al., 1999; Haney and Lukowiak, 2001; Menzel, 2001; Law et al., 2004; Skow and Jakob, 2006; Zhang et al., 2006).

A series of factors may interfere in this process, such as:

- The time of day at which the experiment is conducted (which does not necessarily correspond to the animal's peak of activity in natural conditions);
- The feeding regime;
- The experimental setting to which the animal is exposed; and
- The prey types utilized in captivity that do not necessarily correspond to those fed upon in the wild.

Concerning this last point, for example, the animals' performance in the new context may be affected by individual dietary preferences derived from previous feeding habits (e.g., for *S. officinalis* Darmaillacq et al., 2006), which have also been shown to influence the performance in visual and tactile discrimination tasks during associative learning (e.g., for *O. vulgaris*: Messenger and Sanders, 1972; Bradley and Messenger, 1977).

1.31.4.2 Neophobia/Neophilia and the Shy–Bold Continuum

Another neglected issue in the study of learning in cephalopods is whether novelty may interfere with the animals' decision-making processes (Greenberg and Mettke-Hofmann, 2001). In other words, familiar objects or prey types should be preferred to novel ones, and the natural exploratory drive, connected to cephalopods' voracious appetite, should be reduced by the presence of novel stimuli.

In *O. vulgaris*, for example, the behavioral flexibility (in terms of learning capabilities) of this species corresponds to ecological plasticity, where opportunistic behaviors and reduced neophobia are exhibited (see also Section 1.31.2.3). *O. vulgaris* seems to show less feeding specialization and a higher versatility in foraging than other cephalopods. This appears to be related to the changes in the lifestyle during ontogeny (Hanlon and Messenger, 1996; Nixon and Mangold, 1998) and to the frequent horizontal and vertical migrations by the different age classes moving in the water column (e.g., Oosthuizen and Smale, 2003). Therefore, octopuses have to deal with different environments both at a small and a large time scale (seasons and life history, respectively) that expose them to potentially different degrees of complexity. Under such circumstances, a low neophobia is expected for *O. vulgaris*, as results from current experimental work.

On the other hand, ecological stereotypy may favor individuals (or species) that contrast novel situations by exhibiting less flexible behaviors. This should be investigated.

A consequence of the neophobia/neophilia behavioral types discussed above, at any level (from the individual to the species), leads to the shy–bold continuum (or in the cephalopod sense, to the approach–withdrawal axis *sensu*; Packard, 1963). This has been shown in several cephalopods: *S. officinalis* (Hanlon and Messenger, 1988; Calvé, 2005), *Euprymna tasmanica* (Sinn and Moltschaniwskyj, 2005), *O. vulgaris* (Packard, 1963; Borrelli, 2007), and *O. rubescens* (Mather and Anderson, 1993).

As described by Calvé (2005), cuttlefishes are classified as shy when they mostly remain inactive and when, following stimulation, respond by inking and jetting away. At the opposite end of the spectrum, bold animals appear active in the tank and interact more with humans (i.e., are tame; Buytendijk, 1993; Hochner et al., 2006). Of course, individuals will respond differently to the same tests on the basis of whether their behavioral traits tend more toward one or the other of the opposite shy–bold extremes of the axis.

Similar findings have been shown for *O. rubescens*, where individuals were classified into three major

behavioral components (activity, reactivity, avoidance; Mather and Anderson, 1993).

As already mentioned, the individual differences of behavioral traits in cephalopods confirm the phenomenon to be widespread among different taxa, ranging from invertebrates to vertebrates (e.g., Armitage, 1986; Kagan et al., 1988; Coleman and Wilson, 1998; López et al., 2005; Mettke-Hofmann et al., 2005a; for a review, see also Gosling, 2001; Sih et al., 2004b; Mettke-Hofmann et al., 2005b).

In planning future studies testing neophobia/neophilia in cephalopods, the importance of population differences (i.e., genetic polymorphism) and individual experience on environmental factors should be considered, as has been done in other animals. For example, it could be interesting to test how the response of individuals captured with different fishing methods in the wild would appear along the shy–bold continuum in laboratory conditions, taking advantage of what is known in the pumpkinseed sunfish (Coleman and Wilson, 1998). Moreover, Coleman and Wilson (1998) discovered that animals that behaved boldly in threatening contexts did not act necessarily the same when exposed to novel foods (i.e., foraging contexts). Would it not be intriguing to find similar – or even contrasting – results in cephalopods?

1.31.5 Memory in Cephalopods

Despite the considerable number of studies published on the extent of memory recall and on the effects of its impairment induced by experimental interference (for a review, see Sanders, 1975; Wells, 1978), very little is known on the ability of cephalopods to encode and retrieve information.

From the classic works of Sanders and Young (1940) and Schiller (1949), it was shown that cuttlefishes and octopuses are capable of short- and long-term memory, although differences emerged between the two species and among paradigms (**Table 2**).

It is astonishing that in many cases the memory trace was reported to last for a very long time (e.g., in octopus for weeks, according to Boal, 1991; Fiorito and Scotto, 1992; for months, according to Sanders,

Table 2 Summary of studies on the time course of memory recall in *Sepia officinalis* (*So*) and *Octopus vulgaris* (*Ov*)

Paradigm	*Species*	*Training*	*STM*	*MTM*	*ARM*	*LTM*	*PSD*	*Refs*
Prawn-in-the tube	*So*	1-t	20 m			48 h		6
Prawn-in-the tube	*So*	1-t	5 m					7
Prawn-in-the tube	*So*	1-t				24 h	+	8
Prawn-in-the tube	*So*	Spaced				24 h		6
Instrumental conditioning	*So*	Spaced				14 d		10
Avoidance	*So*	Spaced				3 d		9
Classical conditioning	*Ov*	Massed				2 d		2
Classical conditioning	*Ov*	Massed				2 d		4
Classical conditioning	*Ov*	Massed				24 h	–	11
Classical conditioning	*Ov*	Spaced				4 w		1
Classical conditioning	*Ov*	Spaced				16 w		3
Avoidance	*Ov*	Massed	1h	8 h		1 d		5
Avoidance	*Ov*	Massed			+	24 h	–	11

Different learning paradigms and training procedures with different intervals (massed vs. spaced) or length (single trial, 1-t vs. training to criterion) produce memories of variable time span. Moreover, the extent of the recall at each stage (STM, short term; MTM, medium term; LTM, long term) has not been systematically measured by each of the cited papers (see following, so a blank cell stands for missing data. Finally, only a handful of studies have addressed questions on whether long-term memory is anesthesia resistant (ARM; +, resistance) or protein synthesis dependent (PSD; + dependence; – no effect). Time units are as follows: minutes (m), hours (h), days (d), weeks (w). The references (Refs) included are: 1. Sutherland, 1957a, cited in Sanders GD (1975) The Cephalopods. 1970). Many unpublished observations carried out in our laboratory confirm this view. However, it was found that this remarkably long memory trace is not common to all individuals that learn a given task (Sanders, 1970). The reasons behind this surprising result of only certain individuals having a particularly long memory should be further investigated.

Unfortunately, the systematic analysis of the memory phases (**Table 2**), together with the time course of retention and memory consolidation (and perhaps reconsolidation), in cephalopods remains insufficient, especially when compared with the knowledge currently available for other taxa (for a review, see, e.g., McGaugh, 2000; Dudai, 2004).

Whether the memory recall observed in cephalopods corresponds to a more phylogenetically conserved consolidation mechanism is an issue that has been tested in *O. vulgaris* using several approaches (Maldonado, 1968, 1969; Zarrella, unpublished data). The data suggest that the establishment of long memory traces, to learn conditioned or associative responses, is maintained in *Octopus* following anesthetic treatments and protein synthesis inhibition (Zarrella, unpublished data) applied before or after training (massed intervals). In contrast, electroconvulsive shocks cause significant deficits in retention of previously learned paradigms (spaced intervals: Maldonado, 1968, 1969).

Moreover, protein synthesis inhibition was found to impair memory recall for the prawn-in-the-tube protocol in *S. officinalis* (Agin et al., 2003).

The above studies, although limited in number and species studied, show how promising it could be to test the role of the biological machinery in the establishment of long-term memories in cephalopods, especially when considering the contrasting evidence between species that has emerged so far.

1.31.6 Concluding Remarks

Whoever has had the chance to interact with a cephalopod, in the tank or at sea, remains struck by the richness of its behavioral repertoire, its distinct personality traits, and its penetrating gaze, which make it an extraordinary and fascinating creature. There is no doubt that cephalopods are learning animals, although it is difficult to give an objective view of the variety and extent of their learning capabilities.

What is still lacking in the field is more communication and exchange of ideas among cephalopod researchers and the focus on common aims or objectives that could strengthen the work in these animal models. The contribution to the knowledge of the behavioral biology in cephalopods should not be restricted to a handful of workers but be of interest to a greater number of scientists.

Through our behavioral analysis of learning and memory in cephalopods, we hope to have contributed to increasing the understanding and scientific interest and awareness of these animals.

As a last note, the study of cephalopods, despite the long historical tradition, suffers from the lack (or incomplete) availability of tools that are now available for other invertebrate models (such as *Apis*, *Aplysia*, *Caenorhabditis*, and *Drosophila*). The approach and direction of studies such as those pioneered and masterly conducted by Maldonado and coworkers on *Chasmagnathus* should be the example (see the review in Romano et al., 2006). The recent work on *Octopus*' genomics (Ogura et al., 2004; Choy et al., 2006) has contributed outstanding results that give us hope for the future.

Acknowledgments

Research in our laboratory was partly supported by Istituto Banco di Napoli, Fondazione.

1.32 Behavioral Analysis of Learning and Memory in *C. elegans*

A. C. Giles and C. H. Rankin, University of British Columbia, Vancouver, BC, Canada

1.32.1 Introduction

Caenorhabditis elegans was first developed as a model system by Sydney Brenner in the 1960s, with the goal of having a simple multicellular system in which to study the cellular and molecular mechanisms of development using modern genetic and molecular biological techniques. *C. elegans* is a 1-mm soil-dwelling nematode. In the laboratory it lives on a bacterial lawn of *Escherichia coli* in an agar-filled Petri dish. Brenner, along with John Sulston, who mapped the complete cell lineage of the organism, and Robert Horvitz, who elucidated the first programmed cell death mechanisms, won the Nobel Prize in Physiology or Medicine in 2002 for this work. For our purposes *C. elegans* is an excellent model for studying the behavioral, cellular, and molecular mechanisms involved in learning and memory.

Rankin et al. (1990) were the first to recognize *C. elegans* as a model for learning and memory when they showed that *C. elegans* is capable of both short- and long-term memory for the nonassociative form of learning known as habituation. Since 1990, many labs have investigated a variety of types (i.e., mechanosensory, chemosensory, and thermosensory) of both nonassociative (habituation) and associative learning (classical conditioning) in *C. elegans*. As a model of the cellular and molecular mechanisms of learning and memory *C. elegans* has many advantageous qualities. Composed of only 302 neurons, with only 5000 synaptic connections, all of which are identified, the *C. elegans* nervous system offers an opportunity to study a system in which all the neurons that mediate a learned behavior or memory can be identified (keep in mind that even the simplest mammals have nervous systems containing millions of neurons, between which are billions of synaptic connections). *C. elegans* can serve as a model of the mammalian nervous system because many of the elements that constitute the *C. elegans* nervous system are homologous to those of mammals, and these elements are incorporated into conserved pathways for many cellular functions, such as neurotransmission and intracellular signaling. *C. elegans* is an excellent subject for techniques that probe into cellular mechanisms because they have a short life cycle, they live in clonal populations, and their bodies are transparent. Because of this transparency, manipulations of the neural circuitry can easily be performed using techniques such as laser ablation. In addition, the worm's genome has been sequenced; there are thousands of identified mutants available for analysis, and there is a knockout consortium that accepts gene knockout requests at no cost. Finally, and most importantly for this chapter, *C. elegans* exhibits well-described and measurable behaviors, and these behaviors can change with experience.

It is absolutely crucial to understand the behavioral characteristics of learning and memory in *C. elegans* to properly elucidate the molecular mechanisms involved. The focus of this chapter is the behavioral analysis of the different types of learning and memory that have been discovered in *C. elegans*; however, we also briefly touch on how these behavioral studies have already begun to help elucidate cellular and molecular mechanisms of learning and memory. In the first section, we discuss how *C. elegans* changes with the experience of individual stimuli that it encounters in its environment, such as a mechanical tap or exposure to a certain chemical stimulus. The second section is an overview of how *C. elegans* learns to predict the presence of food using cues like chemical concentration and temperature. The third and final section reviews how *C. elegans* learns to avoid harmful stimuli such as pathogenic bacteria.

1.32.2 Learning about the Environment

During an organism's life, it is constantly bombarded with stimuli. To be successful, it needs to allocate energy, resources, and attention appropriately. One way to achieve this is by learning to ignore stimuli that are irrelevant, thereby avoiding the waste of energy caused by unnecessary responses; this is known as habituation. More objectively, it is a decrease in response to an irrelevant stimulus over repeated stimulation (Groves and Thompson, 1970). Habituation is considered a nonassociative form of learning. This phenomenon can be distinguished from decreases in response resulting from sensory adaptation or motor fatigue (or both) by the process of dishabituation. Dishabituation is achieved by following habituation training with a novel or noxious stimulus, such as electric shock used for dishabituation of the gill withdrawal response in *Aplysia* (Carew et al., 1971). If a habituated animal is given a dishabituating stimulus, its response to the initial stimulus will immediately increase above the habituated level. In contrast, sensory adaptation or motor fatigue will only recover after a period of rest.

1.32.2.1 Mechanical Stimuli

In its natural environment, *C. elegans* can sense mechanical forces that might include bumping into subterranean obstacles in their path of travel, bumping into other similarly sized organisms, or even vibration of the surrounding environment from a close encounter with a larger organism. In the laboratory, these stimuli can be mimicked by touching the anterior or posterior body with a hair or by a discreet tap to the side of the Petri dish in which they live. To study habituation, the latter of these stimuli was used because the frequency and intensity of the stimulus could be easily controlled and manipulated. *C. elegans* responds to this stimulus with a reversal, which is called the tap withdrawal response (Rankin et al., 1990). When this stimulus was repeated at a constant interstimulus interval (ISI) of 10 s, the magnitude of the response significantly decreased over a period of 40 stimuli (Rankin et al., 1990). An analysis across 60 trials showed that habituation consisted of an initial steep downward slope of decreasing response magnitude during the first 10–20 stimuli, followed by a relatively flat asymptotic stage for the remainder of the stimuli (Rankin and Broster, 1992). The response to tap was also measured at various time intervals (30 s, 10 min, 20 min, and 30 min) after the 60th stimulus, and it was observed that the response magnitude spontaneously recovered over time (Rankin and Broster, 1992). Dishabituation was observed by applying an electrical shock to the agar near the worm immediately after the taps; response magnitude to subsequent taps significantly increased (Rankin et al., 1990). Dishabituation indicates that the response decrement observed after repeated stimuli was in fact habituation and not a form of sensory adaptation or motor fatigue.

The most important procedural factor that affects habituation of the tap withdrawal response in *C. elegans* is the length of the ISI. Short ISIs (i.e., 10 s) produced steep slopes in the initial stage of habituation and very low asymptotic levels of response during the second stage, whereas long ISIs (i.e., 60 s) produced shallow slopes and high asymptotic levels (Rankin and Broster, 1992). Variations in ISI also affected the spontaneous recovery after habituation; spontaneous recovery was faster and more complete after short ISIs than after long ISIs (Rankin and Broster, 1992). This was an important finding because it provided an alternate and more elegant way to distinguish habituation from sensory adaptation and motor fatigue than dishabituation, which can be quite variable. The rate of recovery following sensory adaptation or motor fatigue is determined by the degree of decrement, and so greater decrement, which is observed at short ISIs, would take

longer to recover than long ISIs, and this is opposite to what is observed after habituation.

Rankin and Broster (1992) investigated the effects of habituation level, achievement of the asymptotic level, and number of missed stimuli before the recovery test on the rate of spontaneous recovery. To test the effects of habituation level, they set a criterion for the level of decrement *C. elegans* had to reach before recovery began, regardless of ISI. *C. elegans* stimulated at a 10 s ISI achieved the criterion level after fewer stimuli than those tapped at a 60 s ISI; however, the 10-s ISI group still showed faster and more complete spontaneous recovery than the 60-s ISI group, even though they were habituated to the same response level.

Although the level of habituation did not affect spontaneous recovery, whether *C. elegans* had reached the asymptotic stage of habituation was found to be an important factor. *C. elegans* that reached asymptote after only 8 stimuli recovered at the same ISI dependent rate as worms that had received 60 stimuli (Rankin and Broster, 1992). This result supports the idea that reaching the asymptotic level of habituation is an important factor in determining rate of spontaneous recovery, but the number of stimuli an animal experiences after reaching the asymptotic stage has very little effect on the spontaneous recovery of the behavior.

Finally, Rankin and Broster (1992) tested how the number of missed stimuli affected recovery. For example, at the 10-min recovery test worms habituated at a 10-s ISI would have missed 60 stimuli, whereas worms habituated at a 60-s ISI would only have missed 10 stimuli. Spontaneous recovery of *C. elegans* trained at a 10-s ISI still showed significantly greater recovery at 5 min (30 missed stimuli) compared to worms trained at a 60-s ISI after 30 min of recovery (also 30 missed stimuli; Rankin and Broster, 1992). Therefore, ISI length is a crucial factor for both habituation and spontaneous recovery from habituation in *C. elegans*, regardless of the habituated level, the number of stimuli (as long as asymptote is achieved), or the number of missed stimuli during recovery.

The purpose of studying *C. elegans* as a simple model of learning is to be able to more easily research questions involving the cellular and molecular mechanisms that mediate learning. These behavioral analyses have created a foundation that can now be used to conduct this investigation. In fact, one of the most important mechanistic hypotheses regarding habituation has been identified by these behavioral analyses: That is, that habituation is not a single process but, instead, habituation at different ISIs must be mediated at least in part by different mechanisms (Rankin and Broster, 1992). This hypothesis has been supported by the identification of mutations that selectively disrupt habituation at either short or long ISIs, but not both (*See* Chapter 4.04).

The neural circuit that mediates the tap withdrawal response has been described in detail (Wicks and Rankin, 1995). It consists of five sensory neurons and four pairs of command interneurons; the most likely site for plasticity has been identified as the chemical synapses between the mechanosensory neurons and the command interneurons within the circuit (Wicks and Rankin, 1997). The chemical synapses between these sensory neurons and interneurons, as well as some of the synapses between interneurons, are glutamatergic (Brockie and Maricq, 2006), suggesting a possible role for glutamate in habituation. This was confirmed by a study that found that mutants that lack a glutamate vesicular transporter (*eat-4*), which is important for loading vesicles ready for neurotransmission, showed abnormal habituation (Rankin and Wicks, 2000). Recently, dopamine has been shown to play a role in habituation because mutants with disrupted dopamine neurotransmission (*dop-1* and *cat-2*) show abnormal habituation (Sanyal et al., 2004). Together these results are of general interest because glutamate–dopamine interactions have been noted in other animal learning and are associated with human disorders that are usually associated with learning and memory deficits (Palomo et al., 2004; David et al., 2005). More research is necessary to fully understand the mechanisms of habituation; however, it is clear that glutamate, dopamine, and the synapses between the mechanosensory neurons and the command interneurons are important for habituation of the tap withdrawal response in *C. elegans*.

So far this section has focused on the short-term effects of habituation to a mechanosensory stimulus. Under the right conditions *C. elegans* can also show long-term memory for this mechanosensory habituation. This was first observed by Rankin et al. (1990) and then studied in more detail by Beck and Rankin (1995, 1997) using a protocol adapted from a study of long-term memory for habituation, in *Aplysia*. Beck and Rankin (1997) investigated the parameters necessary for long-term memory for habituation in *C. elegans*. They tested distributed training, which features a number of blocks of stimuli separated by hour-long rest periods, and massed training, in which the same number of stimuli is administered without

any rest periods (a longer single block). Distributed versus massed training appears to be a fundamental feature of memory because it has been shown to enhance long-term memory in many other training paradigms in a number of other organisms, such as habituation in *Aplysia* (Carew et al., 1972), classical conditioning in *Drosophila* (Tully et al., 1994), and memorization of lists of nonsense syllables in humans (Ebbinghaus 1885). The ISI within blocks was either 10 s or 60 s, and the number of taps varied between 40 (10 per block) and 60 (20 per block). Only distributed training at a 60-s ISI with either 40 (4 blocks of 10 taps) or 60 (3 blocks of 20 taps) stimuli was capable of reliable expression of memory 24 h after training. In general, more stimulation (60 stimuli) was better at producing long-term memory than less stimulation (40 stimuli). Beck and Rankin (1997) concluded that training protocols with a high total number of stimuli, long ISIs, and distributed training produced significant long-term memory of habituation in *C. elegans*.

One very important aspect that defines long-term memory and helps distinguish it from shorter forms is the fact that the mechanisms that store long-term memory are protein synthesis dependent. Long-term memory for habituation in *C. elegans* was found to be protein synthesis dependent by a set of heat shock experiments (Beck and Rankin, 1995). Heat shock is a technique that can block protein synthesis in the worm because at high temperatures (32 °C), all nonessential protein synthesis is stopped to give way to the synthesis of a set of heat shock proteins important for protection against cellular stress (Lindquist, 1986). Heat shock for the first 45 min during each of the 1-h rest periods of the long-term protocol blocked the formation of the long-term memory without disrupting the short-term effects of habituation (Beck and Rankin, 1995). Heat shock immediately prior to training or testing had no effect on long-term memory formation. This suggests that the protein synthesis that is taking place during the rest periods after each training block leads to consolidation of long-term memory for habituation of the tap withdrawal response in *C. elegans*. Interestingly, 15 min of heat shock exposure during either the first 15 min of the period or the second 15 min of the period is enough to disrupt the formation of long-term memory, whereas heat shock during the last 15 min of the rest period had no effect (Beck and Rankin, 1995). This suggests that the protein synthesis portion of the molecular mechanism responsible for the formation of long-term memory takes place during the first 30 min after each training block.

The consolidation of this long-term memory is not always permanent. If the memory is recalled by 10 reminder taps 24 h after the training, the memory becomes labile and must undergo consolidation again (Rose and Rankin, 2006); this is known as reconsolidation (Nader et al., 2000). By blocking protein synthesis immediately after the reminder, the memory is lost; nontrained worms showed similar responses to the trained worms 48 h after training (24 h after reminder). Protein synthesis blockade 24 h after training in the absence of a set of reminder taps has no effect on the long-term memory; trained animals had significantly lower magnitudes of response than nontrained animals.

Similar to short-term habituation, glutamate appears to be an important molecule for the consolidation of long-term memory. Mutants with defective glutamate neurotransmission (*eat-4* and *glr-1*) cannot form long-term memory for habituation, and pharmacological agents that disrupt glutamate neurotransmission block the formation of long-term memory (Rose et al., 2002, 2003). Also, pharmacological blockade of glutamate neurotransmission during 10 reminder taps 24 h after training blocks the reconsolidation of the long-term memory (Rose and Rankin, 2006). A subunit of an AMPA-like glutamate receptor (*glr-1*) appears to play an especially important role in the mechanism of long-term memory consolidation, as its expression, assessed by quantitative measurements of a GLR-1::GFP fusion construct using confocal imaging, was significantly decreased 24 h after the administration of the long-term memory protocol, which strongly correlates with the observed behavior (Rose et al., 2003). Similarly, GLR-1::GFP levels return to nontrained levels if reconsolidation is disrupted following a reminder 24 h after training (Rose and Rankin, 2006), again directly correlating with the behavior. This evidence supports the idea that the level of expression of these glutamate receptors mediates the level of response to tap, and a portion of the mechanism that mediates the long-term memory is a downregulation of expression of these receptors.

In summary, both short- and long-term habituation of the tap withdrawal response in *C. elegans* have been well characterized at the behavioral level. This behavioral analysis has been an important foundation on which to build a strong investigation for the mechanisms that mediate it, and a number of clues into this mechanism have been uncovered.

1.32.2.2 Chemical Stimuli

The first evidence that behavioral responses to chemical cues are also plastic in *C. elegans* was olfactory adaptation (Colbert and Bargmann, 1995). Usually, *C. elegans* exposed to a concentration gradient of a chemical (such as benzaldehyde and diacetyl) will move up the concentration gradient toward the chemical stimulus. This is known as chemotaxis and is usually measured by placing a group in a gradient and observing the fraction that migrates toward the stimulus. If *C. elegans* is exposed to a strong uniform concentration of the chemical prior to the chemotaxis assay, the fraction that migrates toward the stimulus significantly decreases, indicating that *C. elegans* decreases its response to the chemical stimulus after the preexposure treatment (Colbert and Bargmann, 1995).

This decrease was assumed to always be adaptation until Wen et al. (1997) first suggested it was possible to see habituation to a chemical stimulus by using a longer preexposure with a relatively weaker concentration than that used in the sensory adaptation paradigm. They used solubilized Na^+ as the chemical stimulus and found that a smaller number of *C. elegans* migrated toward the Na^+ spot during the chemotaxis assay compared to naïve controls. Importantly, this decrease in approach behavior could be immediately reversed or dishabituated by a short exposure to a high concentration of Na^+ solution, indicating that the change in approach behavior was habituation and not fatigue.

Bernhard and van der Kooy (2000) investigated the difference between chemosensory habituation and adaptation by using various preexposure concentrations. High preexposure concentrations of diacetyl (like those used in the sensory adaptation paradigm) led to a chemotaxis decrement that is irreversible, whereas low concentrations caused a decreased chemotaxis response that was immediately reversible by a dishabituating stimulus. These results suggest that habituation to chemical stimuli can occur in *C. elegans*; however, unless tests for dishabituation are done, the results observed in the sensory adaptation paradigms cannot be considered habituation. Similar to mechanosensory habituation, chemical habituation to diacetyl requires normal glutamate neurotransmission because *C. elegans* mutants lacking the AMPA-type glutamate receptor subunit *glr-1* are not capable of diacetyl habituation (Morrison and van der Kooy, 2001). This is an interesting similarity, but more research needs to be conducted to understand whether the mechanism for habituation is conserved across sensory modalities.

1.32.2.3 Context Conditioning for Habituation

Although habituation and other forms of nonassociative learning are initially dependent only on a single stimulus, later learning concerning the same stimulus can be dependent on environmental conditions during the initial training session (Wagner, 1976, 1978, 1979). One example of this is context conditioning in which there is greater retention of the initial learning during a later training session if some contextual cue was present in the environment during both the initial and later training sessions. This has been observed in a number of organisms, including rats (Evans and Hammond, 1983), crabs (Tomsic et al., 1998), and *Aplysia* (Colwill et al., 1988). *C. elegans* is also capable of such context conditioning using habituation of the response (Rankin, 2000). Worms habituated in the presence of sodium acetate showed greater retention of habituation during a later habituation session only if they were also exposed to sodium acetate during the second session (**Figure 1**(**a**) and (**b**)). It was very important that the worms experience this contextual environment only during the habituation sessions to form the association, as Rankin (2000) showed that if this was not the case, latent inhibition and extinction blocked the enhanced learning (**Figure 1**(**c**)). Latent inhibition occurs when the animal is preexposed to the contextual cue for a period of time before it is used in training. When *C. elegans* was exposed to the sodium acetate for 1 h prior to habituation training, there was no difference between the initial training session and the later test session. Extinction occurs when the contextual cue remains present in the absence of habituation after the initial training. This was done by leaving the worms on sodium acetate between the training session and the test; no difference was observed between sessions in this case either. Finally, reverse context conditioning was observed when worms were reared on sodium acetate plates and then trained and tested on normal growth medium (**Figure 1**(**c**)). Therefore, *C. elegans* is capable of associating a chemical concentration with habituation of the tap withdrawal response, and this context conditioning is sensitive to latent inhibition and extinction.

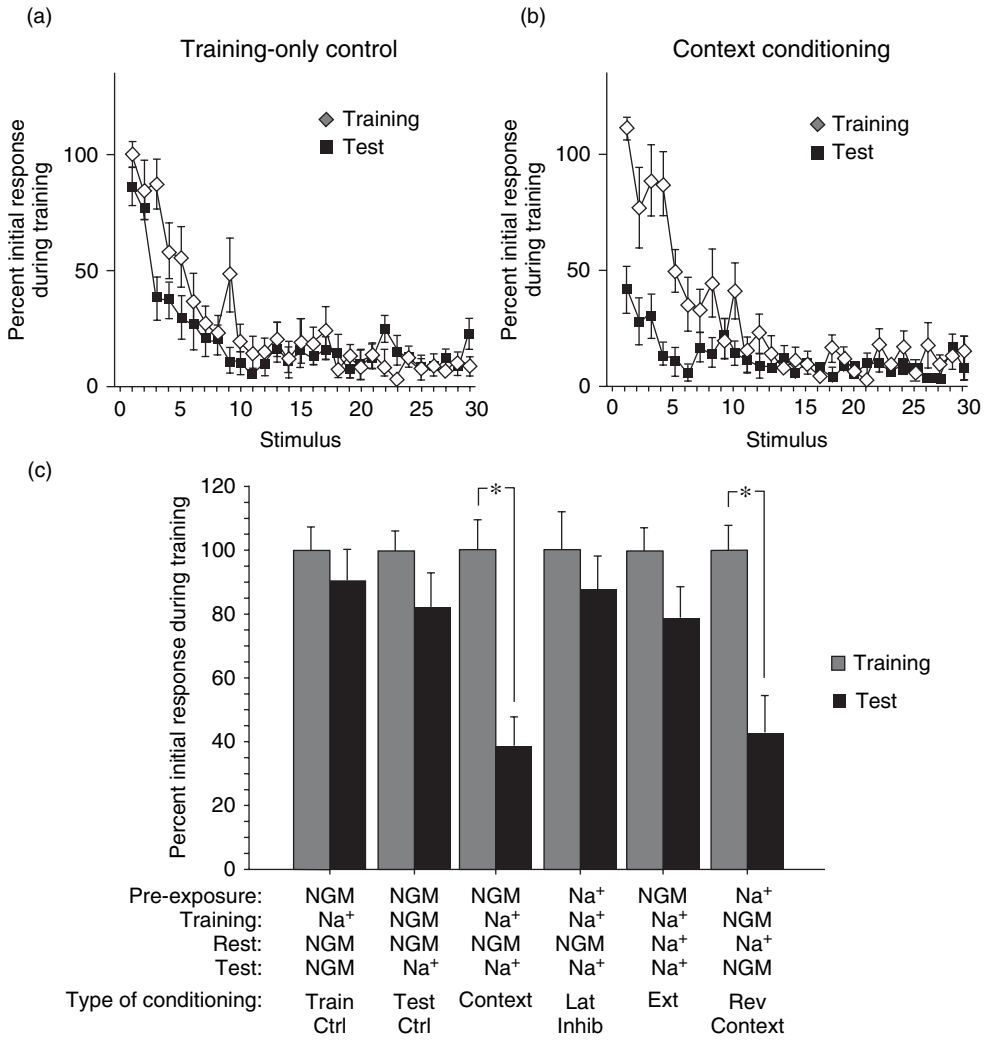

Figure 1 Context conditioning of habituation of the tap withdrawal response. (a and b) Habituation curves during the initial training (light diamonds) and later testing (dark squares) sessions for *C. elegans* that experienced sodium acetate context only during the training session (training-only control; (a)) and *C. elegans* that experienced the sodium acetate context during training and testing (context conditioning; (b)). (c) Initial responses during the initial training (light bars) and later testing (dark bars) habituation sessions for all conditioned groups: training-only control (Train Ctrl; sodium acetate only during training), testing-only control (Test Ctrl; sodium acetate only during testing), context (sodium acetate during training and during testing), latent inhibition (Lat Inhib; sodium acetate for 1 h prior to training, during training and during testing), extinction (Ext; sodium acetate during training, during the 1 h between training and testing, and during testing), reverse context (Rev Context; sodium acetate for the 1 h prior to training and for the 1 h between training and testing). *C. elegans* were exposed to either the sodium acetate (Na^+) context cue or to standard nematode growth medium (NGM) during preexposure, training, testing, and the period in between the training and test sessions (rest). * indicates significant difference between the initial response during training and test sessions. Rankin CH (2000) Context conditioning in habituation in the nematode *C. elegans. Behav. Neurosci.* 114: 496–505. Adapted from APA.

1.32.2.4 State-Dependent Learning

A similar form of learning is known as state-dependent learning because it uses a physiological state within the organism to act as a cue for a nonassociative learning behavior. One method of artificially manipulating internal state in an organism is with the use of neuroactive drugs. Ethanol exposure during the chemotaxis assay did not affect the naïve attraction toward benzaldehyde, nor did it affect benzaldehyde adaptation; however, if *C. elegans* was

preexposed to benzaldehyde in the presence of ethanol, then it would only show adaptation if it was also exposed to ethanol during the chemotaxis assay (Bettinger and McIntire, 2004). This suggests that *C. elegans* can learn to associate a physiological state with a nonassociative training paradigm and that this training will only be expressed when experiencing that same physiological state.

1.32.3 Predicting Food

Associative learning involves the formation of an association between two previously unrelated stimuli. The common stimulus used in most of the associative learning paradigms for *C. elegans* is food. Food is an extremely important resource for any animal; therefore, it is not surprising that most animals studied have the ability to learn to associate specific sensory cues with food. In 1997, Wen et al. were the first to show that even an organism as simple as *C. elegans* can learn to predict the location of food based on previous experience.

1.32.3.1 Appetitive Classical Conditioning using Chemical Cues

Classical conditioning is a form of associative learning that involves presentation of a conditioned stimulus (CS) with an unconditioned stimulus (US) so that an association between the CS and the presence of the US is learned. Wen et al. (1997) used a discriminative classical conditioning paradigm, which involves two CSs, one paired with the US and the other unpaired. They incorporated this paradigm into a chemotaxis assay to investigate associative learning in *C. elegans*. Sodium acetate and lithium chloride concentrations were chosen as the CSs such that *C. elegans* shows the same preference to them; if sodium acetate and lithium chloride are spotted on opposite ends of a chemotaxis plate, 50% of a naïve group will migrate toward sodium, and 50% will migrate toward chloride. When worms were preexposed to sodium paired with food, followed by chloride paired without food, 70–80% of the group migrated toward sodium during the chemotaxis assay; similar results were observed when chloride was paired with food and sodium was unpaired, except the majority of the group moved toward the chloride (Wen et al., 1997).

Using slight variations on this original paradigm, many researchers are now investigating the cellular and molecular mechanisms involved in the association of chemical cues with prediction of food source. For example, genetic screens have been conducted to identify mutants with defects in this behavior (Wen et al., 1997; Saeki et al., 2001); however, the function of the genes identified in these screens (such as *lrn-1* and *lrn-2*) has not yet been identified. Another study found a secretory protein with a low-density lipoprotein receptor (LDLR) motif (*hen-1*) that is important for sensory integration and that played a role in food-related associative learning (Ishihara et al., 2002). It is difficult to understand how these molecules and genes might fit together into a possible mechanism, but as more molecules are identified, the pathway(s) will be more apparent.

1.32.3.2 Thermotaxis

In 1975, Hedgecock and Russell discovered that worms could track changes in temperature and move toward or away from temperatures; they called this behavior thermotaxis. They found that thermotaxis could be altered by experience: *C. elegans* would migrate toward a preferred temperature on a concentration gradient, and the preferred temperature was the temperature at which it is cultivated from hatching until the test assay. Interestingly, animals starved during cultivation would avoid the temperature at which they were cultivated, whereas well-fed worms could change their temperature preference after cultivation in a well-fed environment at a new temperature for several hours. This behavior was investigated using genetic and neural circuit analysis to understand the cellular and molecular mechanisms that mediate it (Hedgecock and Russell, 1975; Mori and Ohshima, 1995), but it was not recognized as a form of learning until several reviews were published in the late 1990s (Bargmann and Mori, 1997; Mori, 1999). In the more recent review, Mori (1999) suggested that for thermotaxis to occur, two processes must take place: first, *C. elegans* must be able to memorize its current cultivation temperature, and then it must be able to associate that temperature with the state of food in its current environment. If there is an abundance of food, then the worms will migrate toward this cultivation temperature in the future. If there is no food, and the worms are starving, this cultivation temperature will be avoided.

After the identification of an intriguing mutant (*aho-2*) that was capable of memorizing a cultivation temperature but was defective at associating that temperature with the food state, thereby always

migrating to its cultivation temperature regardless of whether it was well fed or starved during its previous exposure, Mori and colleagues conducted an elegant behavior dissection of the two processes involved in thermotaxis (Mohri et al., 2005). This was accomplished by cultivating *C. elegans* at a particular temperature (17 °C vs. 25 °C) with a particular food condition (well fed vs. starved). Groups of worms were then switched in one of the conditions, and worms were tested using the thermotaxis assay at various time intervals after the switch (**Figure 2**). This allowed Mohri et al. (2005) to watch as either the new temperature was learned or the new food state was associated as time passed. The results

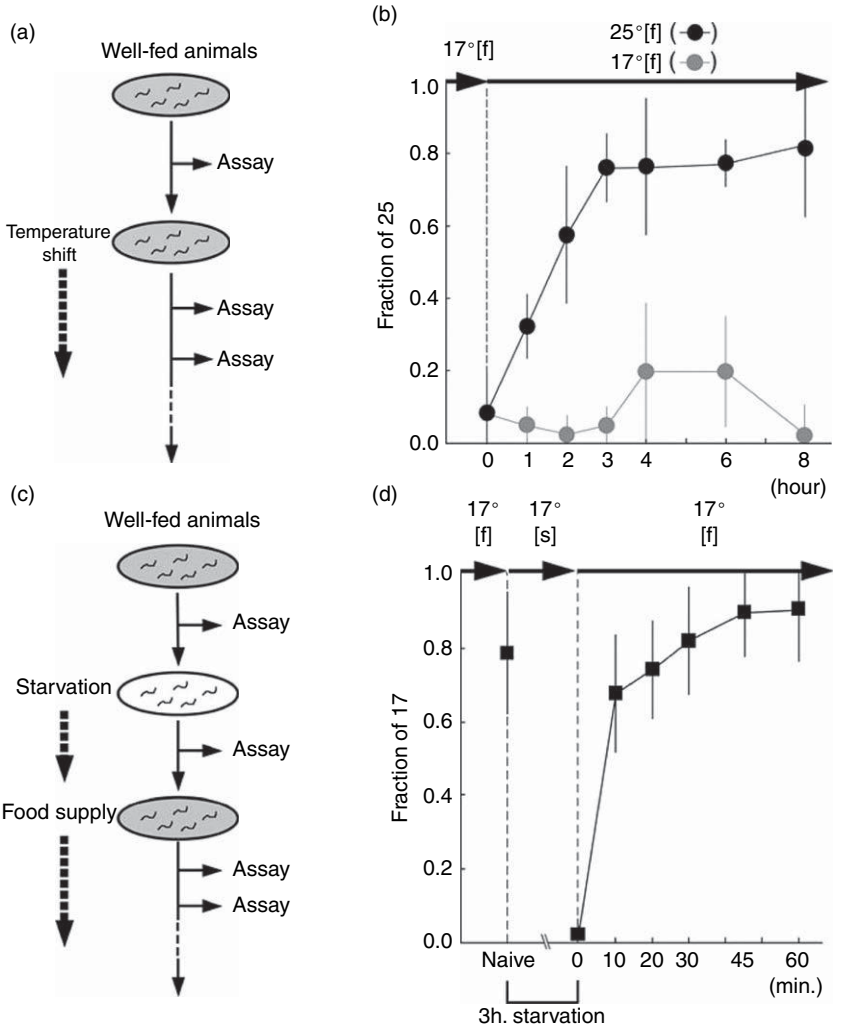

Figure 2 Dissection of temperature memory and food-temperature association of thermotaxis. (a) Procedural diagram for observing the kinetics for learning a new cultivation temperature; *C. elegans* was cultivated at 17 °C on plates with food, assayed, and then switched to a new cultivation temperature of 25 °C and then assayed every hour. (b) The fraction of worms that migrate toward 25 °C during each of the thermotaxis assays for the temperature switch paradigm (upper dark circles). *C. elegans* worms kept at 17 °C were assayed as a control (lower light circles). (c) Procedural diagram for observing the kinetics for association of a new feeding state; *C. elegans* cultivated at 17 °C on a well-fed plate was assayed, transferred to plates with no food for 3 h, assayed again, then transferred back to food and assayed every 10–15 min. (d) The fraction of *C. elegans* that migrates toward 17 °C during each of the thermotaxis assays for the feeding-state switch paradigm. Note that the time scale for (b) is in hours, and (d) is in minutes. Adapted from Mohri A, Kodama E, Kimura KD, Koike M, Mizuno T, and Mori I (2005) Genetic control of temperature preference in the nematode *Caenorhabditis elegans*. *Genetics* 169: 1437–1450.

suggested that it takes *C. elegans* roughly 3 h to learn and memorize a cultivation temperature, whereas it can change the food-state association with that memorized temperature in a matter of minutes (10–25 min, depending on the direction of the switch). This study was instrumental in raising our level of understanding of this behavior, which will be crucial as we attempt to understand the molecular mechanisms that mediate the thermosensory learning and memory of which *C. elegans* is capable.

The neural circuit underlying thermotaxis has been determined (Mori and Oshima, 1995). A number of genes expressed in these neurons have been found to play a role in thermotaxis learning. These include a calcium sensor, *nsc-1* (Gomez et al., 2001); a secretory protein with a LDLR motif, *hen-1* (Ishihara et al., 2002); a LIM homeobox gene, *ceh-1* (Cassata et al., 2000); genes that affect the amount of oxidative stress; and genes that disrupt the insulin/IGF-1/TGF-β endocrine pathway (Murakami and Murakami, 2005; Murakami et al., 2005). A number of mutations have been discovered to disrupt normal thermotaxis as well (such as *aho-2*); however, their respective genes have not yet been identified (Mohri et al., 2005). Unfortunately, to date no relationship between these molecules has been identified, so the mechanisms involved in thermotaxis learning are still unclear.

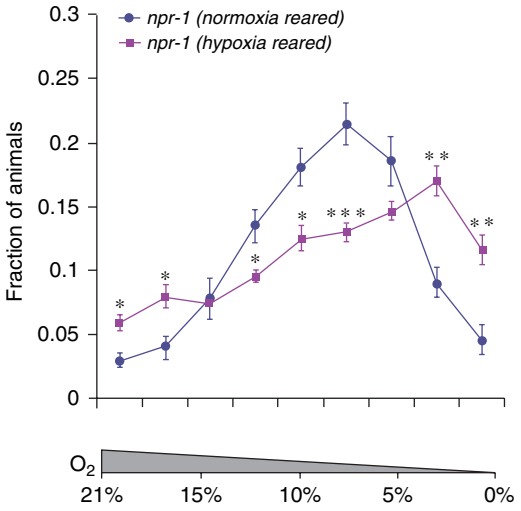

Figure 3 Experience-dependent behavioral plasticity of aerotaxis for *npr-1* mutant *C. elegans*. Fraction of *npr*-1 mutant *C. elegans* (similar variant to Hawaiian strain) that migrate to different oxygen concentrations (0–21%) after being cultivated in normoxia (21%; circles) versus hypoxia (1%; squares) conditions. Asterisks indicate significant differences between fractions at each oxygen concentration. Reprinted from Cheung BH, Cohen M, Rogers C, Albayram O, and de Bono M (2005) Experience-dependent modulation of *C. elegans* behavior by ambient oxygen. *Curr. Biol.* 15: 905–917. Copyright (2005), with permission from Elsevier.

1.32.3.3 Aerotaxis

C. elegans can also sense oxygen concentrations in their environment (Gray et al., 2004). Cheung et al. (2005) invested the effects of oxygen on the behavior of *C. elegans*, as well as the preference for different concentrations of oxygen. Given a concentration gradient, *C. elegans* will migrate toward a preferred oxygen level of 7–12%. This preference is exaggerated by a natural genetic variant found in a strain of *C. elegans* from Hawaii, such that a much larger fraction of the Hawaiian strain accumulates in the 7–12% oxygen content region of the assay plate. These *C. elegans* worms were all cultivated in the laboratory at a standard oxygen concentration of 21%; however, when the worms were cultivated at 1% oxygen concentration, a shift in the oxygen preference was observed during the aerotaxis assay. These hypoxia-reared *C. elegans* migrated to the 0–5% region of the assay plate (**Figure 3**), suggesting that the *C. elegans* learned that a low concentration of oxygen predicts the occurrence of food. Oddly, this learned behavior was only observed in the worms with the recessive Hawaiian genotype, which carry a mutation in a gene called *npr-1* that is homologous to a mammalian neuropeptide Y receptor, and not in the worms with the standard laboratory wild-type (from Bristol, England). This is not surprising, considering that the Bristol strain lacks other oxygen-related behaviors, such as social aggregation during feeding at high levels of oxygen (Cheung et al., 2005). Cheung et al. (2005) identify a set of neurons responsible for the behavior and a set of soluble guanylyl cyclases that are expressed in these neurons that play a role in this learned behavior, suggesting the beginnings of a putative mechanism.

1.32.4 Predicting Harm

Being able to predict the presence of food is not the only thing that is advantageous for survival. The foresight and avoidance of harm or death would also increase the chances of a long and successful reproductive life.

1.32.4.1 Aversive Learning toward Pathogenic Food

One important source of potential harm is food. When *C. elegans* is in its natural environment in the soil, it encounters various types of bacteria, some of which it approaches and some of which it avoids; the types that it is attracted to, it will consume. Unfortunately, a number of these bacteria are pathogenic to *C. elegans*, causing harm and even death. Zhang et al. (2005) investigated whether *C. elegans* could learn to avoid these pathogenic bacteria after a period of preexposure long enough to lead to harmful infection.

Zhang et al. (2005) choose pathogenic bacterial strains, *Pseudomonas aeruginosa* and *Serratia marcescens*, to which *C. elegans* is naively attracted. These bacteria proliferate within the digestive tract of the nematode, causing a harmful infection that can lead to death after long exposures. Zhang et al. (2005) modified the standard chemotaxis assay by using small bacterial lawns grown on opposite sides of the testing plate instead of chemical solutions; one lawn was the test bacteria, and there other was *E. coli* OP50 (a standard food source for *C. elegans* in the laboratory) as a control. Naive *C. elegans* worms (cultivated on *E. coli* OP50) tested in this assay were equally attracted to *P. aeruginosa* and *E. coli* and showed a slight preference for *S. marcescens* compared to *E. coli*. When *C. elegans* was cultivated in an environment that included *E. coli* and *P. aeruginosa* (cultivation in *P. aeruginosa* alone caused severe infections that lead to death), significantly fewer animals migrated toward *P. aeruginosa* during the taxis assay compared to naive worms, suggesting after preexposure to the pathogenic bacteria, the worms now strongly preferred the *E. coli*; the same was true when they were preexposed and tested with *S. marcescens*. This strongly supports the hypothesis that *C. elegans* learns to avoid bacteria that cause infectious harm.

In the preceding experiments *C. elegans* worms were preexposed to the test bacteria for their entire development, which is approximately 4 days. To test the kinetics of this olfactory avoidance learning, Zhang et al. (2005) cultivated *C. elegans* worms on *E. coli* until they were adults and then preexposed animals to the test conditioning environment (test bacteria plus *E. coli*) or a control conditioning environment (*E. coli* alone) for various amounts of time and then tested the groups using the taxis assay. They found that the shortest preexposure time that achieved a similar difference in preference to that observed after preexposure during all of development was 4 h of conditioning. Therefore, adult *C. elegans* worms needed to be exposed to pathogenic bacteria for at least 4 h to learn to avoid it.

This paradigm does not address the question of whether the learning that is occurring is strengthening the aversion toward the pathogenic bacteria, the attraction toward the control bacteria, or both. Zhang et al. (2005) tested this by developing a multiarm maze that contained four types of bacteria, the pathogenic test bacteria, the nonpathogenic control bacteria, novel pathogenic bacteria, and novel nonpathogenic bacteria (**Figure 4**(**a**)). A group of *C. elegans* was placed in a central decision area and then had to choose an arm to move down to get to a bacterial lawn; the percentage of worms that ended up at each bacterial lawn was measured. A greater percentage chose the control bacterial lawn, and a lesser percentage chose the test bacterial lawn in the preexposed group compared to the naive group (**Figure 4**(**b**)). The percentage of worms found in both of the novel bacterial lawns was found to be the same between groups. This suggests that this pathogenesis-induced olfactory aversive learning is caused by both an increase in aversion to the previously experienced pathogenic bacteria and an increase in attraction to the previously experienced nonpathogenic bacteria. Interestingly, Zhang et al. (2005) found that the kinetics of these different aspects were not the same because *C. elegans* worms that were exposed to the pathogenic bacteria for only 4 h showed aversion to the pathogenic test bacterial lawn but not an increased attraction to the nonpathogenic control lawn. This suggests that *C. elegans* can learn the aversive aspect more quickly than it can learn the attractive aspect of this behavior.

Serotonin is an important neurotransmitter for food-related behaviors in *C. elegans* (Croll, 1975; Horvitz et al., 1982; Avery and Horvitz, 1990), so it is not surprising that mutations that affect serotonin neurotransmission disrupt learning of pathogenic bacteria avoidance (Zhang et al., 2005). Using neuron-specific expression of wild-type constructs that rescue these serotonin deficits, the site of plasticity was identified. The researchers believe the ADF serotonergic chemosensory neuron is activated during bacterial infection and releases serotonin onto the interneurons involved in integrating chemosensory information, AIY and AIZ. The serotonin induces some sort of neural plasticity, not yet understood, that leads to the behavioral plasticity observed during the behavior.

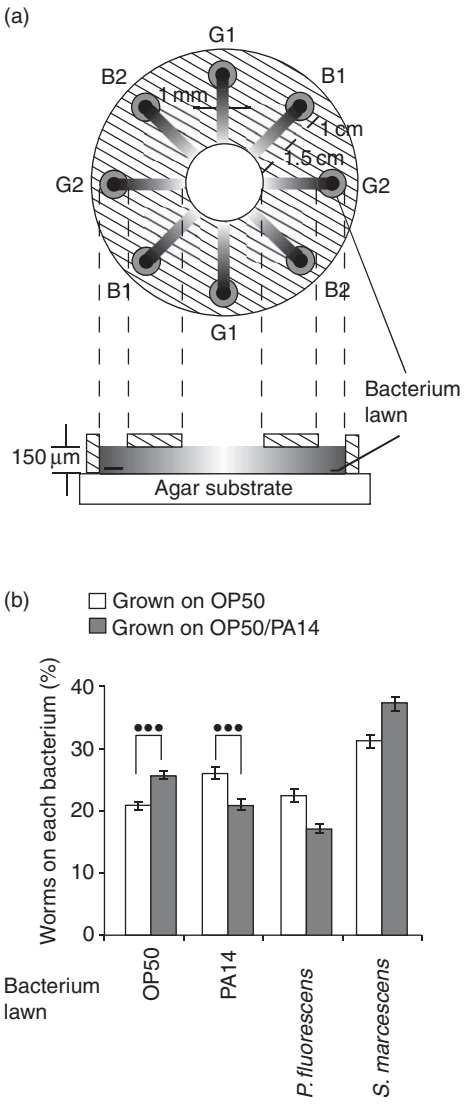

Figure 4 Learned avoidance of pathogenic bacteria. (a) Multiarm maze for testing attractive versus aversive nature of pathogenic bacteria avoidance. *E. coli* OP50, previously experienced nonpathogenic bacteria, was placed at G1; *P. aeruginosa* PA14, previously experienced pathogenic bacteria, was placed at B1; *P. fluorescens*, novel nonpathogenic bacteria, was placed at G2; *S. marcescens*, novel pathogenic bacteria, was placed at B2. *C. elegans* worms were placed in the center of the apparatus and allowed to choose which bacterial lawn to migrate toward. (b) Fraction of *C. elegans* worms, which were preexposed only to *E. coli* OP50 (light bars) versus preexposed to *E. coli* OP50 and *P. aeruginosa* PA14 (dark bars), that migrated to the different bacterial lawn. *** indicates significant differences ($p < 0.05$) between different preexposure conditions. 1.32.5 Summary

C. elegans possesses a plethora of behaviors that can change with experience, which covers every aspect of its sensory abilities that has been investigated. Understanding the details of this learning and memory is much easier than understanding the complex behavioral repertoire of higher-order organisms. This detailed understanding is essential for helping to understand the mechanisms that mediate these organisms because a mechanism must be able to explain all aspects of the learning to be complete. *C. elegans* also offers the advantage of accessible manipulation at the molecular level, which allows for investigation of cellular and molecular mechanisms of learning and memory. These results can then be carefully extended from this model system to higher-order organisms in the hopes of better understanding the biological foundations of learning and memory.

1.33 Computational Models of Hippocampal Functions

E. T. Rolls, University of Oxford, Oxford, UK

1.33.1 Introduction

In this chapter, a computational approach to the function of the hippocampus in memory is described and compared to other approaches. The theory is quantitative and takes into account the internal and systems-level connections of the hippocampus, the effects on memory of damage to different parts of the hippocampus, and the responses of hippocampal neurons recorded during memory tasks. The theory was developed by Rolls (1987, 1989a,b,c, 1996b, 2007), Treves and Rolls (1992, 1994), and with other colleagues (Rolls et al., 2002; Rolls and Stringer, 2005; Rolls and Kesner, 2006). The theory was preceded by the work of Marr (1971), who developed a mathematical model, which, although not applied to particular networks within the hippocampus and dealing with binary neurons and binary synapses that utilized heavily the properties of the binomial distribution, was important in utilizing computational concepts and in considering how recall could occur in a network with recurrent collateral connections. Analyses of these autoassociation or attractor networks developed rapidly (Gardner-Medwin, 1976; Kohonen, 1977; Hopfield, 1982; Amit, 1989; Treves and Rolls, 1991; Rolls and Treves, 1998). Rolls (1987, 1989b) produced a theory of the hippocampus in which the CA3 neurons operated as an autoassociation memory to store episodic memories including object and place memories, and the dentate granule cells operated as a preprocessing stage for this by performing pattern separation so that the mossy fibers could act to set up different representations for each memory to be stored in the CA3 cells. He suggested that the CA1 cells operate as a recoder for the information recalled from the CA3 cells to a partial memory cue, so that the recalled information would be represented more efficiently to enable recall, via the backprojection synapses, of activity in the neocortical areas similar to that which had been present during the original episode. At about the same time, McNaughton and Morris (1987) suggested that the CA3 network might be an autoassociation network, and that the mossy fiber–to-CA3 connections might implement detonator synapses. The concepts that the diluted mossy fiber connectivity might implement selection of a new random set of CA3 cells for each new memory and that a direct perforant path input to CA3 was needed to initiate retrieval were introduced by Treves and Rolls (1992). Since then, many investigators have contributed to our understanding of hippocampal computation, with some of these approaches described in the section titled 'Comparison with other theories of hippocampal function' and throughout the chapter.

1.33.2 A Theory of Hippocampal Function

1.33.2.1 Systems-Level Functions of the Hippocampus

Any theory of the hippocampus must state at the systems level what is computed by the hippocampus. Some of the relevant evidence comes from the effects of damage to the hippocampus, the responses of neurons in the hippocampus during behavior, and the systems-level connections of the hippocampus, described in more detail elsewhere (Rolls and Kesner, 2006; Rolls, 2007).

1.33.2.1.1 Evidence from the effects of damage to the hippocampus

Damage to the hippocampus or to some of its connections such as the fornix in monkeys produces deficits in learning about the places of objects and about the places where responses should be made (Buckley and Gaffan, 2000). For example, macaques and humans with damage to the hippocampal system or fornix are impaired in object–place memory tasks in which not only the objects seen but where they were seen must be remembered (Gaffan, 1994; Burgess et al., 2002; Crane and Milner, 2005). Posterior parahippocampal lesions in macaques impair even a simple type of object-place learning in which the memory load is just one pair of trial-unique stimuli (Malkova and Mishkin, 2003). Further, neurotoxic lesions that selectively damage the primate hippocampus impair spatial scene memory, tested by the ability to remember where in a scene to touch to obtain reward (Murray et al., 1998). Rats with hippocampal lesions are impaired in using environmental spatial cues to remember particular places (O'Keefe and Nadel, 1978; Jarrard, 1993; Cassaday and Rawlins, 1997; Martin et al., 2000; Kesner et al., 2004). These memory functions are important in event or episodic memory, in which the ability to remember what happened where on typically a single occasion is important.

It will be suggested below that an autoassociation memory implemented by the CA3 neurons enables event or episodic memories to be formed by enabling associations to be formed between spatial and other including object representations.

1.33.2.1.2 The necessity to recall information from the hippocampus

Information stored in the hippocampus will need to be retrieved and affect other parts of the brain in order to be used. The information about episodic events recalled from the hippocampus could be used to help form semantic memories (Rolls, 1989b,d, 1990a; Treves and Rolls, 1994). For example, remembering many particular journeys could help to build a geographic cognitive map in the neocortex. The hippocampus and neocortex would thus be complementary memory systems, with the hippocampus being used for rapid, on-the-fly, unstructured storage of information involving activity potentially arriving from many areas of the neocortex, while the neocortex would gradually build and adjust the semantic representation on the basis of much accumulating information (Rolls, 1989b; Treves and Rolls, 1994; McClelland et al., 1995; Moscovitch et al., 2005). The present theory shows how information could be retrieved within the hippocampus and how this retrieved information could enable the activity in neocortical areas that was present during the original storage of the episodic event to be reinstated, thus implementing recall, by using hippocampo-neocortical backprojections (see **Figure 1**).

1.33.2.1.3 Systems-level neurophysiology of the primate hippocampus

The systems-level neurophysiology of the hippocampus shows what information could be stored or processed by the hippocampus. To understand how the hippocampus works, it is not sufficient to state just that it can store information – one needs to know what information. The systems-level neurophysiology of the primate hippocampus has been reviewed recently by Rolls and Xiang (2006), and a brief summary is provided here because it provides a perspective relevant to understanding the function of the human hippocampus that is somewhat different from that provided by the properties of place cells in rodents, which have been reviewed elsewhere (see McNaughton et al., 1983; O'Keefe, 1984; Muller et al., 1991; Jeffery et al., 2004; Jeffery and Hayman, 2004).

The primate hippocampus contains spatial cells that respond when the monkey looks at a certain part of space, for example, at one quadrant of a video monitor, while the monkey is performing an object–place memory task in which he must remember where on the monitor he has seen particular images (Rolls et al., 1989). Approximately 9% of the hippocampal neurons have such spatial view fields, and about 2.4% combine information about the position in space with information about the object that is in that position in space (Rolls et al., 1989). The representation of space is for the majority of hippocampal

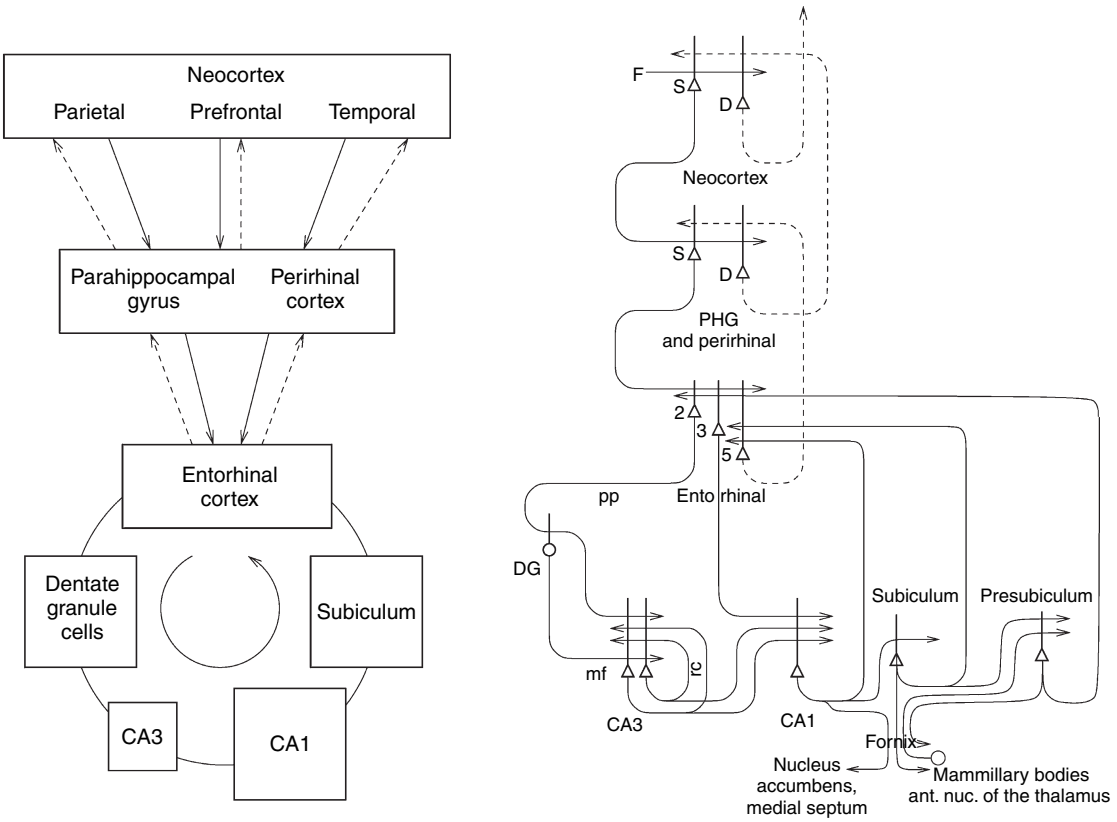

Figure 1 Forward connections (solid lines) from areas of cerebral association neocortex via the parahippocampal gyrus and perirhinal cortex, and entorhinal cortex, to the hippocampus; and backprojections (dashed lines) via the hippocampal CA1 pyramidal cells, subiculum, and parahippocampal gyrus to the neocortex. There is great convergence in the forward connections down to the single network implemented in the CA3 pyramidal cells and great divergence again in the backprojections. Left: block diagram. Right: more detailed representation of some of the principal excitatory neurons in the pathways. Abbreviations: D, deep pyramidal cells; DG, dentate granule cells; F, forward inputs to areas of the association cortex from preceding cortical areas in the hierarchy; mf, mossy fibers. PHG, parahippocampal gyrus and perirhinal cortex; pp, perforant path; rc, recurrent collateral of the CA3 hippocampal pyramidal cells; S, superficial pyramidal cells; 2, pyramidal cells in layer 2 of the entorhinal cortex; 3, pyramidal cells in layer 3 of the entorhinal cortex. The thick lines above the cell bodies represent the dendrites.

neurons in allocentric – not egocentric – coordinates (Feigenbaum and Rolls, 1991). These spatial view cells can be recorded while monkeys move themselves round the test environment by walking (or running) on all fours (Rolls et al., 1997a, 1998; Robertson et al., 1998; Georges-François et al., 1999). These hippocampal spatial view neurons respond significantly differently for different allocentric spatial views, and have information about spatial view in their firing rate, but do not respond differently just on the basis of eye position, head direction, or place. If the view details are obscured by curtains and darkness, then some spatial view neurons (especially those in CA1 and less those in CA3) continue to respond when the monkey looks toward the spatial view field, showing that these neurons can be updated for at least short periods by idiothetic (self-motion) cues including eye position and head direction signals (Rolls et al., 1997b; Robertson et al., 1998).

A fundamental question about the function of the primate including human hippocampus is whether object as well as allocentric spatial information is represented. To investigate this, Rolls et al. (2005) made recordings from single hippocampal formation neurons while macaques performed an object–place memory task that required the monkeys to learn associations between objects, and where they were shown in a room. Some neurons (10%) responded differently to different objects independently of location; other neurons (13%) responded to the spatial view independently of which object was present at

the location; and some neurons (12%) responded to a combination of a particular object and the place where it was shown in the room. These results show that there are separate as well as combined representations of objects and their locations in space in the primate hippocampus. This is a property required in an episodic memory system, for which associations between objects and the places where they are seen are prototypical. The results thus show that a requirement for a human episodic memory system, separate and combined neuronal representations of objects and where they are seen out there in the environment, are present in the primate hippocampus (Rolls et al., 2005). What may be a corresponding finding in rats is that some rat hippocampal neurons respond on the basis of the conjunction of location and odor (Wood et al., 1999).

Primate hippocampal neuronal activity has also been shown to be related to the recall of memories. In a one–trial object place recall task, images of an object in one position on a screen and of a second object in a different position on the screen were shown successively. Then one of the objects was shown at the top of the screen, and the monkey had to recall the position in which it had been shown earlier in the trial and to touch that location (Rolls and Xiang, 2006). In addition to neurons that responded to the objects or places, a new type of neuronal response was found in which 5% of hippocampal neurons had place-related responses when a place was being recalled by an object cue.

The primate anterior hippocampus (which corresponds to the rodent ventral hippocampus) receives inputs from brain regions involved in reward processing such as the amygdala and orbitofrontal cortex (Pitkanen et al., 2002). To investigate how this affective input may be incorporated into primate hippocampal function, Rolls and Xiang (2005) recorded neuronal activity while macaques performed a reward-place association task in which each spatial scene shown on a video monitor had one location, which if touched yielded a preferred fruit juice reward, and a second location that yielded a less preferred juice reward. Each scene had different locations for the different rewards. Of 312 hippocampal neurons analyzed, 18% responded more to the location of the preferred reward in different scenes, and 5% to the location of the less preferred reward (Rolls and Xiang, 2005). When the locations of the preferred rewards in the scenes were reversed, 60% of 44 neurons tested reversed the location to which they responded, showing that the reward–place associations could be altered by new learning in a few trials. The majority (82%) of these 44 hippocampal reward–place neurons tested did not respond to object–reward associations in a visual discrimination object–reward association task. Thus the primate hippocampus contains a representation of the reward associations of places out there being viewed, and this is a way in which affective information can be stored as part of an episodic memory, and how the current mood state may influence the retrieval of episodic memories. There is consistent evidence that rewards available in a spatial environment can influence the responsiveness of rodent place neurons (Hölscher et al., 2003; Tabuchi et al., 2003).

1.33.2.1.4 Systems-level anatomy

The primate hippocampus receives inputs via the entorhinal cortex (area 28) and the highly developed parahippocampal gyrus (areas TF and TH) as well as the perirhinal cortex from the ends of many processing streams of the cerebral association cortex, including the visual and auditory temporal lobe association cortical areas, the prefrontal cortex, and the parietal cortex (Van Hoesen, 1982; Amaral, 1987; Amaral et al., 1992; Suzuki and Amaral, 1994b; Witter et al., 2000b; Lavenex et al., 2004) (see **Figure 1**). The hippocampus is thus by its connections potentially able to associate together object and spatial representations. In addition, the entorhinal cortex receives inputs from the amygdala and the orbitofrontal cortex, which could provide reward-related information to the hippocampus (Suzuki and Amaral, 1994a; Carmichael and Price, 1995; Stefanacci et al., 1996; Pitkanen et al., 2002).

The primary output from the hippocampus to neocortex originates in CA1 and projects to subiculum, entorhinal cortex, and parahippocampal structures (areas TF-TH), as well as prefrontal cortex (Van Hoesen, 1982; Witter, 1993; Delatour and Witter, 2002; van Haeften et al., 2003) (see **Figure 1**), though there are other outputs (Rolls and Kesner, 2006).

1.33.2.2 The Operation of Hippocampal Circuitry as a Memory System

1.33.2.2.1 Hippocampal circuitry

(see Figure 1; Amaral and Witter, 1989; Storm-Mathiesen et al., 1990; Amaral, 1993; Witter et al., 2000b; Naber et al., 2001; Lavenex et al., 2004)

Projections from the entorhinal cortex layer 2 reach the granule cells (of which there are 10^6 in the rat) in the dentate gyrus (DG), via the perforant path (pp) (Witter, 1993). The granule cells project to CA3 cells via the mossy fibers (mf), which provide a sparse but possibly powerful connection to the $3{\cdot}10^5$

CA3 pyramidal cells in the rat. Each CA3 cell receives approximately 50 mf inputs, so that the sparseness of this connectivity is thus 0.005%. By contrast, there are many more – possibly weaker – direct perforant path inputs also from layer 2 of the entorhinal cortex onto each CA3 cell, in the rat on the order of $4{\cdot}10^3$. The largest number of synapses (approximately $1.2{\cdot}10^4$ in the rat) on the dendrites of CA3 pyramidal cells is, however, provided by the (recurrent) axon collaterals of CA3 cells themselves (rc) (see **Figure 2**). It is remarkable that the recurrent collaterals are distributed to other CA3 cells throughout the hippocampus (Amaral and Witter, 1989; Amaral et al., 1990; Ishizuka et al., 1990; Amaral and Witter, 1995), so that effectively the CA3 system provides a single network, with a connectivity of approximately 2% between the different CA3 neurons given that the connections are bilateral. The neurons that comprise CA3, in turn, project to CA1 neurons via the Schaffer collaterals. In addition, projections that terminate in the CA1 region originate in layer 3 of the entorhinal cortex (see **Figure 1**).

1.33.2.2.2 Dentate granule cells

The theory is that the dentate granule cell stage of hippocampal processing that precedes the CA3 stage acts in a number of ways to produce during learning the sparse yet efficient (i.e., nonredundant) representation in CA3 neurons that is required for the autoassociation implemented by CA3 to perform well (Rolls, 1989b; Treves and Rolls, 1992; Rolls and Kesner, 2006; Rolls et al., 2006).

The first way is that the perforant path – the dentate granule cell system with its Hebb-like modifiability is suggested to act as a competitive learning network to remove redundancy from the inputs producing a more orthogonal, sparse, and categorized set of outputs (Rolls, 1987, 1989a,b,d, 1990a,b, Rolls and Treves, 1998; Rolls, 2007). (Competitive networks are described elsewhere: Hertz et al., 1991; Rolls and Treves, 1998; Rolls and Deco, 2002; Rolls, 2008). The nonlinearity in the *N*-methyl-D-aspartate (NMDA) receptors may help the operation of such a competitive net, for it ensures that only the most active neurons left after the competitive feedback inhibition have synapses that become modified and thus learn to respond to that input (Rolls, 1989a). Because of the feedback inhibition, the competitive process may result in a relatively constant number of strongly active dentate neurons relatively independently of the number of active perforant path inputs to the dentate cells. The operation of the dentate granule cell system as a competitive network may also be facilitated by a Hebb rule of the form:

$$\delta w_{ij} = k \,.\, r_i \,(r'_j - w_{ij}), \qquad [1]$$

where k is a constant, r_i is the activation of the dendrite (the postsynaptic term), r'_j is the presynaptic firing rate, w_{ij} is the synaptic weight, and r'_j and w_{ij} are in appropriate units (Rolls, 1989a). Incorporation of a rule such as this which implies heterosynaptic long-term depression (LTD) as well as long-term potentiation (LTP) (see Levy and Desmond, 1985; Levy et al., 1990) makes the sum of the synaptic weights on each neuron remain roughly constant during learning (cf. Oja, 1982; see Rolls, 1989a; Rolls and Treves, 1998; Rolls, 2008; Rolls and Deco, 2002).

This functionality could be used to help build hippocampal place cells in rats from the grid cells present in the medial entorhinal cortex (Hafting et al., 2005). Each grid cell responds to a set of places in a spatial environment, with the places to which a cell responds set out in a regular grid. Different grid cells have different phases (positional offsets) and grid spacings (or frequencies) (Hafting et al., 2005). We (Rolls et al., 2006) have simulated the dentate granule cells as a system that receives as inputs the activity of a population of entorhinal cortex grid cells as the animal traverses a spatial environment and

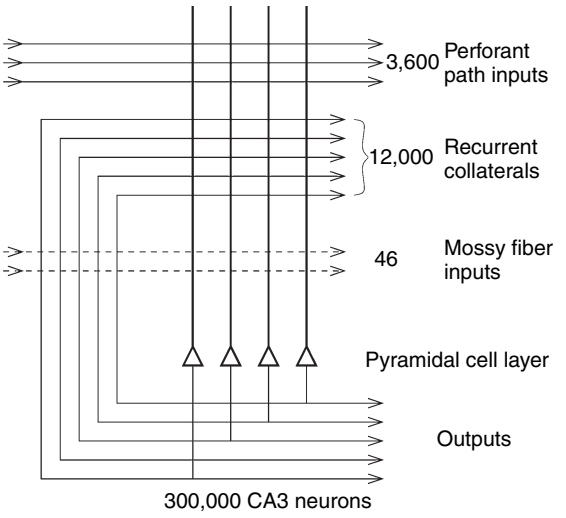

Figure 2 The numbers of connections from three different sources onto each CA3 cell from three different sources in the rat. After Treves A and Rolls ET (1992) Computational constraints suggest the need for two distinct input systems to the hippocampal CA3 network. *Hippocampus* 2: 189–199; Rolls ET and Treves A (1998) *Neural Networks and Brain Function.* Oxford: Oxford University Press.

have shown that the competitive net builds dentate-like place cells from such entorhinal grid cell inputs (see **Figure 3**). This occurs because the firing states of entorhinal cortex cells that are active at the same time when the animal is in one place become associated together by the learning in the competitive net, yet each dentate cell represents primarily one place because the dentate representation is kept sparse, thus helping to implement symmetry breaking (Rolls et al., 2006).

The second way is also a result of the competitive learning hypothesized to be implemented by the dentate granule cells (Rolls, 1987, 1989a,b,d, 1990a,b, 1994). It is proposed that this allows overlapping (or very similar) inputs to the hippocampus to be separated in the following way (see also Rolls, 1996b). Consider three patterns B, W, and BW, where BW is a linear combination of B and W. (To make the example very concrete, we could consider binary patterns where B = 10, W = 01, and BW = 11.) Then the memory system is required to associate B with reward and W with reward, but BW with punishment. Without the hippocampus, rats might have more difficulty in solving such problems, particularly when they are spatial, for

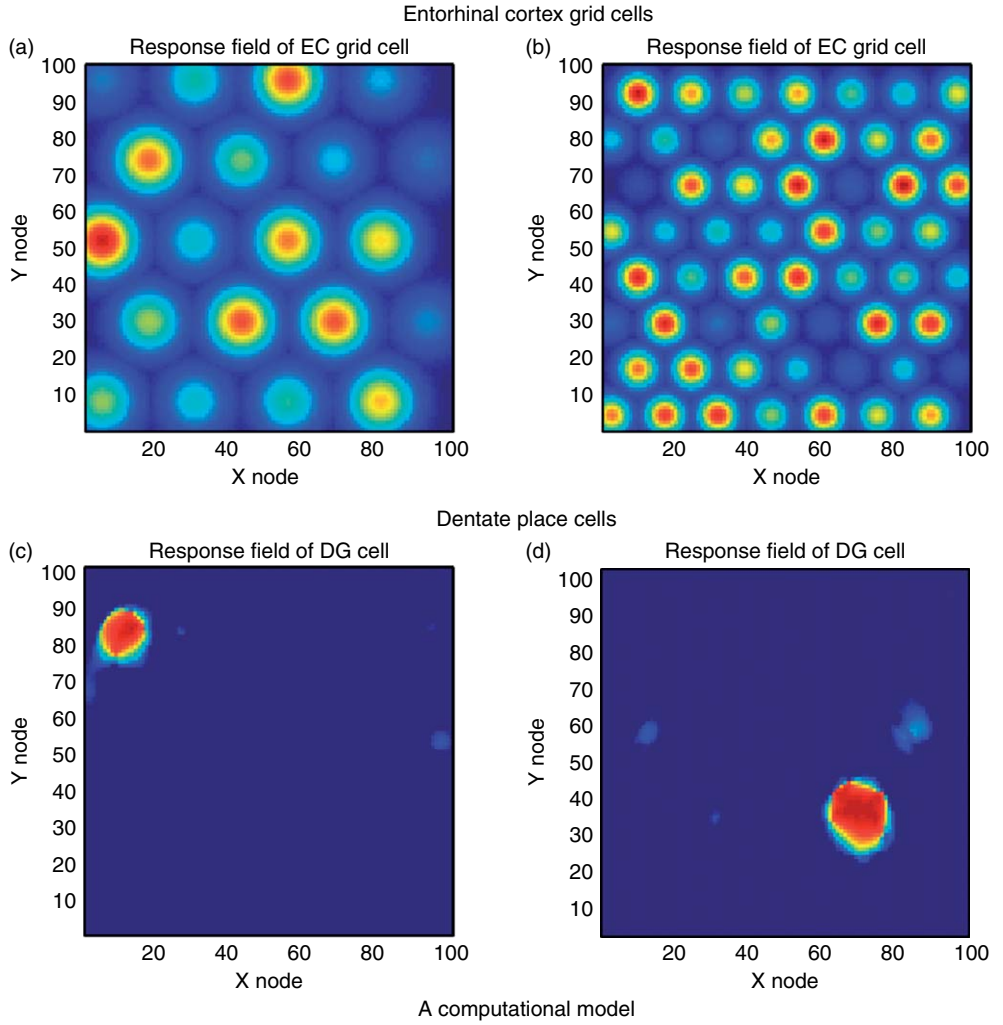

Figure 3 Simulation of competitive learning in the dentate gyrus to produce place cells from the entorhinal cortex grid cell inputs. (a), (b). Firing rate profiles of two entorhinal cortex grid cells with frequencies of four and seven cycles. In the simulation, cells with frequencies of four to seven cycles were used, and with 25 phases or spatial offsets. (A phase is defined as an offset in the X and Y directions, and five offset values were used in each direction.) The standard deviation of the peak heights was set to 0.6. (c), (d): Firing rate profiles of two dentate gyrus cells after competitive network training with the Hebb rule. After Rolls ET, Stringer SM, and Elliot T (2006) Entorhinal cortex grid cells can map to hippocampal place cells by competitive learning. *Netw. Comput. Neural Sys.* 17: 447–465.

the dentate/CA3 system in rodents is characterized by being implicated in spatial memory. However, it is a property of competitive neuronal networks that they can separate such overlapping patterns, as has been shown elsewhere (Rolls, 1989a; Rolls and Treves, 1998; Rolls, 2008); normalization of synaptic weight vectors is required for this property. It is thus an important part of hippocampal neuronal network architecture that there is a competitive network that precedes the CA3 autoassociation system. Without the dentate gyrus, if a conventional autoassociation network were presented with the mixture BW having learned B and W separately, then the autoassociation network would produce a mixed output state and would therefore be incapable of storing separate memories for B, W, and BW. It is suggested, therefore, that competition in the DG is one of the powerful computational features of the hippocampus and could enable it to help solve spatial pattern separation tasks (Rolls and Kesner, 2006).

This computational hypothesis and its predictions have been tested. Rats with DG lesions are impaired at a metric spatial pattern separation task (Gilbert et al., 2001; Goodrich-Hunsaker et al., 2005) (see **Figure 4**). The recoding of grid cells in the entorhinal cortex (Hafting et al., 2005) into small place field cells in the dentate granule cells that has been modeled (Rolls et al., 2006) can also be considered to be a case where overlapping inputs must be recoded so that different spatial components can be treated

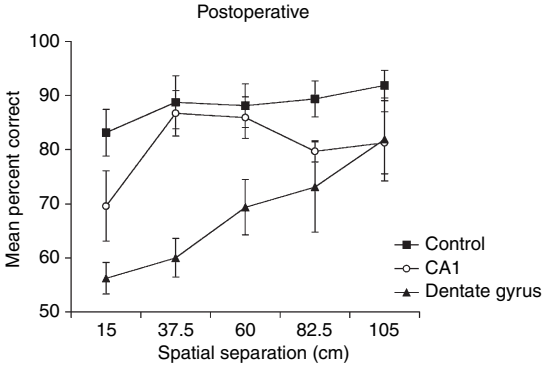

Figure 4 Pattern separation impairment produced by dentate gyrus lesions. Mean percent correct performance as a function of spatial separation of control group, CA1 lesion group, and dentate gyrus lesion group on postoperative trials. A graded impairment was found as a function of the distance between the places only following dentate gyrus lesions. After Gilbert PE, Kesner RP, and Lee I (2001) Dissociating hippocampal subregions: Double dissociation between dentate gyrus and CA1. *Hippocampus* 11: 626–636.

differently. I note that Sutherland and Rudy's configural learning hypothesis was similar but was not tested with spatial pattern separation. Instead, when tested with, for example, tone and light combinations, it was not consistently found that the hippocampus was important (Sutherland and Rudy, 1991; O'Reilly and Rudy, 2001). I suggest that application of the configural concept, but applied to spatial pattern separation, may capture part of what the DG – acting as a competitive network – could perform, particularly when a large number of such overlapping spatial memories must be stored and retrieved.

The third way in which the DG is hypothesized to contribute to the sparse and relatively orthogonal representations in CA3 arises because of the very low contact probability in the mf–CA3 connections and is described in the section titled 'Mossy fiber inputs to the CA3 cells' and by Treves and Rolls (1992).

A fourth way is that, as suggested and explained in the section titled 'Mossy fiber inputs to the CA3 cells,' the dentate granule cell–mf input to the CA3 cells may be powerful, and its use, particularly during learning, would be efficient in forcing a new pattern of firing onto the CA3 cells during learning.

In the ways just described, the dentate granule cells could be particularly important in helping to build and prepare spatial representations for the CA3 network. The actual representation of space in the primate hippocampus includes a representation of spatial view, whereas in the rat hippocampus it is of the place where the rat is. The representation in the rat may be related to the fact that with a much less developed visual system than the primate, the rat's representation of space may be defined more by the olfactory and tactile as well as distant visual cues present and may thus tend to reflect the place where the rat is. However, the spatial representations in the rat and primate could arise from essentially the same computational process as follows (Rolls, 1999; de Araujo et al., 2001). The starting assumption is that in both the rat and the primate, the dentate granule cells (and the CA3 and CA1 pyramidal cells) respond to combinations of the inputs received. In the case of the primate, a combination of visual features in the environment will, because of the fovea providing high spatial resolution over a typical viewing angle of perhaps 10°–20°, result in the formation of a spatial view cell, the effective trigger for which will thus be a combination of visual features within a relatively small part of space. In contrast, in the rat, given the very extensive visual field

subtended by the rodent retina, which may extend over 180°–270°, a combination of visual features formed over such a wide visual angle would effectively define a position in space that is a place (de Araujo et al., 2001).

Although spatial view cells are present in the parahippocampal areas (Rolls et al., 1997a, 1998; Robertson et al., 1998; Georges-François et al., 1999), and neurons with place-like fields (though in some cases as a grid [Hafting et al., 2005]) are found in the medial entorhinal cortex (Moser and Moser, 1998; Brun et al., 2002; Fyhn et al., 2004; Moser, 2004), there are backprojections from the hippocampus to the entorhinal cortex and thus to parahippocampal areas, and these backprojections could enable the hippocampus to influence the spatial representations found in the entorhinal cortex and parahippocampal gyrus. On the other hand, as described above, the grid-like place cells in the medial entorhinal cortex could, if transformed by the competitive net functionality of the dentate cells, result in the place cell activity (without a repeating grid) that is found in dentate and rat hippocampal neurons.

1.33.2.2.3 CA3 as an autoassociation memory

1.33.2.2.3.(i) Arbitrary associations and pattern completion in recall Many of the synapses in the hippocampus show associative modification as shown by long-term potentiation, and this synaptic modification appears to be involved in learning (see Morris, 1989, 2003; Morris et al., 2003; Lynch, 2004). On the basis of the evidence summarized above, Rolls (1987, 1989a,b,d, 1990a,b, 1991) and others (McNaughton and Morris, 1987; Levy, 1989; McNaughton, 1991) have suggested that the CA3 stage acts as an autoassociation memory that enables episodic memories to be formed and stored in the CA3 network, and that subsequently the extensive recurrent collateral connectivity allows for the retrieval of a whole representation to be initiated by the activation of some small part of the same representation (the cue). The crucial synaptic modification for this is in the recurrent collateral synapses. A description of the operation of autoassociative networks is provided by Hertz et al. (1991), Rolls and Treves (1998), Rolls and Deco (2002), and Rolls (2007). The architecture of an autoassociation network is shown in **Figure 2**, and the learning rule is as shown in eqn [1], except that the subtractive term could be the presynaptic firing rate (Rolls and Treves, 1998; Rolls and Deco, 2002).

The hypothesis is that because the CA3 operates effectively as a single network, it can allow arbitrary associations between inputs originating from very different parts of the cerebral cortex to be formed. These might involve associations between information originating in the temporal visual cortex about the presence of an object, as well as information originating in the parietal cortex about where it is. I note that although there is some spatial gradient in the CA3 recurrent connections, so that the connectivity is not fully uniform (Ishizuka et al., 1990), nevertheless the network will still have the properties of a single interconnected autoassociation network allowing associations between arbitrary neurons to be formed, given the presence of many long-range connections that overlap from different CA3 cells.

Crucial issues include how many memories could be stored in this system (to determine whether the autoassociation hypothesis leads to a realistic estimate of the number of memories that the hippocampus could store); whether the whole of a memory could be completed from any part; whether the autoassociation memory can act as a short-term memory, for which the architecture is inherently suited, and whether the system could operate with spatial representations, which are essentially continuous because of the continuous nature of space. These and related issues are considered in the remainder of this section and in more detail elsewhere (Rolls and Kesner, 2006; Rolls, 2008).

1.33.2.2.3.(i).(a) Storage capacity We have performed quantitative analyses of the storage and retrieval processes in the CA3 network (Treves and Rolls, 1991, 1992). We have extended previous formal models of autoassociative memory (see Amit, 1989) by analyzing a network with graded response units, so as to represent more realistically the continuously variable rates at which neurons fire, and with incomplete connectivity (Treves, 1990; Treves and Rolls, 1991). We have found that in general, the maximum number $p_{\max}$ of firing patterns that can be (individually) retrieved is proportional to the number C^{RC} of (associatively) modifiable recurrent collateral synapses per cell, by a factor that increases roughly with the inverse of the sparseness a of the neuronal representation (Each memory is precisely defined in the theory: It is a set of firing rates of the population of neurons – which represent a memory – that can be stored and later retrieved, with retrieval being possible from a fraction of the originally stored set of neuronal firing rates.) The

sparseness of response (or selectivity) of a single cell to a set of stimuli (which in the brain has approximately the same value as the sparseness of the response of the population of neurons to any one stimulus, which can in turn be thought of as the proportion of neurons that is active to any one stimulus if the neurons had binary responses; see Franco et al., 2007) is defined as

$$a = \left(\sum_{i=1,n} r_i/n\right)^2 \Big/ \sum_{i=1,n}\left(r_i^2/n\right), \qquad [2]$$

where r_i is the firing rate to the ith stimulus in the set of n stimuli. The sparseness ranges from $1/n$, when the cell responds to only one stimulus, to a maximal value of 1.0, attained when the cell responds with the same rate to all stimuli. Approximately,

$$p_{\max} \cong \frac{C^{\mathrm{RC}}}{a\ln(1/a)}k, \qquad [3]$$

where k is a factor that depends weakly on the detailed structure of the rate distribution, on the connectivity pattern, and so on, but is roughly on the order of 0.2–0.3 (Treves and Rolls, 1991). The sparseness a in this equation is strictly the population sparseness (Treves and Rolls, 1991; Franco et al., 2007). The population sparseness a^{p} would be measured by measuring the distribution of firing rates of all neurons to a single stimulus at a single time. The single-cell sparseness or selectivity a^{s} would be measured by the distribution of firing rates to a set of stimuli, which would take a long time. These concepts are elucidated by Franco et al. (2007). The sparseness estimates obtained by measuring early gene changes, which are effectively population sparsenesses, would thus be expected to depend greatly on the range of environments or stimuli in which these were measured. If the environment was restricted to one stimulus, this would reflect the population sparseness. If the environment was changing, the measure from early gene changes would be rather undefined, as all the populations of neurons activated in an undefined number of testing situations would be likely to be activated. For example, for $C^{\mathrm{RC}} = 12{,}000$ and $a = 0.02$, $p_{\max}$ is calculated to be approximately 36,000. This analysis emphasizes the utility of having a sparse representation in the hippocampus, for this enables many different memories to be stored. Third, in order for most associative networks to store information efficiently, heterosynaptic LTD (as well as LTP) is required (Fazeli and Collingridge, 1996; Rolls and Deco, 2002; Rolls and Treves, 1990, 1998; Treves and Rolls, 1991). Simulations that are fully consistent with the analytic theory are provided by Simmen et al. (1996) and Rolls et al. (1997b).

We have also indicated how to estimate I, the total amount of information (in bits per synapse) that can be retrieved from the network. I is defined with respect to the information i_{p} (in bits per cell) contained in each stored firing pattern, by subtracting the amount i_{l} lost in retrieval and multiplying by p/C^{RC}:

$$I = \frac{p}{C^{\mathrm{RC}}}(i_p - i_i) \qquad [4]$$

The maximal value $I_{\max}$ of this quantity was found (Treves and Rolls, 1991) to be in several interesting cases around 0.2–0.3 bits per synapse, with only a mild dependency on parameters such as the sparseness of coding a.

We may then estimate (Treves and Rolls, 1992) how much information has to be stored in each pattern for the network to efficiently exploit its information retrieval capacity $I_{\max}$. The estimate is expressed as a requirement on i_{p}:

$$i_p > a\ln(1/a) \qquad [5]$$

As the information content of each stored pattern i_{p} depends on the storage process, we see how the retrieval capacity analysis, coupled with the notion that the system is organized so as to be an efficient memory device in a quantitative sense, leads to a constraint on the storage process.

A number of points that arise are treated elsewhere (Rolls and Kesner, 2006; Rolls, 2007). Here I note that given that the memory capacity of the hippocampal CA3 system is limited, it is necessary to have some form of forgetting in this store, or another mechanism to ensure that its capacity is not exceeded. (Exceeding the capacity can lead to a loss of much of the information retrievable from the network.) Heterosynaptic LTD could help this forgetting, by enabling new memories to overwrite old memories (Rolls, 1996a, 2007). The limited capacity of the CA3 system does also provide one of the arguments that some transfer of information from the hippocampus to neocortical memory stores may be useful (see Treves and Rolls, 1994). Given its limited capacity, the hippocampus might be a useful store for only a limited period, which might be on the order of days, weeks, or months. This period may well depend on the acquisition rate of new episodic

memories. If the animal were in a constant and limited environment, then as new information is not being added to the hippocampus, the representations in the hippocampus would remain stable and persistent. These hypotheses have clear experimental implications, both for recordings from single neurons and for the gradient of retrograde amnesia, both of which might be expected to depend on whether the environment is stable or frequently changing. They show that the conditions under which a gradient of retrograde amnesia might be demonstrable would be when large numbers of new memories are being acquired, not when only a few memories (few in the case of the hippocampus being less than a few hundred) are being learned.

1.33.2.2.3.(i).(b) Recall A fundamental property of the autoassociation model of the CA3 recurrent collateral network is that the recall can be symmetric, that is, the whole of the memory can be retrieved from any part. For example, in an object–place autoassociation memory, an object could be recalled from a place retrieval cue, and vice versa. This is not the case with a pattern association network. If, for example, the CA3 activity represented a place–spatial view, and perforant path inputs with associative synapses to CA3 neurons carried object information (consistent with evidence that the lateral perforant path [LPP] may reflect inputs from the perirhinal cortex connecting via the lateral entorhinal cortex [Hargreaves et al., 2005]), then an object could recall a place, but a place could not recall an object.

A prediction of the theory is thus that the CA3 recurrent collateral associative connections enable arbitrary associations to be formed between whatever is represented in the hippocampus, in that, for example, any place could be associated with any object, and in that the object could be recalled with a spatial recall cue, or the place with an object recall cue.

In one test of this, Day et al. (2003) trained rats in a study phase to learn in one trial an association between two flavors of food and two spatial locations. During a recall test phase they were presented with a flavor that served as a cue for the selection of the correct location. They found that injections of an NMDA blocker (AP5) or alpha-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA) blocker (CNQX) to the dorsal hippocampus prior to the study phase impaired encoding, but injections of AP5 prior to the test phase did not impair the place recall, whereas injections of CNQX did impair the place recall. The interpretation is that somewhere in the hippocampus NMDA receptors are necessary for forming one-trial odor–place associations, and that recall can be performed without further involvement of NMDA receptors.

In a hippocampus subregion test of this, rats in a study phase are shown one object in one location, and then a second object in another location. (There are 50 possible objects and 48 locations.) In the test phase, the rat is shown one object in the start box and then after a 10-s delay must go to the correct location (choosing between two marked locations). CA3 lesions made after training in the task produced chance performance on this one-trial object–place recall task. A control, fixed visual conditional-to-place task (Rolls and Kesner, 2006) with the same delay was not impaired, showing that it is recall after one-trial (or rapid) learning that is impaired. In the context of arbitrary associations between whatever is represented in CA3, the theory also predicts that cued place–object recall tasks and cued place–odor recall tasks should be impaired by CA3 lesions.

Evidence that the CA3 system is not necessarily required during recall in a reference memory spatial task, such as the water maze spatial navigation for a single spatial location task, is that CA3-lesioned rats are not impaired during recall of a previously learned water maze task (Brun et al., 2002; Florian and Roullet, 2004). However, if completion from an incomplete cue is needed, then CA3 NMDA receptors are necessary (presumably to ensure satisfactory CA3–CA3 learning), even in a reference memory task (Nakazawa et al., 2002). Thus, the CA3 system appears to be especially needed in rapid, one-trial object–place recall and when completion from an incomplete cue is required.

In a neurophysiological investigation of one-trial object–place learning followed by recall of the spatial position in which to respond when shown the object, Rolls and Xiang (2005) showed that some primate hippocampal (including CA3) neurons respond to an object cue with the spatial position in which the object had been shown earlier in the trial. Thus, some hippocampal neurons appear to reflect spatial recall given an object recall cue.

1.33.2.2.3.(i).(c) Completion Another fundamental property is that the recall can be complete even from a small fragment. Thus, it is a prediction that when an incomplete retrieval cue is given, CA3 may be especially important in the retrieval process. Tests of this prediction of a role for CA3 in pattern completion have been performed, as follows.

Rats were tested on a cheese board with a black curtain with four extramaze cues surrounding the apparatus. (The cheese board is like a dry-land water maze with 177 holes on a 119-cm-diameter board.) Rats were trained to move a sample phase object covering a food well that could appear in one of five possible spatial locations. During the test phase of the task, following a 30-s delay, the animal needs to find the same food well in order to receive reinforcement with the object now removed. After reaching stable performance in terms of accuracy to find the correct location, rats received lesions in CA3. During postsurgery testing, four extramaze cues were always available during the sample phase. However, during the test phase zero, one, two, or three cues were removed in different combinations. The results indicate that controls performed well on the task regardless of the availability of one, two, three, or all cues, suggesting intact spatial pattern completion. Following the CA3 lesion, however, there was an impairment in accuracy compared to the controls especially when only one or two cues were available, suggesting impairment in spatial pattern completion in CA3-lesioned rats (Gold and Kesner, 2005) (see **Figure 5**). A useful aspect of this task is that the test for the ability to remember a spatial location learned in one presentation can be tested with a varying number of available cues, and many times in which the locations vary, to allow for accurate measurement of pattern completion ability when the information stored on the single presentation must be recalled.

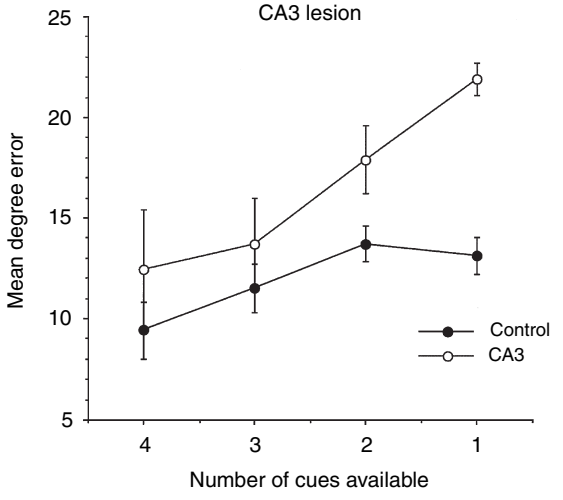

Figure 5 Pattern completion impairment produced by CA3 lesions. The mean (and SEM) degree of error in finding the correct place in the cheeseboard task when rats were tested with 1, 2, 3, or 4 of the cues available. A graded impairment in the CA3 lesion group as a function of the number of cues available was found. The task was learned in the study phase with the four cues present. The performance of the control group is also shown. After Gold AE and Kesner RP (2005) The role of the CA3 subregion of the dorsal hippocampus in spatial pattern completion in the rat. *Hippocampus* 15: 808–814.

In another study, Nakazawa et al. (2002) trained CA3 NMDA receptor-knockout mice in an analogous task, using the water maze. When the animals were required to perform the task in an environment where some of the familiar cues were removed, they were impaired in performing the task. The result suggests that the NMDA receptor–dependent synaptic plasticity mechanisms in CA3 are critical to perform the pattern completion process in the hippocampus.

1.33.2.2.3.(ii) Continuous spatial patterns and CA3 representations The fact that spatial patterns, which imply continuous representations of space, are represented in the hippocampus has led to the application of continuous attractor models to help understand hippocampal function. This has been necessary because space is inherently continuous, because the firing of place and spatial view cells is approximately Gaussian as a function of the distance away from the preferred spatial location, because these cells have spatially overlapping fields, and because the theory is that these cells in CA3 are connected by Hebb-modifiable synapses. This specification would inherently lead the system to operate as a continuous attractor network. Continuous attractor network models have been studied by Amari (1977), Zhang (1996), Taylor (1999), Samsonovich and McNaughton (1997), Battaglia and Treves (1998), Stringer et al. (2002a,b, 2004), Stringer and Rolls (2002), and Rolls and Stringer (2005) (see Rolls, 2007; Rolls and Deco, 2002) and are described next.

A continuous attractor neural network (CANN) can maintain the firing of its neurons to represent any location along a continuous physical dimension such as spatial position and head direction. It uses excitatory recurrent collateral connections between the neurons (as are present in CA3) to reflect the distance between the neurons in the state space of the animal (e.g., place or head direction). These networks can maintain the bubble of neural activity constant for long periods wherever it is started, to represent the current state (head direction, position, etc.) of the animal, and are likely to be involved in many aspects of spatial processing and memory, including spatial vision. Global inhibition is used to keep the number

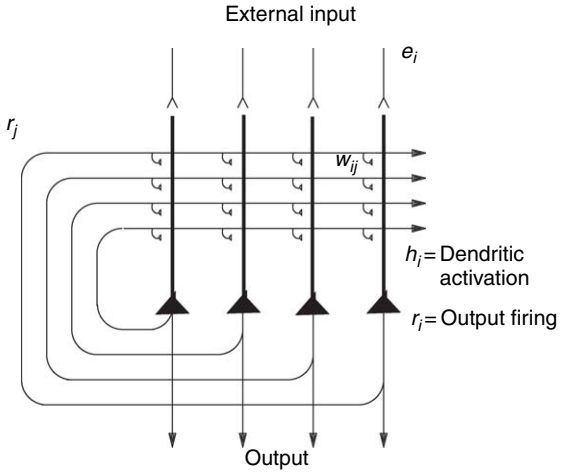

Figure 6 The architecture of a continuous attractor neural network. The architecture is the same as that of a discrete attractor neural network.

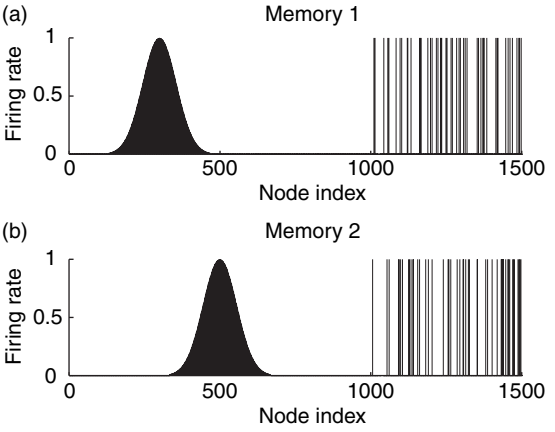

Figure 7 The types of firing patterns stored in continuous attractor networks are illustrated for the patterns present on neurons 1–1000 for Memory 1 (when the firing is that produced when the spatial state represented is that for location 300), and for Memory 2 (when the firing is that produced when the spatial state represented is that for location 500). The continuous nature of the spatial representation results from the fact that each neuron has a Gaussian firing rate that peaks at its optimal location. This particular mixed network also contains discrete representations that consist of discrete subsets of active binary firing rate neurons in the range 1001–1500. The firing of these latter neurons can be thought of as representing the discrete events that occur at the location. Continuous attractor networks by definition contain only continuous representations, but this particular network can store mixed continuous and discrete representations, and is illustrated to show the difference of the firing patterns normally stored in separate continuous attractor and discrete attractor networks. For this particular mixed network, during learning, Memory 1 is stored in the synaptic weights, then Memory 2, etc., and each memory contains a part that is continuously distributed to represent physical space and a part that represents a discrete event or object.

of neurons in a bubble or packet of actively firing neurons relatively constant and to help to ensure that there is only one activity packet. Continuous attractor networks can be thought of as very similar to autoassociation or discrete attractor networks (see Rolls and Deco 2002) and have the same architecture, as illustrated in **Figure 6**. The main difference is that the patterns stored in a CANN are continuous patterns, with each neuron having broadly tuned firing that decreases with, for example, a Gaussian function as the distance from the optimal firing location of the cell is varied, and with different neurons having tuning that overlaps throughout the space. Such tuning is illustrated in **Figure 7**. For comparison, autoassociation networks normally have discrete (separate) patterns (each pattern implemented by the firing of a particular subset of the neurons), with no continuous distribution of the patterns throughout the space (see **Figure 7**). A consequent difference is that the CANN can maintain its firing at any location in the trained continuous space, whereas a discrete attractor or autoassociation network moves its population of active neurons toward one of the previously learned attractor states, and thus implements the recall of a particular previously learned pattern from an incomplete or noisy (distorted) version of one of the previously learned patterns.

The energy landscape of a discrete attractor network (see Rolls and Deco 2002) has separate energy minima, each one of which corresponds to a learned pattern, whereas the energy landscape of a continuous attractor network is flat, so that the activity packet remains stable with continuous firing wherever it is started in the state space. (The state space refers to the set of possible spatial states of the animal in its environment, e.g., the set of possible places in a room.)

So far we have said that the neurons in the continuous attractor network are connected to each other by synaptic weights w_{ij} that are a simple function, for example, Gaussian, of the distance between the states of the agent in the physical world (e.g., head directions, spatial views, etc.) represented by the neurons. In many simulations, the weights are set by formula to have weights with these appropriate Gaussian values. However, Stringer et al. (2002b) showed how the appropriate weights could be set up by learning. They started with the fact that since

the neurons have broad tuning that may be Gaussian in shape, nearby neurons in the state space will have overlapping spatial fields, and will thus be coactive to a degree that depends on the distance between them. The authors postulated that therefore the synaptic weights could be set up by associative learning based on the coactivity of the neurons produced by external stimuli as the animal moved in the state space. For example, head direction cells are forced to fire during learning by visual cues in the environment that produces Gaussian firing as a function of head direction from an optimal head direction for each cell. The learning rule is simply that the weights w_{ij} from head direction cell j with firing rate r_j^{HD} to head direction cell i with firing rate r_i^{HD} are updated according to an associative (Hebb) rule:

$$\delta w_{ij} = k r_i^{\mathrm{HD}} r_j^{\mathrm{HD}}, \quad [6]$$

where δw_{ij} is the change of synaptic weight and k is the learning rate constant. During the learning phase, the firing rate r_i^{HD} of each head direction cell i might be the following the Gaussian function of the displacement of the head from the optimal firing direction of the cell:

$$r_i^{\mathrm{HD}} = e^{-s_{\mathrm{HD}}^2/2\sigma_{\mathrm{HD}}^2}, \quad [7]$$

where s_{HD} is the difference between the actual head direction x (in degrees) of the agent and the optimal head direction x_i for head direction cell i, and σ_{HD} is the standard deviation. Stringer et al. (2002b) showed that after training at all head directions, the synaptic connections develop strengths that are an almost Gaussian function of the distance between the cells in head direction space.

1.33.2.2.3.(iii) Combined continuous and discrete memory representations in the same (e.g., CA3) network, and episodic memory

Space is continuous, and object representations are discrete. If these representations are to be combined in, for example, an object–place memory, then we need to understand the operation of networks that combine these representations. It has now been shown that attractor networks can store both continuous patterns and discrete patterns (as illustrated in **Figure 7**) and can thus be used to store, for example, the location in (continuous, physical) space (e.g., the place out there in a room represented by spatial view cells) where an object (a discrete item) is present (Rolls et al., 2002).

1.33.2.2.3.(iv) The capacity of a continuous attractor network, and multiple charts

If spatial representations are stored in the hippocampus, the important issue arises in terms of understanding memories that include a spatial component or context of how many such spatial representations could be stored in a continuous attractor network. The very interesting result is that because there are in general low correlations between the representations of places in different maps or charts (where each map or chart might be of one room or locale), very many different maps can be simultaneously stored in a continuous attractor network (Battaglia and Treves, 1998a).

1.33.2.2.3.(v) Idiothetic update by path integration

We have considered how spatial representations could be stored in continuous attractor networks and how the activity can be maintained at any location in the state space in a form of short-term memory when the external (e.g., visual) input is removed. However, many networks with spatial representations in the brain can be updated by internal, self-motion (i.e., idiothetic) cues even when there is no external (e.g., visual) input. The way in which path integration could be implemented in recurrent networks such as the CA3 system in the hippocampus or in related systems is described next.

Single-cell recording studies have shown that some neurons represent the current position along a continuous physical dimension or space even when no inputs are available, for example, in darkness. Examples include neurons that represent the positions of the eyes (i.e., eye direction with respect to the head), the place where the animal is looking in space, head direction, and the place where the animal is located. In particular, examples of such classes of cells include head direction cells in rats (Ranck, 1985; Taube et al., 1990; Muller et al., 1996; Taube et al., 1996) and primates (Robertson et al., 1999), which respond maximally when the animal's head is facing in a particular preferred direction; place cells in rats (O'Keefe and Dostrovsky, 1971; McNaughton et al., 1983; O'Keefe, 1984; Muller et al., 1991; Markus et al., 1995) that fire maximally when the animal is in a particular location; and spatial view cells in primates that respond when the monkey is looking toward a particular location in space (Rolls et al., 1997a; Robertson et al., 1998; Georges-François et al., 1999).

One approach to simulating the movement of an activity packet produced by idiothetic cues (which is a form of path integration whereby the current location is calculated from recent movements) is to employ a look-up table that stores (taking head direction cells as an example), for every possible head direction and head rotational velocity input generated by the vestibular system, the corresponding new head direction (Samsonovich and McNaughton, 1997). An analogous approach has been described for entorhinal cortex grid cells (McNaughton et al., 2006). Another approach involves modulating the strengths of the recurrent synaptic weights in the continuous attractor on one but not the other side of a currently represented position, so that the stable position of the packet of activity, which requires symmetric connections in different directions from each node, is lost, and the packet moves in the direction of the temporarily increased weights, although no possible biological implementation was proposed of how the appropriate dynamic synaptic weight changes might be achieved (Zhang, 1996). Another mechanism (for head direction cells) (Skaggs et al., 1995) relies on a set of cells, termed (head) rotation cells, which are coactivated by head direction cells and vestibular cells and drive the activity of the attractor network by anatomically distinct connections for clockwise and counterclockwise rotation cells, in what is effectively a look-up table. However, these proposals did not show how the synaptic weights for this path integration could be achieved by a biologically plausible learning process.

Stringer et al. (2002b) introduced a proposal with more biological plausibility about how the synaptic connections from idiothetic inputs to a continuous attractor network can be learned by a self-organizing learning process. The mechanism associates a short-term memory trace of the firing of the neurons in the attractor network reflecting recent movements in the state space (e.g., of places) with an idiothetic velocity of movement input (see **Figure 8**). This has been applied to head direction cells (Stringer et al., 2002b), rat place cells (Stringer et al., 2002a,b), and primate spatial view cells (Stringer et al., 2004, 2005; Rolls and Stringer, 2005). These attractor networks provide a basis for understanding cognitive maps and how they are updated by learning and by self-motion. The implication is that to the extent that path integration of place or spatial view representations is performed within the hippocampus itself, then the CA3 system is the most likely part of the hippocampus to be involved in this, because it has

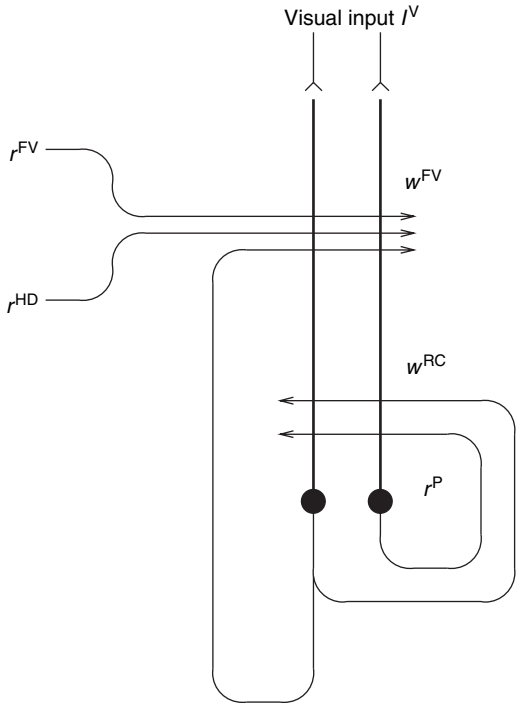

Figure 8 Neural network architecture for two-dimensional continuous attractor models of place cells. There is a recurrent network of place cells with firing rates r^P, which receives external inputs from three sources: (i) the visual system I^V, (ii) a population of head direction cells with firing rates r^{HD}, and (iii) a population of forward velocity cells with firing rates r^{FV}. The recurrent weights between the place cells are denoted by w^{RC}, and the idiothetic weights to the place cells from the forward velocity cells and head direction cells are denoted by w^{FV}.

the appropriate recurrent collateral connections. Consistent with this, Whishaw and colleagues (Maaswinkel et al., 1999; Whishaw et al., 2001; Wallace and Whishaw, 2003) have shown that path integration is impaired by hippocampal lesions. Path integration of head direction is reflected in the firing of neurons in the presubiculum, and mechanisms outside the hippocampus probably implement path integration for head direction.

1.33.2.2.3.(vi) The dynamics of the recurrent network The analysis described earlier of the capacity of a recurrent network such as the CA3 considered steady-state conditions of the firing rates of the neurons. The question arises of how quickly the recurrent network would settle into its final state. With reference to the CA3 network, how long does it take before a pattern of activity, originally evoked in

CA3 by afferent inputs, becomes influenced by the activation of recurrent collaterals? In a more general context, recurrent collaterals between the pyramidal cells are an important feature of the connectivity of the cerebral neocortex. How long would it take these collaterals to contribute fully to the activity of cortical cells? If these settling processes took on the order of hundreds of milliseconds, they would be much too slow to contribute usefully to cortical activity, whether in the hippocampus or the neocortex (Rolls, 1992; Panzeri et al., 2001; Rolls and Deco, 2002; Rolls, 2003).

It has been shown that if the neurons are not treated as McCulloch-Pitts neurons, which are simply updated at each iteration, or cycle of time steps (and assume the active state if the threshold is exceeded), but instead are analyzed and modeled as integrate-and-fire neurons in real continuous time, then the network can effectively relax into its recall state very rapidly in one or two time constants of the synapses (Treves, 1993; Battaglia and Treves, 1998b; Rolls and Treves, 1998; Rolls and Deco, 2002). This corresponds to perhaps 20 ms in the brain. One factor in this rapid dynamics of autoassociative networks with brain-like integrate-and-fire membrane and synaptic properties is that with some spontaneous activity, some of the neurons in the network are close to threshold already before the recall cue is applied, and hence some of the neurons are very quickly pushed by the recall cue into firing, so that information starts to be exchanged very rapidly (within 1–2 ms of brain time) through the modified synapses by the neurons in the network. The progressive exchange of information starting early on within what would otherwise be thought of as an iteration period (of perhaps 20 ms, corresponding to a neuronal firing rate of 50 spikes/s) is the mechanism accounting for rapid recall in an autoassociative neuronal network made biologically realistic in this way. Further analysis of the fast dynamics of these networks if they are implemented in a biologically plausible way with integrate-and-fire neurons, is provided in Section 7.7 of Rolls and Deco (2002), in Appendix A5 of Rolls and Treves (1998), by Treves (1993), and by Panzeri et al. (2001).

1.33.2.2.3.(vii) Mossy fiber inputs to the CA3 cells We hypothesize that the mf inputs force efficient information storage by virtue of their strong and sparse influence on the CA3 cell firing rates (Rolls, 1987, 1989b,d; Treves and Rolls, 1992). (The strong effects likely to be mediated by the mfs were also emphasized by McNaughton and Morris [1987] and McNaughton and Nadel [1990].) We hypothesize that the mf input appears to be particularly appropriate in several ways.

First of all, the fact that mf synapses are large and located very close to the soma makes them relatively powerful in activating the postsynaptic cell. (This should not be taken to imply that a CA3 cell can be fired by a single mf excitatory postsynaptic potential [EPSP].)

Second, the firing activity of dentate granule cells appears to be very sparse (Jung and McNaughton, 1993), and this, together with the small number of connections on each CA3 cell, produces a sparse signal, which can then be transformed into an even sparser firing activity in CA3 by a threshold effect. For example, if only one granule cell in 100 were active in the dentate gyrus, and each CA3 cell received a connection from 50 randomly placed granule cells, then the number of active mf inputs received by CA3 cells would follow a Poisson distribution of average $50/100 = 1/2$, that is, 60% of the cells would not receive any active input, 30% would receive only one, 7.5% two, little more than 1% would receive three, and so on. (It is easy to show from the properties of the Poisson distribution and our definition of sparseness that the sparseness of the mf signal as seen by a CA3 cell would be $x/(1+x)$, with $x = C^{\mathrm{MF}} a_{\mathrm{DG}}$, assuming equal strengths for all mf synapses.) If three mf inputs were required to fire a CA3 cell and these were the only inputs available, we see that the activity in CA3 would be roughly as sparse, in the example, as in the dentate gyrus. C^{MF} is the number of mf connections to a CA3 neuron, and a_{DG} is the sparseness of the representation in the dentate granule cells.

Third, nonassociative plasticity of mfs (see Brown et al., 1989, 1990) might have a useful effect in enhancing the signal-to-noise ratio, in that a consistently firing mf would produce nonlinearly amplified currents in the postsynaptic cell, which would not happen with an occasionally firing fiber (Treves and Rolls, 1992). This plasticity, and also learning in the dentate, would also have the effect that similar fragments of each episode (e.g., the same environmental location) recurring on subsequent occasions would be more likely to activate the same population of CA3 cells, which would have potential advantages in terms of economy of use of the CA3 cells in different memories, and in making some link between different episodic memories with a common feature, such as the same location in space.

Fourth, with only a few, and powerful, active mf inputs to each CA3 cell, setting a given sparseness of the representation provided by CA3 cells would be simplified, for the EPSPs produced by the mfs would be Poisson distributed with large membrane potential differences for each active mf. Setting the average firing rate of the dentate granule cells would effectively set the sparseness of the CA3 representation, without great precision being required in the threshold setting of the CA3 cells (Rolls et al., 1997b). Part of what is achieved by the mf input may be setting the sparseness of the CA3 cells correctly, which, as shown above, is very important in an autoassociative memory store.

Fifth, the nonassociative and sparse connectivity properties of the mf connections to CA3 cells may be appropriate for an episodic memory system that can learn very fast, in one trial. The hypothesis is that the sparse connectivity would help arbitrary relatively uncorrelated sets of CA3 neurons to be activated for even somewhat similar input patterns without the need for any learning of how best to separate the patterns, which in a self-organizing competitive network would take several repetitions (at least) of the set of patterns.

The mf solution may thus be adaptive in a system that must learn in one trial, and for which the CA3 recurrent collateral learning requires uncorrelated sets of CA3 cells to be allocated for each (one-trial) episodic memory. The hypothesis is that the mf sparse connectivity solution performs the appropriate function without the mf system having to learn by repeated presentations of how best to separate a set of training patterns. The perforant path input would, the quantitative analysis shows, not produce a pattern of firing in CA3 that contains sufficient information for learning (Treves and Rolls, 1992).

On the basis of these points, we predict that the mfs may be necessary for new learning in the hippocampus but may not be necessary for recall of existing memories from the hippocampus. Experimental evidence consistent with this prediction about the role of the mfs in learning has been found in rats with disruption of the dentate granule cells (Lassalle et al., 2000).

As acetylcholine turns down the efficacy of the recurrent collateral synapses between CA3 neurons (Hasselmo et al., 1995), then cholinergic activation also might help to allow external inputs rather than the internal recurrent collateral inputs to dominate the firing of the CA3 neurons during learning, as the current theory proposes. If cholinergic activation at the same time facilitated LTP in the recurrent collaterals (as it appears to in the neocortex), then cholinergic activation could have a useful double role in facilitating new learning at times of behavioral activation, when presumably it may be particularly relevant to allocate some of the limited memory capacity to new memories.

1.33.2.2.3.(viii) Perforant path inputs to CA3 cells By calculating the amount of information that would end up being carried by a CA3 firing pattern produced solely by the perforant path input and by the effect of the recurrent connections, we have been able to show (Treves and Rolls, 1992) that an input of the perforant path type, alone, is unable to direct efficient information storage. Such an input is too weak, it turns out, to drive the firing of the cells, as the dynamics of the network are dominated by the randomizing effect of the recurrent collaterals. This is the manifestation, in the CA3 network, of a general problem affecting storage (i.e., learning) in all autoassociative memories. The problem arises when the system is considered to be activated by a set of input axons making synaptic connections that have to compete with the recurrent connections, rather than having the firing rates of the neurons artificially clamped into a prescribed pattern.

An autoassociative memory network needs afferent inputs also in the other mode of operation, that is, when it retrieves a previously stored pattern of activity. We have shown (Treves and Rolls, 1992) that the requirements on the organization of the afferents are in this case very different, implying the necessity of a second, separate input system, which we have identified with the perforant path to CA3. In brief, the argument is based on the notion that the cue available to initiate retrieval might be rather small, that is, the distribution of activity on the afferent axons might carry a small correlation, $q << 1$, with the activity distribution present during learning. In order not to lose this small correlation altogether, but rather transform it into an input current in the CA3 cells that carries a sizable signal – which can then initiate the retrieval of the full pattern by the recurrent collaterals – one needs a large number of associatively modifiable synapses. This is expressed by the formulas that give the specific signal S produced by sets of associatively modifiable synapses, or by nonassociatively modifiable synapses: If C^{AFF} is the number of afferents per cell,

$$S_{\mathrm{ASS}} \sim \frac{\sqrt{C^{\mathrm{AFF}}}}{\sqrt{p}}\, q \quad S_{\mathrm{NONASS}} \sim \frac{1}{\sqrt{C^{\mathrm{AFF}}}}\, q. \qquad [8]$$

Associatively modifiable synapses are therefore needed and are needed in a number C^{AFF} of the same order as the number of concurrently stored patterns p, so that small cues can be effective, whereas nonassociatively modifiable synapses – or even more so, nonmodifiable ones – produce very small signals, which decrease in size the larger the number of synapses. In contrast with the storage process, the average strength of these synapses does not play now a crucial role. This suggests that the perforant path system is the one involved in relaying the cues that initiate retrieval.

1.33.2.2.4 CA1 cells

1.33.2.2.4.(i) Associative retrieval at the CA3 to CA1 (Schaffer collateral) synapses The CA3 cells connect to the CA1 cells by the Schaeffer collateral synapses. The following arguments outline the advantage of this connection being associatively modifiable and apply independently of the relative extent to which the CA3 or the direct entorhinal cortex inputs to CA1 drive the CA1 cells during the learning phase.

The amount of information about each episode retrievable from CA3 has to be balanced against the number of episodes that can be held concurrently in storage. The balance is regulated by the sparseness of the coding. Whatever the amount of information per episode in CA3, one may hypothesize that the organization of the structures that follow CA3 (i.e., CA1, the various subicular fields, and the return projections to neocortex) should be optimized so as to preserve and use this information content in its entirety. This would prevent further loss of information, after the massive but necessary reduction in information content that has taken place along the sensory pathways and before the autoassociation stage in CA3. We have proposed (Treves and Rolls, 1994; Treves, 1995) that the need to preserve the full information content present in the output of an autoassociative memory requires an intermediate recoding stage (CA1) with special characteristics. In fact, a calculation of the information present in the CA1 firing pattern, elicited by a pattern of activity retrieved from CA3, shows that a considerable fraction of the information is lost if the synapses are nonmodifiable, and that this loss can be prevented only if the CA3 to CA1 synapses are associatively modifiable. Their modifiability should match the plasticity of the CA3 recurrent collaterals. The additional information that can be retrieved beyond that retrieved by CA3 because the CA3 to CA1 synapses are associatively modifiable is strongly demonstrated by the hippocampal simulation described by Rolls (1995) and is quantitatively analyzed by Schultz and Rolls (1999).

1.33.2.2.4.(ii) Recoding in CA1 to facilitate retrieval to the neocortex If the total amount of information carried by CA3 cells is redistributed over a larger number of CA1 cells, less information needs to be loaded onto each CA1 cell, rendering the code more robust to information loss in the next stages. For example, if each CA3 cell had to code for two bits of information, for example, by firing at one of four equiprobable activity levels, then each CA1 cell (if there were twice as many as there are CA3 cells) could code for just 1 bit, for example, by firing at one of only two equiprobable levels. Thus, the same information content could be maintained in the overall representation while reducing the sensitivity to noise in the firing level of each cell. In fact, there are more CA1 cells than CA3 cells in rats (2.5×10^5). There are even more CA1 cells (4.6×10^6) in humans (and the ratio of CA1 to CA3 cells is greater). The CA1 cells may thus provide the first part of the expansion for the return projections to the enormous numbers of neocortical cells in primates, after the bottleneck of the single network in CA3, the number of neurons in which may be limited because it has to operate as a single network.

Another argument on the operation of the CA1 cells is also considered to be related to the CA3 autoassociation effect. In this, several arbitrary patterns of firing occur together on the CA3 neurons and become associated together to form an episodic or whole scene memory. It is essential for this CA3 operation that several different sparse representations are present conjunctively in order to form the association. Moreover, when completion operates in the CA3 autoassociation system, all the neurons firing in the original conjunction can be brought into activity by only a part of the original set of conjunctive events. For these reasons, a memory in the CA3 cells consists of several different simultaneously active ensembles of activity. To be explicit, the parts A, B, C, D, and E of a particular episode would each be represented, roughly speaking, by its own population of CA3 cells, and these five populations would be linked together by autoassociation. It is suggested that the CA1 cells, which receive these groups of simultaneously active ensembles, can detect the conjunctions of firing of the different ensembles that represent the episodic memory and

allocate by competitive learning neurons to represent at least larger parts of each episodic memory (Rolls, 1987, 1989a,b,d, 1990a,b). In relation to the simple example above, some CA1 neurons might code for ABC, and others for BDE, rather than having to maintain independent representations in CA1 of A, B, C, D, and E. This implies a more efficient representation, in the sense that when eventually, after many further stages, neocortical neuronal activity is recalled (as discussed later), each neocortical cell need not be accessed by all the axons carrying each component A, B, C, D, and E but, instead, by fewer axons carrying larger fragments, such as ABC and BDE. This process is performed by competitive networks, which self-organize to find categories in the input space, where each category is represented by a set of simultaneously active inputs (Rolls and Treves, 1998; Rolls, 2000; Rolls and Deco, 2002).

1.33.2.2.4.(iii) CA1 inputs from CA3 vs direct entorhinal inputs Another feature of the CA1 network is its double set of afferents, with each of its cells receiving most synapses from the Schaeffer collaterals coming from CA3, but also a proportion (about 1/6; Amaral et al., 1990) from direct perforant path projections from entorhinal cortex. Such projections appear to originate mainly in layer 3 of entorhinal cortex (Witter et al., 1989) from a population of cells only partially overlapping with that (mainly in layer 2) giving rise to the perforant path projections to DG and CA3. This suggests that it is useful to include in CA1 not only what it is possible to recall from CA3 but also the detailed information present in the retrieval cue itself (see Treves and Rolls, 1994).

Another possibility is that the perforant path input provides the strong forcing input to the CA1 neurons during learning and that the output of the CA3 system is associated with this forced CA1 firing during learning (McClelland et al., 1995). During recall, an incomplete cue could then be completed in CA3, and the CA3 output would then produce firing in CA1 that would correspond to that present during the learning. This suggestion is essentially identical to that of Treves and Rolls (1994) about the backprojection system and recall, except that McClelland et al. (1995) suggest that the output of CA3 is associated at the CA3 to CA1 (Schaeffer collateral) synapses with the signal present during training in CA1, whereas in the theory of Treves and Rolls (1994), the output of the hippocampus consists of CA1 firing, which is associated in the entorhinal cortex and earlier cortical stages with the firing present during learning, providing a theory of how the correct recall is implemented at every backprojection stage though the neocortex (see the next section).

1.33.2.2.5 Backprojections to the neocortex – a hypothesis

The need for information to be retrieved from the hippocampus to affect other brain areas was noted in the introduction. The way in which this could be implemented via backprojections to the neocortex is now considered.

It is suggested that the modifiable connections from the CA3 neurons to the CA1 neurons allow the whole episode in CA3 to be produced in CA1. This may be assisted as described above by the direct perforant path input to CA1. This might allow details of the input key for the recall process, as well as the possibly less information-rich memory of the whole episode recalled from the CA3 network, to contribute to the firing of CA1 neurons. The CA1 neurons would then activate, via their termination in the deep layers of the entorhinal cortex, at least the pyramidal cells in the deep layers of the entorhinal cortex (see **Figure 1**). These entorhinal cortex layer 5 neurons would then, by virtue of their backprojections (Lavenex and Amaral, 2000; Witter et al., 2000a) to the parts of cerebral cortex that originally provided the inputs to the hippocampus, terminate in the superficial layers (including layer 1) of those neocortical areas, where synapses would be made onto the distal parts of the dendrites of the (superficial and deep) cortical pyramidal cells (Rolls, 1989a, 1989b, 1989d). The areas of cerebral neocortex in which this recall would be produced could include multimodal cortical areas (e.g., the cortex in the superior temporal sulcus, which receives inputs from temporal, parietal, and occipital cortical areas, and from which it is thought that cortical areas such as 39 and 40, related to language, developed), and also areas of unimodal association cortex (e.g., inferior temporal visual cortex). The backprojections, by recalling previous episodic events, could provide information useful to the neocortex in the building of new representations in the multimodal and unimodal association cortical areas, which by building new long-term representations can be considered as a form of memory consolidation (Rolls, 1989a,b,d, 1990a,b), or in organizing actions.

The hypothesis of the architecture with which this would be achieved is shown in **Figure 1**. The feedforward connections from association areas of the

cerebral neocortex (solid lines in Figure 1) show major convergence as information is passed to CA3, with the CA3 autoassociation network having the smallest number of neurons at any stage of the processing. The backprojections allow for divergence back to neocortical areas. The way in which I suggest that the backprojection synapses are set up to have the appropriate strengths for recall is as follows (Rolls, 1989a,b,d). During the setting up of a new episodic memory, there would be strong feedforward activity progressing toward the hippocampus. During the episode, the CA3 synapses would be modified, and via the CA1 neurons and the subiculum, a pattern of activity would be produced on the backprojecting synapses to the entorhinal cortex. Here the backprojecting synapses from active backprojection axons onto pyramidal cells being activated by the forward inputs to entorhinal cortex would be associatively modified. A similar process would be implemented at preceding stages of neocortex, that is, in the parahippocampal gyrus/perirhinal cortex stage, and in association cortical areas, as shown in Figure 1.

The concept is that during the learning of an episodic memory, cortical pyramidal cells in at least one of the stages would be driven by forward inputs but would simultaneously be receiving backprojected activity (indirectly) from the hippocampus, which would, by pattern association from the backprojecting synapses to the cortical pyramidal cells, become associated with whichever cortical cells were being made to fire by the forward inputs. Then, later on, during recall, a recall cue from perhaps another part of cortex might reach CA3, where the firing during the original episode would be completed. The resulting backprojecting activity would then, as a result of the pattern association learned previously, bring back the firing in any cortical area that was present during the original episode. Thus, retrieval involves reinstating the activity that was present in different cortical areas during the learning of an episode. (The pattern association is also called heteroassociation, to contrast it with autoassociation. The pattern association operates at multiple stages in the backprojection pathway, as made evident in Figure 1.) If the recall cue was an object, this might result in recall of the neocortical firing that represented the place in which that object had been seen previously. As noted elsewhere in this chapter and by McClelland et al. (1995), that recall might be useful to the neocortex to help it build new semantic memories, which might inherently be a slow process and is not part of the theory of recall.

1.33.2.2.6 Backprojections to the neocortex – quantitative aspects

A plausible requirement for a successful hippocampus-directed recall operation is that the signal generated from the hippocampally retrieved pattern of activity, and carried backward toward neocortex, remains undegraded when compared to the noise due, at each stage, to the interference effects caused by the concurrent storage of other patterns of activity on the same backprojecting synaptic systems. That requirement is equivalent to that used in deriving the storage capacity of such a series of heteroassociative memories, and it was shown in Treves and Rolls (1991) that the maximum number of independently generated activity patterns that can be retrieved is given, essentially, by the same formula as eqn (3) above where, however, a is now the sparseness of the representation at any given stage and C is the average number of (back)projections each cell of that stage receives from cells of the previous one. (k′ is a similar, slowly varying factor to that introduced above.) If p is equal to the number of memories held in the hippocampal memory, it is limited by the retrieval capacity of the CA3 network, $p_{\max}$. Putting together the formula for the latter with that shown here, one concludes that, roughly, the requirement implies that the number of afferents of (indirect) hippocampal origin to a given neocortical stage (C^{HBP}), must be $C^{\mathrm{HBP}} = C^{\mathrm{RC}} a_{\mathrm{nc}}/a_{\mathrm{CA3}}$, where C^{RC} is the number of recurrent collaterals to any given cell in CA3, the average sparseness of a representation is a_{nc}, and a_{CA3} is the sparseness of memory representations there in CA3.

This requirement is very strong: Even if representations were to remain as sparse as they are in CA3, which is unlikely, to avoid degrading the signal, C^{HBP} should be as large as C^{RC}, that is, 12,000 in the rat. If then C^{HBP} has to be of the same order as C^{RC}, one is led to a very definite conclusion: A mechanism of the type envisaged here could not possibly rely on a set of monosynaptic CA3-to-neocortex backprojections. This would imply that, to make a sufficient number of synapses on each of the vast number of neocortical cells, each cell in CA3 has to generate a disproportionate number of synapses (i.e., C^{HBP} times the ratio between the number of neocortical and the number of CA3 cells). The required divergence can be kept within reasonable limits only by assuming that the backprojecting system is polysynaptic, provided that the number of cells involved grows gradually at each

stage, from CA3 back to neocortical association areas (Treves and Rolls, 1994) (cf. **Figure 1**).

The theory of recall by the backprojections thus provides a quantitative account of why the cerebral cortex has as many backprojection as forward projection connections. Further aspects of the operation of the backprojecting systems are described elsewhere (Rolls, 2008).

1.33.3 Comparison with Other Theories of Hippocampal Function

The overall theory described here is close in different respects to those of a number of other investigators (Marr, 1971; Brown and Zador, 1990; McNaughton and Nadel, 1990; Eichenbaum et al., 1992; Gaffan, 1992; Squire, 1992; Moscovitch et al., 2005), and of course priority is not claimed on all the propositions put forward here.

Some theories postulate that the hippocampus performs spatial computation. The theory of O'Keefe and Nadel (1978), that the hippocampus implements a cognitive map, placed great emphasis on spatial function. It supposed that the hippocampus at least holds information about allocentric space in a form that enables rats to find their way in an environment even when novel trajectories are necessary, that is, it permits an animal to "go from one place to another independent of particular inputs (cues) or outputs (responses), and to link together conceptually parts of the environment which have never been experienced at the same time" (O'Keefe and Nadel, 1978). O'Keefe (1990) extended this analysis and produced a computational theory of the hippocampus as a cognitive map, in which the hippocampus performs geometric spatial computations. Key aspects of the theory are that the hippocampus stores the centroid and slope of the distribution of landmarks in an environment and stores the relationships between the centroid and the individual landmarks. The hippocampus then receives as inputs information about where the rat currently is and where the rat's target location is and computes geometrically the body turns and movements necessary to reach the target location. In this sense, the hippocampus is taken to be a spatial computer, which produces an output that is very different from its inputs. This is in contrast to the present theory, in which the hippocampus is a memory device that is able to recall what was stored in it, using as input a partial cue. A prototypical example in Rolls' theory is the learning of object–place association memory and the recall of the whole memory from a part, which can be used as a model of event or episodic memory. O'Keefe's theory postulates that the hippocampus actually performs a spatial computation. A later theory (Burgess et al., 1994, 2000) also makes the same postulate, but now the firing of place cells is determined by the distance and approximate bearing to landmarks, and the navigation is performed by increasing the strength of connections from place cells to goal cells and then performing a gradient-ascent style search for the goal using the network.

McNaughton et al. (1991) have also proposed that the hippocampus is involved in spatial computation. They propose a compass solution to the problem of spatial navigation along novel trajectories in known environments, postulating that distances and bearings (i.e., vector quantities) from landmarks are stored, and that computation of a new trajectory involves vector subtraction by the hippocampus. They postulate that a linear associative mapping is performed, using as inputs a cross-feature (combination) representation of (head) angular velocity and (its time integral) head direction, to produce as output the future value of the integral (head direction) after some specified time interval. The system can be reset by learned associations between local views of the environment and head direction, so that when later a local view is seen, it can lead to an output from the network that is a (corrected) head direction. They suggest that some of the key signals in the computational system can be identified with the firing of hippocampal cells (e.g., local view cells) and subicular cells (head direction cells). It should be noted that this theory requires a (linear) associative mapping with an output (head direction) different in form from the inputs (head angular velocity over a time period, or local view). This is pattern association (with the conditioned stimulus local view and the unconditioned stimulus head direction), not autoassociation, and it has been postulated that this pattern association can be performed by the hippocampus (cf. McNaughton and Morris, 1987). This theory is again in contrast to the present theory, in which the hippocampus operates as a memory to store events that occur at the same time and can recall the whole memory from any part of what was stored. (A pattern associator uses a conditioned stimulus to map an input to a pattern of firing in an output set of neurons, which is like that produced in the output neurons by the unconditioned stimulus. A description of pattern associations and autoassociators in a neurobiological context is provided by Rolls (1996a, 2007) and Rolls

and Treves (1998). The present theory is fully consistent with the presence of spatial view cells and whole-body motion cells in the primate hippocampus (Rolls, 1999; Rolls and O'Mara, 1993; Rolls and Xiang, 2006) (or place or local view cells in the rat hippocampus, and head direction cells in the presubiculum), for it is often important to store and later recall where one has been (views of the environment, body turns made, etc.), and indeed such (episodic) memories are required for navigation by dead reckoning in small environments.

The present theory thus holds that the hippocampus is used for the formation of episodic memories using autoassociation. This function is often necessary for successful spatial computation but is not itself spatial computation. Instead, I believe that spatial computation is more likely to be performed in the neocortex (utilizing information if necessary recalled from the hippocampus). Consistent with this view, hippocampal damage impairs the ability to learn new environments but not to perform spatial computations such as finding one's way to a place in a familiar environment, whereas damage to the parietal cortex and parahippocampal cortex can lead to problems such as topographical and other spatial agnosias in humans (see Gruesser and Landis, 1991; Kolb and Whishaw, 2003). This is consistent with spatial computations normally being performed in the neocortex. In monkeys, there is evidence for a role of the parietal cortex in allocentric spatial computation. For example, monkeys with parietal cortex lesions are impaired at performing a landmark task in which the object to be chosen is signified by the proximity to it of a landmark (another object; Ungerleider and Mishkin, 1982).

A theory closely related to the present theory of how the hippocampus operates has been developed by McClelland et al. (1995). It is very similar to the theory we have developed (Rolls, 1987, 1989a,b,d; Treves and Rolls, 1992, 1994; Rolls, 2007) at the systems level, except that it takes a stronger position on the gradient of retrograde amnesia, emphasizes that recall from the hippocampus of episodic information is used to help build semantic representations in the neocortex, and holds that the last set of synapses that are modified rapidly during the learning of each episode are those between the CA3 and the CA1 pyramidal cells, as described above (see **Figure 1**). It also emphasizes the important point that the hippocampal and neocortical memory systems may be quite different, with the hippocampus specialized for the rapid learning of single events or episodes and the neocortex for the slower learning of semantic representations, which may necessarily benefit from the many exemplars needed to shape the semantic representation.

Lisman and colleagues (2005) have considered how the memory of sequences could be implemented in the hippocampus. This theory of sequential recall within the hippocampus is inextricably linked to the internal timing within the hippocampus imposed, he believes, by the theta and gamma oscillations, and this makes it difficult to recall each item in the sequence as it is needed. It is not specified how one would read out the sequence information, given that the items are only 12 ms apart. The Jensen and Lisman (1996) model requires short, time constant NMDA channels and is therefore unlikely to be implemented in the hippocampus. Hasselmo and Eichenbaum (2005) have taken up some of these sequence ideas and incorporated them into their model, which has its origins in the Rolls and Treves model (Rolls, 1989b; Treves and Rolls, 1992, 1994), but proposes, for example, that sequences are stored in entorhinal cortex layer III. The proposal that acetylcholine could be important during encoding by facilitating CA3–CA3 LTP, and should be lower during retrieval (Hasselmo et al., 1995), is an important concept.

Another type of sequence memory uses synaptic adaptation to effectively encode the order of the items in a sequence (Deco and Rolls, 2005). This could be implemented in recurrent networks such as the CA3 or the prefrontal cortex.

In this chapter, we have seen that quantitative approaches to the functions of the hippocampus in memory are being developed by a number of investigators and that these theories are consistent with the quantitative circuitry of the hippocampus as well as with neuronal recordings and the effects of lesions. Moreover, we have seen that the predictions of these theories are now being tested.

1.34 Neural Computation Theories of Learning

S. B. Moldakarimov, Salk Institute for Biological Studies, La Jolla, CA, USA

T. J. Sejnowski, Salk Institute for Biological Studies and University of California at San Diego, La Jolla, CA, USA

1.34.1 Introduction

The anatomical discoveries in the nineteenth century and the physiological studies in the twentieth century showed that brains were networks of neurons connected through synapses. This led to the theory that learning could be the consequence of changes in the strengths of the synapses.

The best-known theory of learning based on synaptic plasticity is that proposed by Donald Hebb, who postulated that connection strengths between neurons are modified based on neural activities in the presynaptic and postsynaptic cells:

> When an axon of cell A is near enough to excite cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased. (Hebb, 1949)

This postulate was experimentally confirmed in the hippocampus with high-frequency stimulation of a presynaptic neuron that caused long-term potentiation (LTP) in the synapses connecting it to the postsynaptic neuron (Bliss and Lomo, 1973). LTP takes place only if the postsynaptic cell is also active and sufficiently depolarized (Kelso et al., 1986). This is due to the *N*-methyl-D-aspartate (NMDA) type of glutamate receptor, which opens when glutamate is bound to the receptor, and the postsynaptic cell is sufficiently depolarized at the same time (*See* Chapters 1.33, 1.35).

Hebb's postulate has served as the starting point for studying the learning capabilities of artificial neural networks (ANN) and for the theoretical analysis and computational modeling of biological neural systems. The architecture of an ANN determines its behavior and learning capabilities. The architecture of a network is defined by the connections among the artificial neural units and the function that each unit performs on its inputs (*See* Chapter 1.35). Two general classes are feedforward and recurrent architecture.

The simplest feedforward network has one layer of input units and one layer of output units (**Figure 1**, left). All connections are unidirectional and project from the input units to the output units. The perceptron is an example of a simple feedforward network (Rosenblatt, 1958). It can learn to classify patterns from examples. It turned out that the perceptron can only classify patterns that are linearly separable – that is, if the positive patterns can be separated from all negative patterns by a plane in the space of input patterns. More powerful multilayer feedforward networks can discriminate patterns that are not linearly separable. In a multilayer feedforward network, the 'hidden' layers of units between the input and output layers allow more flexibility in learning features. Multilayer feedforward networks have also been applied to solve some other difficult problems (Rumelhart and McClelland, 1986).

In contrast to strictly feedforward network models, recurrent networks also have feedback connections

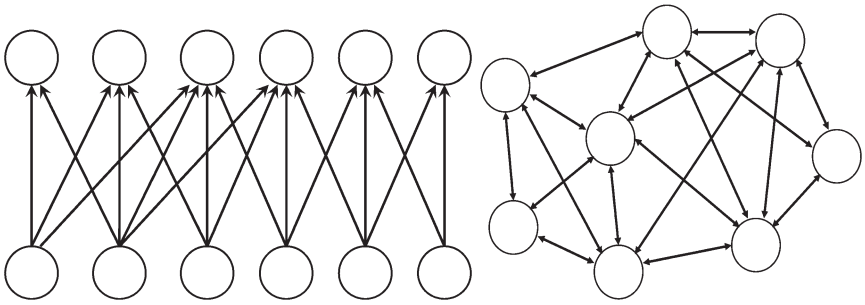

Figure 1 Network architectures. Left: Feedforward network. Right: Recurrent network. Open circles represent neuronal units, and arrowhead lines represent synaptic connections.

among units in the network (**Figure 1**, right). A simple recurrent network can have a uniform architecture such as all-to-all connectivity combined with symmetric weights between units, as in a Hopfield network (Hopfield, 1982), or it can be a network with specific connections designed to model a particular biological system.

Modeling learning processes in networks implies that the strengths of connections and other parameters are adjusted according to a learning rule (*See* Chapter 1.33). Other parameters that may change include the threshold of the unit, time constants, and other dynamical variables. A learning rule is a dynamical equation that governs changes in the parameters of the network. There are three main categories of learning rules: unsupervised, supervised, and reinforcement. Unsupervised learning rules are those that require no feedback from a teaching signal. Supervised learning rules require a teacher, who provides detailed information on the desired values of the output units of the network, and connections are adjusted based on discrepancies between the actual output and the desired one. Reinforcement learning is also error correcting but involves a single scalar signal about the overall performance of the network. Thus, reinforcement learning requires less-detailed information than supervised learning.

A learning algorithm specifies how and under what conditions a learning rule or a combination of learning rules should be applied to adjust the network parameters. For a simple task, it is possible to invent an algorithm that includes only one type of learning rule, but for more complex problems, an algorithm may involve a combination of several different learning rules.

In the following sections, we give an overview of basic learning rules and examples of learning algorithms used in neural network models, and describe specific problems solved by neural networks with adjustable parameters.

1.34.2 Hebbian Learning

Implementations of Hebb's rule can take different forms (Sejnowski and Tesauro, 1988). Simple associative Hebbian learning is based on the coincidence of activities in presynaptic and postsynaptic neurons. The dynamics of Hebbian learning are governed by a differential equation:

$$\frac{\mathrm{d}w_{ij}}{\mathrm{d}t} = \alpha \cdot v_i \cdot u_j$$

where w_{ij} is the weight of a connection from an input unit j with activity u_j to an output unit i with activity v_i, and α is a learning rate.

The Hebbian learning rule has been used to model a wide variety of problems, including feature selectivity and cortical map development.

Cortical neurons respond selectively to particular feature stimuli, such as selectivity for ocular dominance and orientation in the visual cortex. To understand challenges of modeling the development of feature selectivity, consider a network with many input units and one output unit. We would like to explore under what conditions the output unit will respond well to few input units and less to the others. If we apply a stimulus to the input units and allow the connections to develop according to the Hebbian learning rule, then all connections will grow and eventually saturate, and no selectivity will emerge. To develop selectivity, some dependencies among weights are needed, so that changes at one connection will influence the others. There are many different ways to introduce dependencies. One

approach is to introduce weight normalization (Miller and Mackay, 1994). A different approach, based on competition among input patterns, called the BCM (Bienenstock, Cooper, and Munro) rule (Bienenstock et al., 1982), has been used to model the development of orientation selectivity and ocular dominance in neural networks.

Neuronal response selectivity varies across the cortex in regular patterns called cortical maps. Although some aspects of cortical map formation during development are activity independent, neuronal activity can modify the maps. Hebbian learning rules have also been applied to model the effects of cortical activity on map formations. For comprehensive overviews of neural network models that develop orientation selectivity maps and ocular dominance columns, see Swindale (1996) and Ferster and Miller (2000).

Models of cortical map formation can become extremely complex when multiple features, such as retinotopic location, ocular dominance, orientation preference, and others, are considered simultaneously. To deal with such problems, a more abstract class of models was developed by Kohonen (1982). The Kohonen algorithm is usually applied to two-layer networks with feedforward connections from an input layer to an output layer. The input layer is an N-dimensional vector layer. The output layer is normally a one- or two-dimensional array. There are no lateral connections in the output layer, but the algorithm can accomplish what models with lateral connections can achieve at less computational cost. The algorithm does this by a weight updating procedure that involves neighboring units. At every step, it chooses a 'winner' among output units whose weights are closest to the input pattern. Then it updates the weights of the winner and the nearby neighbors of the winner. The number of neighbors that participate in weight updating is controlled through a neighborhood function, which is dynamically changed during learning to ensure convergence. The neighborhood function starts out long range and is reduced as learning proceeds. This allows the network to organize a map rapidly and then refine it more slowly with subsequent learning.

Models based on the Kohonen algorithm perform dimensionality reduction, which facilitates data analysis, taking input vectors from a high-dimensional feature space and projecting them onto a low-dimensional representation.

1.34.3 Unsupervised Hebbian Learning

If the goal of learning is to discover the statistical structure in unlabeled input data, then the learning is said to be unsupervised. A common method for unsupervised learning is principal component analysis (PCA). Suppose the data are a set of N-dimensional input vectors. The task is to find an $M < N$ dimensional representation of N-dimensional input vectors that contains as much information as possible of the input data. This is an example of dimensionality reduction, which can significantly simplify subsequent data analysis.

A simple network that can extract the first principal component (the one with the maximal variance) is a network with N input units and one output unit. At each time step an N-dimensional input vector is applied to the input layer. If we allow the connections to be modified according to the Hebbian learning rule, then in the case of zero mean value of the input vector, the weights will form an N-dimensional vector, along which the variance will be the largest. This is the principal eigenvector or component. A network with N input and M output units, augmented with a generalized Hebbian learning rule, can learn first M components. The projections of the input data onto the components give us M-dimensional representation of the N-dimensional input data.

PCA is appropriate when the data obey Gaussian statistics, but images, audio recordings, and many types of scientific data often do not have Gaussian distributions. As an example of such a problem, consider a room where a number of people are talking simultaneously (cocktail party), and the task is to focus on one of the speakers. The human brain can, to some extent, solve this auditory source separation problem by using knowledge of the speaker, but this becomes a more difficult problem when the signals are arbitrary. The goal of blind source separation (BSS) is to recover source signals given only sensor signals that are linear mixtures of the independent source signals. Independent component analysis (ICA) is a method that solves the BSS problem for non-Gaussian signals. In contrast to correlation-based algorithms such as PCA and factor analysis, ICA finds a nonorthogonal linear coordinate system such that the resulting signals are as statistically independent from each other as possible.

One approach to BSS derives unsupervised learning rules based on information theory. The input is

assumed to be N mixtures of N independent sources, and the goal is to maximize the mutual information between the inputs and the outputs of a two-layer neural network. The resulting stochastic gradient learning rules are highly effective in the blind separation and deconvolution of hundreds of non-Gaussian sources (Bell and Sejnowski, 1995).

ICA is particularly effective at analyzing electroencephalograms (EEG) and functional magnetic resonance imaging (fMRI) data (Jung et al., 2001). Consider, for example, electrical recordings of brain activity at many different locations on the scalp. These EEG potentials are generated by underlying components of brain activity and various muscle and eye movements. This is similar to the cocktail-party problem: We would like to recover the original components of the brain activity, but we can only observe mixtures of the components. ICA can reveal interesting information of the brain activity by giving access to its independent components. ICA also gives useful insights into task-related human brain activity from fMRI recordings when the underlying temporal structure of the sources is unknown.

Another application of ICA is feature extraction (Lee, 1998). A fundamental problem in signal processing is to find suitable representations for images, audio recordings, and other kinds of data. Standard linear transformations used in image and auditory processing, such the Fourier transforms and cosine transforms, may not be optimal, and but it would be useful to find the most efficient linear transformation, based on the statistics of the data, to optimally compress the data.

1.34.4 Supervised Learning

Consider the problem of learning to retrieve an output pattern given an input pattern. To remember the patterns, the Hebbian rule can be applied to adjust weights between input and output units. As mentioned earlier, however, the associative Hebbian learning rule will lead to saturation with multiple repetitions, which reduces the capacity of the network. To resolve this problem, one can augment the Hebbian rule with a weight normalization algorithm as in the case of unsupervised learning algorithms.

Another disadvantage of using the associative Hebbian learning rule is that weight adjustments do not depend on the actual performance of the network. An effective way to adjust weights would be by using information of the actual performance of the network. Supervised learning can do this. Supervised learning requires a teacher, who provides detailed information of the desired outputs of the network and adjusts the connections based on discrepancies between the actual outputs and the desired ones.

The perceptron uses a supervised learning rule to learn to classify input patterns (Rosenblatt, 1958). The perceptron is a two-layer network with one output unit that can classify input patterns into two categories. The Hebbian learning rule can be used to solve the task, but the perceptron with the Hebbian learning rule works well only if the number of input patterns is significantly less than the number of input units. An error-correcting supervised learning algorithm for weight adjustments is more effective for a large number of input patterns:

$$\frac{\mathrm{d}w_{ij}}{\mathrm{d}t} \propto u_j \cdot (R_i - v_i)$$

where w_{ij} is a weight of a connection from the input unit j with activity u_j to an output unit i with activity v_i, R_i is a target value of the output unit, and

$$v_i = \sum_j w_{ij} \cdot u_j$$

The perceptron learning rule uses the performance of the network to decide how much adjustment is needed and in which direction the weights should be changed to decrease the discrepancy between the actual network outputs and the desired ones. If input patterns are linearly separable, then the perceptron learning rule guarantees to find a set of weights that allow pattern classification.

A simple unsupervised Hebbian learning rule adjusts synaptic weights based on correlations between presynaptic and postsynaptic neurons. However, this approach is inefficient when the goal of the network is to perform a specific function, rather than simply represent data. To perform a specific task, the network should receive some information about the task.

An example of how Hebbian plasticity can be incorporated into a supervised learning framework is a two-layer network that was trained to perform a function approximation task (Swinehart and Abbott, 2005). The feedforward connections from input units to output units were modified according to an unsupervised Hebbian rule, and a supervised learning mechanism was used to adjust connections from a supervisor to the network. The supervisor is a network that assesses the performance of the training

network and, based on that information, modifies the gains of the input units using an error-correcting learning rule. The purpose of the supervised modulation was to enhance connections between the input and the output units to facilitate the synaptic plasticity needed to learn the task. Thus, Hebbian plasticity did not have direct access to the supervision, and the supervised modulations did not produce any permanent changes. Nonetheless, this network could learn to approximate different functions. In the initial phase the improvement in the network performance was mostly due to the gain modulation, and the synaptic adjustments were minimal. But later, the synaptic adjustments and the gain modulation were equally involved in shaping the performance. Once the network learned the task with the supervisor, it was possible to turn off the supervision, relying only on further Hebbian plasticity to refine the approximation.

The role of the supervisor in the model was to compute an error by comparing the actual and the desired output of the network and to use this error to direct the modification of network parameters such that the network performance improves. Conventionally, the major targets of this process were the synaptic weights. The novel feature of this supervised learning scheme was that supervision took place at the level of neuronal responsiveness rather than synaptic plasticity.

A simple two-layer perceptron cannot solve higher-order problems, but adding additional layers to the feedforward network provides more representational power. Then new learning algorithms are needed to train multilayer networks. The simple error-correcting learning rule was effective for training two-layer networks. With the rule, the connections from the input layer to the output one are adjusted based on discrepancies between the desired output and the actual output produced by the network. In a multilayer network, however, there are intermediate 'hidden' layers that also need to be trained. The back-propagation learning algorithm was developed to train multilayer networks (Rumelhart and McClelland, 1986). The learning rule relies on passing an error from the output layer back to the input layer. Multilayer networks trained with the back-propagation learning rule have been effective in solving many difficult problems.

An example of a multilayer network that was trained using a back-propagation algorithm is a model of song learning in songbirds (Fiete et al., 2004). Juvenile male songbirds learn their songs from adult male tutors of the same species. Birdsong is a learned complex motor behavior driven by a discrete set of premotor brain nuclei with well-studied anatomy (*See* Chapter 1.17). Syringeal and respiratory motor neurons responsible for song production are driven by precisely executed sequences of neural activity in the premotor nucleus robustus archistriatalis (RA) of songbirds (**Figure 2**). Activity in RA is driven by excitatory feedforward inputs from the forebrain nucleus high vocal center (HVC), whose RA-projecting neural population displays temporally sparse, precise, and stereotyped sequential activity. Individual RA-projecting HVC neurons burst just once in an entire song motif and fire almost no spikes elsewhere in the motif. The temporal sparseness of HVC activity implies that these HVC–RA synapses are used in a special way during song; that is, each synapse is used only once during the motif. The goal of the work was to study the effect of HVC sparseness on the learning speed of the network. They studied multilayer feedforward network with an HVC layer that provides input to a

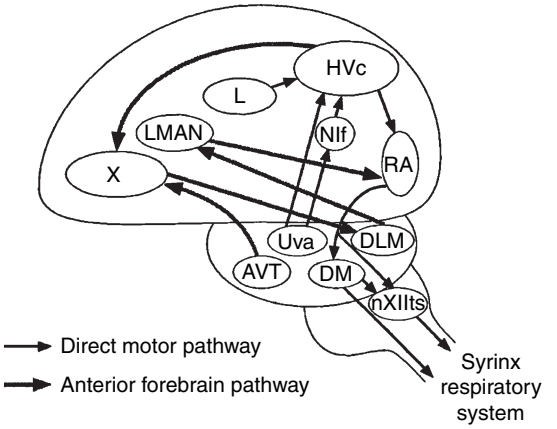

Figure 2 Schematic diagram of the major songbird brain nuclei involved in song control (*See also* Chapter 1.17). The thinner arrows show the direct motor pathway, and the thicker arrows show the anterior forebrain pathway. Abbreviations: Uva, nucleus uvaeformis of the thalamus; NIf, nucleus interface of neostriatum; L, field L (primary auditory area of the forebrain); HVc, higher vocal center; RA, robust nucleus of the archistriatum; DM, dorsomedial part of the nucleus intercollicularis; nXIIts, tracheosyringeal part of the hypoglossal nucleus; AVT, ventral area of Tsai of the midbrain; X, area X of lobus parolfactorius; DLM, medial part of the dorsolateral nucleus of the thalamus; LMAN, lateral magnocellular nucleus of the anterior neostriatum. From Doya K and Sejnowski TJ (2000) A computational model of avian song learning. In: Gazzaninga MS (ed.) *The New Cognitive Neurosciences*, 2nd edn., p. 469. Cambridge, MA: MIT Press; used with permission.

'hidden' RA layer and RA projecting to an output layer of motor units. Song learning is thought to involve plasticity of synapses from HVC to RA because these synapses display extensive synaptic growth and redistribution during the critical period. So in the model, the weights from HVC layer to RA layer were modified. Because there is no evidence of plasticity in the synapses from RA to motor neurons, those connections in the model were kept fixed. For learning, the connections from HVC to RA were adjusted to minimize discrepancy between the desired outputs and the actual outputs produced by the network. They used the back-propagation gradient descent rule and varied the number of bursts in HVC neurons per motif. The network learned the motif for any number of bursts in HVC neurons, but the learning time for two bursts per motif nearly doubled compared to the one burst case and increased rapidly with the number of bursts. Based on these simulations, they concluded that the observed sparse coding in HVC minimized interference and the time needed for learning. It is important to note here that the back-propagation learning algorithm was not used to model the biological learning process itself, but rather to determine if the network architecture can solve the problem and what constraints the representation may have on the speed of learning.

1.34.5 Reinforcement Learning

Learning about stimuli or actions based solely on rewards and punishments is called reinforcement learning. Reinforcement learning is minimally supervised because animals are not told explicitly what actions to take in a particular situation. The reinforcement learning paradigm has attracted considerable interest because of the notion that the learner is able to learn from its own experience at attempting to perform a task without the aid of an intelligent 'teacher.' In contrast, in the more commonly employed paradigm of supervised learning, a detailed 'teacher signal' is required that explicitly tells the learner what the correct output pattern is for every input pattern.

A computational model of birdsong learning based on reinforcement learning has been proposed (Doya and Sejnowski, 2000). A young male songbird learns to sing by imitating the song of a tutor, which is usually the father or other adult males in the colony. If a young bird does not hear a tutor song during a critical period, it will sing short, poorly structured songs. If a bird is deafened during the period when it practices vocalization, it develops highly abnormal songs. Thus, there are two phases in song learning – the sensory learning phase, when a young bird memorizes song templates, and the sensorimotor learning phase, in which the bird establishes the motor programs using auditory feedback. These two phases can be separated by several months in some species, implying that birds have remarkable capability for memorizing complex temporal sequences. Once a song is crystallized, its pattern is very stable. Even deafening the bird has little immediate effect.

The anterior forebrain pathway, which is not involved in song production, is necessary for song learning. In the previously discussed model (Fiete et al., 2004), it was assumed that HVC is a locus of pattern memorization during the first phase of learning, song acquisition, and RA is a motor command area (*See* Chapter 1.17). Therefore, the patterns stored in HVC serve as inputs to RA to produce motor commands. It was also assumed that evaluation of the similarity of the produced song to the memorized tutor song takes place in area X in the anterior forebrain. This assumption is supported by a finding that area X receives dopaminergic input. Depending on how closely the produced song is to the tutor's song, the connections from HVC to RA are modulated via the lateral magnocellular nucleus (LMAN).

The learning algorithm consisted of making small random changes in the HVC to RA synapses and keeping the new weights only if overall performance was improved. The network learned artificial song motifs and was even able to replicate realistic birdsongs within the number of trials that birds take to learn their songs.

Reinforcement learning has thus far had few practical successes in solving large-scale complex real-world problems. In the case of reinforcement learning with delay, the temporal credit assignment aspect of the problem has made learning very slow. However, a method called temporal difference (TD) learning has overcome some of these limitations (Sutton and Barto, 1998). The basic idea of TD learning is to compute the difference between temporally successive predictions. In other words, the goal of learning is to make the learner's current prediction for the current input pattern more closely match the prediction at the next time step. One of the most effective of these TD methods is an algorithm called TD(λ), in which there is an exponentially decaying feedback of the error in time, so that previous estimates for

previous states are also corrected. The time scale of the exponential decay is governed by the λ parameter.

Perhaps the most successful application of TD(λ) is TD-Gammon, which was designed for networks to learn to play backgammon (Tesauro, 1995). Backgammon is an ancient two-player game that is played on an effectively one-dimensional track. The players take turns rolling dice and moving their checkers in opposite directions along the track as allowed by the dice roll. The first player to move all his checkers all the way forward and off his end of the board is the winner.

At the heart of TD-Gammon is a neural network with a standard multilayer architecture. Its output is computed by a feedforward flow of activation from the input nodes, representing the game position, to the output node, which evaluates the strength of the position. Each of the connections in the network is parameterized by a real valued weight. Each of the nodes in the network outputs a real number equal to a weighted linear sum of inputs feeding into it, followed by a nonlinear sigmoid operation. At each time step, the TD(λ) algorithm is applied to the output, which is then back-propagated to change the network's weights.

During training, the neural network selects moves for both sides. At each time step during the course of a game, the neural network scores every possible legal move. The move that is then selected is the move with maximum expected outcome for the side making the move. In other words, the neural network learns by playing against itself. At the start of self-play, the network's weights are random, and hence its initial strategy is random. But after a few hundred thousand games, TD-Gammon played significantly better than any previous backgammon program, equivalent to an advanced level of play. In particular, it is not dependent on a human teacher, which would limit the level of play it can achieve (Tesauro and Sejnowski, 1989). After one million games, TD-Gammon was playing at a championship level.

One of the essential features of reinforcement learning is a trade-off between exploration and exploitation. The learning system should exploit a successful strategy to reach the goal of the task it learns, but it should also explore other strategies to find out if there is a better one. In models, exploration has been implemented by stochasticity. The source of such stochasticity in the brain remains unclear. A model implementing this trade-off between exploration and exploitation has been proposed (Seung, 2003). The model is based on the probabilistic nature of synaptic release by a presynaptic terminal when an action potential arrives at the terminal. The model combines this local synaptic release-failure event and a global reward signal received outside based on the output of the model. The main assumption is that synapses are hedonistic: they increase their probabilities of release or failure depending on which action immediately preceded reward. This concept of the hedonistic synapse is potentially relevant to any brain area in which a global reinforcement signal is received (Klopf, 1982).

This version of reinforcement learning was used to address the matching law phenomenon (Seung, 2003). When animals are presented with repeated choices between competing alternatives, they distribute their choices so that returns from two alternatives are approximately the same. A return is the total reward obtained from an alternative divided by the number of times it was chosen. Before trials, the alternatives are baited with unequal probabilities. The network had to learn a probabilistic strategy in which one alternative is favored over the other one. The network started from equal choices for both alternatives, but over time, it learned a preference that satisfied the matching law.

In the present model, stochastic vesicle release was assumed to be a source of stochasticity in the brain. However, there might be many other possible sources of noise, such as fluctuations in quantal size, irregular action potential firing, and on a slower time scale, the stochastic creation and destruction of synapses. Thus, identifying specific sources of randomness is essential for connecting mathematical models and neurobiology.

1.34.6 Spike-Timing Dependent Plasticity

The traditional coincidence version of the Hebbian learning rule implies simply that the correlation of activities of presynaptic and postsynaptic neurons drives learning. This approach has been implemented in many types of neural network models using average firing rate or average membrane potentials of neurons (*See* Chapter 1.35). Although Hebb's formulation implicitly recognized the idea of causality and relative spike timing (Hebb, 1949; Sejnowski, 1999), this was not appreciated by a generation of modelers because rate coding was generally accepted as the primary form of information processing, and high-frequency

stimulation protocols were used to induce plasticity at synapses. More recently, the relative timing of spikes has been shown to be critical for the direction and magnitude of synaptic plasticity in the cortex as well as the hippocampus (Markram et al., 1997; Bi and Poo, 1998). Potentiation of a synapse takes place if the presynaptic spike precedes the postsynaptic spike, and depression occurs when presynaptic spike follows the postsynaptic spike. This spike-timing dependent plasticity (STDP) is an asymmetric function of relative spike times in the presynaptic and postsynaptic neurons. The time window for the plasticity can be as short as 10 ms and as long as 100 ms, depending on the synapse.

A natural application for STDP is temporal sequence learning (*See* Chapters 1.34, 1.35). If neurons are activated in a sequential manner then, due to the asymmetry of the learning rule, synapses from previously activated neurons to following active neurons will be strengthened. For example, such a spike-timing dependent learning algorithm has been used to train a network to link sequential hippocampal place cells while a rat navigates a maze (Blum and Abbott, 1996). The goal was to predict the direction of a future motion on the basis of a previous experience. Asymmetric synaptic weights develop in the model because of the temporal asymmetry of LTP induction and because place fields are activated sequentially during locomotion. This learning algorithm closely resembles the STDP learning rule. The only essential difference is time scale, which in the model was 200 ms, longer than the STDP windows found in cortical or hippocampal neurons.

This model of a navigational map was based on three observations. First, NMDA-dependent LTP in hippocampal slices occurs only if presynaptic activity precedes postsynaptic activity by less than approximately 200 ms. Presynaptic activity following postsynaptic firing produces either no LTP or long-term depression (LTD). Second, place cells are broadly tuned and make synaptic connections with each other both within the CA3 region and between CA3 and CA1. Third, a spatial location can be determined by appropriately averaging the activity of an ensemble of hippocampal place cells. These three observations imply that when an animal travels through its environment, causing different sets of place cells to fire, information about both temporal and spatial aspects of its motion will be reflected in changes of the strengths of synapses between place cells. Because this LTP affects a subsequent place cell firing, it can shift the spatial location coded by the place cell activity. These shifts suggest that an animal could navigate by heading from its present location toward the position coded by the place cell activity. To illustrate both how a spatial map arises and how it can be used to guide movement, these ideas were applied to navigation in the Morris maze. The network was trained using this spike-timing dependent learning algorithm to form a direction map, which improved with training.

Timing is important in auditory processing, and a number of perceptual tasks, such as sound localization, explicitly use temporal information. Sound localization is important to the survival of many species, in particular to those that hunt in the dark. Interaural time differences (ITD) are often used as a spatial cue. However, the question of how temporal information from both ears can be transmitted to a site of comparison, where neurons are tuned to ITDs, and how those ITD-tuned neurons can be organized in a map remains unclear. A network model based on STDP can successfully account for a fine precision of barn owl sound localization (Kempter et al., 2001). The model converts ITDs into a place code by combining axonal delay lines from both ears and STDP in synapses with distributed delays. The neurons are organized as a single-layer network for each frequency and receive inputs from both ears through axonal arbors. The axons have different time delays. After training, each neuron adjusts its connections to axons with the appropriate time delays in agreement with the neuron's spatial position. In this way, a map with neurons tuned to particular ITDs can be formed.

There is an interesting connection between STDP and TD learning at the computational level (Rao and Sejnowski, 2003). If, consistent with TD learning, synaptic weights between Hodgkin–Huxley type spiking neurons are updated based on the difference in the postsynaptic voltage at time $t + \Delta t$ and at time t, where t is the time when the presynaptic neuron fired a spike, and Δt is a fixed time interval, then the learning rule resembles the conventional STDP learning rule. Networks with this spike-dependent TD learning rule are able to learn and predict temporal sequences, as demonstrated by the development of direction selectivity in a recurrent cortical network. The network consisted of a single chain of recurrently connected excitatory neurons. Each neuron initially received symmetric excitatory and inhibitory inputs of the same magnitude. For training, the neurons in the network were exposed to 100 trials of retinotopic sensory inputs consisting of moving pulses of excitation in the rightward direction.

The effect of learning on the network was in developing a profound asymmetry in the pattern of excitatory connections from preceding and successor neurons. The synaptic conductances of excitatory connections from the left side were strengthened, whereas the ones from the right side were weakened. Because neurons on the left side fired (on average) a few milliseconds before a considered neuron, whereas neurons on the right side fired (on average) a few milliseconds after, as a result, the synaptic strengths of connections from the left side were increased, whereas the synaptic strengths for connections from the right side were decreased. As expected from the learned pattern of connections, the neuron responded vigorously to rightward motion but not to leftward motion.

To investigate the question of how selectivity for different directions of motion may emerge simultaneously, they also simulated a network comprising two parallel chains of neurons, with mutual inhibition between corresponding pairs of neurons along the two chains. As in the previous simulation, a given excitatory neuron received both excitation and inhibition from its predecessors and successors. To break the symmetry between the two chains, they provided a slight bias in the recurrent excitatory connections, so that neurons in one chain fired slightly earlier than neurons in the other chain for a given motion direction. To evaluate the consequences of spike-based TD learning in the two-chain network, the model neurons were exposed alternately to leftward- and rightward-moving stimuli for a total of 100 trials. As in the previous simulation, the excitatory and inhibitory connections to a neuron in one chain showed asymmetry after training, with stronger excitatory connections from the left neurons and stronger inhibitory connections from the right neurons. A corresponding neuron in the other chain exhibited the opposite pattern, and as expected from the learned patterns of connectivity, neurons in one chain were selective to rightward motion, and neurons in the other chain were selective to the leftward motion. This explanation was consistent with the development of directionally selective neurons in the visual cortex of kittens.

1.34.7 Plasticity of Intrinsic Excitability

Several lines of evidence argue for the presence of activity-dependent modification of intrinsic neuronal excitability during development and learning (Daoudal and Debanne, 2003; *See* Chapter 4.40). In the dentate gyrus of the hippocampus, for example, in addition to homosynaptic LTP of excitatory synaptic transmission, the probability of discharge of the postsynaptic neurons to a fixed excitatory synaptic input is enhanced by high-frequency stimulation (HFS, 100 Hz) of the afferent fibers (Bliss et al., 1973). This second component has been called excitatory postsynaptic potential (EPSP)-to-spike potentiation (E-S potentiation) (Frick et al., 2004). Synaptic plasticity (LTP) and nonsynaptic E-S potentiation are complementary. As in LTP, E-S potentiation requires the activation of NMDA receptor (NMDAR) for its induction. These two forms of plasticity may share common induction pathways. In a recent study of deep cerebellar nuclei neurons, tetanization of inputs to these neurons produces a rapid and long-lasting increase in intrinsic excitability that depends on NMDAR activation (Aizenman and Linden, 2000). These studies suggest that plasticity of intrinsic excitability may be important in developmental plasticity and information storage.

Another form of plasticity in intrinsic excitability has been demonstrated in spontaneously firing vestibular nucleus neurons, which may be responsible for learning of the vestibuloocular reflex. Purkinje cells, which are inhibitory, contact a subset of the neuron in the vestibular nucleus, which receive direct vestibular input and project to the oculomotor nuclei. Brief periods of synaptic inhibition or membrane hyperpolarization produced a dramatic increase in both spontaneous firing rate and responses to intracellularly injected current (Gittis and du Lac, 2006). A similar change occurred after silencing the vestibular nerve. Neurons in the vestibular system fire at remarkably high rates in the intact animal, with resting rates on the order of 50–100 spikes/s and responses to head movements ranging up to 300 spikes/s. Loss of peripheral vestibular function silences the vestibular nerve, resulting in a significant loss of spontaneous firing in the neurons of the vestibular nucleus, which then returns to control values within about a week, even in the absence of vestibular nerve recovery. This plasticity of intrinsic excitability could potentially contribute either to adaptive changes in vestibular function during recovery from peripheral damage or to oculomotor learning in intact animals.

A similar phenomenon has been demonstrated in cultured neocortical pyramidal neurons (Desai et al., 1999). Prolonged activity blockade lowers the threshold for spike generation, and neurons fire at a higher

frequency for any given level of current injection. These changes occurred through selective modifications in the magnitude of voltage-dependent currents: sodium currents increase and persistent potassium currents decrease, whereas calcium currents and transient potassium currents are unaltered. Increase of neuronal excitability in response to reduced activity may contribute to the activity-dependent stabilization of firing rates. The stability in neuronal firing rates is maintained through many mechanisms, and regulation of neuronal excitability may be one of them.

Information about the outside world is transformed into spike trains in the nervous system. How do the neurons learn to represent the information, and do they change their behavior based on changing external stimuli? In the discussion of unsupervised learning and the ICA algorithm, it was shown that information theoretical approaches can be effective in solving real-world problems. A similar information theoretical approach can be implemented to search for an optimal representation. A Hodgkin–Huxley type model of a neuron that can adjust its membrane conductances to maximize information transfer has been proposed (Stemmler and Koch, 1999). The slope of the neuronal gain function should line up with the peak of the input to maximize information transfer. The learning rules they implemented in the model performed this matchup by adjusting the membrane conductances. The conductance modulations did not require calculation of mutual information but were based solely on local characteristics of the neuron. They showed that for different input distributions the model could successfully line up the gain function and the input distributions leading to maximization of information transfer. Thus, the ability of activity-dependent selective modification of the gain functions based on the active balance of inward and outward ion channels could serve a number of important functions, including fine-tuning of the output properties of neurons to match the properties of their inputs.

Plasticity of intrinsic excitability can also participate in regulating the conventional synaptic plasticity. For details, see the previously discussed model, which combines Hebbian and supervised learning (Swinehart and Abbott, 2005), in the section titled 'Supervised learning.'

1.34.8 Homeostatic Plasticity

Correlation-based Hebbian plasticity is thought to be crucial for information storage because it produces associative changes in the strength of individual synaptic connections. However, correlation-based learning in neural networks can be unstable. According to the Hebb rule, if a presynaptic neuron participates in firing of a postsynaptic neuron, it leads to strengthening the synapses between the neurons. This makes it more likely that next time the presynaptic neuron fires, it will cause firing in the postsynaptic neuron, which leads to further strengthening of the synapse. Simple associative Hebbian algorithm causes instability in the network by increasing the total activity of the network and losing selectivity among synapses. To keep the network stable and maintain the selectivity of the network, an additional mechanism must stabilize the properties of neuronal networks.

Homeostatic plasticity is a mechanism by which the neurons regulate the network's activity (Turrigiano and Nelson, 2000). There are many different ways neural activities could be regulated to keep them within a functional dynamical range. One mechanism that could maintain relatively constant activity levels is to increase the strength of all excitatory connections into a neuron in response to a prolonged drop in firing rates, and vice versa. This form of homeostatic plasticity is called synaptic scaling.

Regulating synaptic strength is not the only mechanism by which homeostatic activity can be maintained. Previously discussed plasticity of intrinsic excitability also contributes to the homeostatic regulation by controlling the firing rates of the neurons.

All theoretical models implementing associative Hebbian learning rule have to deal with the instability problem. For example, the BCM learning rule deals with unconstrained growth of synaptic weights by dynamically adjusting the threshold between potentiation and depression (Bienenstock et al., 1982). This algorithm is biologically plausible and reflects experimental findings indicating that calcium level is crucial for the direction of plasticity. The dynamical threshold modulation implemented in the BCM rule not only prevents the synapses from unconstrained growth but also maintains the activity level of the units at the appropriate value (*See* Chapters 1.33, 1.35).

In the next section we present some other examples of learning algorithms involving homeostatic plasticity as a critical element of learning.

1.34.9 Complexity of Learning

The learning paradigms discussed earlier were based on a single mechanism for plasticity (e.g., STDP versus homeostatic and synaptic versus intrinsic

neuronal). However, many difficult tasks cannot be solved using a single learning rule, but require combinations of several learning rules working together. Another essential element of modeling learning processes is the time scale of learning. There are multiple time scales for plasticity, from milliseconds to years, and depending on the demands of the task, different mechanisms for plasticity with different time scales may be involved.

Long-term memory is vulnerable to degradation from passive decay of the memory trace and ongoing formation of new memories. Memory based on synapses with two states shows exponential decay, but experimental data shows that forgetting (memory degradation) follows a power law. A cascade model was developed to address this problem (Fusi et al., 2005). In the model, synapses had two states, weak and strong, but in addition to transition between these two states, there were metaplastic transitions within each state. Based on the stage of metaplasticity, the synapses showed the range of behavior from being highly plastic to being resistant to any plasticity at all. The metaplastic transitions effectively introduced multiple time scales into the model.

The cascade model outperformed alternative models and exhibited a power law for the decay of memory as a function of time. The dependence of memory lifetime on the number of synapses in the model is also a power law function. Memory lifetimes diminish when the balance between excitation and inhibition is disturbed, but the effect is much less severe in the cascade model than in noncascade models.

The function of homeostatic plasticity is to maintain the activity of the cortex at a functional level. But are there any other computational or functional advantages of such plasticity? One study has shown that a combination of Hebbian and homeostatic plasticity can lead to temporal sharpening in response to multiple applications of transient sensory stimuli (Moldakarimov et al., 2006). The model included two types of homeostatic mechanisms, fast and slow. Relatively fast plasticity was responsible for maintaining the average activity of the units. To maintain activity in the excitatory neurons at a target homeostatic level, they implemented a learning rule, according to which inhibitory connections have been adjusted. The slow plasticity was used to determine the value of the target average activities. Thus, the model had three time scales for synaptic adjustments: Hebbian, fast homeostatic, and slow homeostatic mechanisms. Repeated presentations of a transient signal taught the network to respond to the signal with a high amplitude and short duration, in agreement with experimental findings. This sharpening enhances the processing of transients and may also be relevant for speech perception.

A standard approach in models of self-organized map (SOM) formation is the application of Hebbian plasticity augmented with a mechanism of weight normalization. A conventional way to normalize weights is based on a sum of weights coming into each neuron: The soma collects information on every weight, sums them, and then decides on the amount of normalization. An alternative approach to weight normalization has been proposed (Sullivan and de Sa, 2006). The normalization algorithm did not need information from every synapse but rather was based on the average activities of the units and homeostatic plasticity. When Hebbian and homeostatic mechanisms were combined, the average activities of the units were better maintained compared to the standard Hebbian models.

Dimensionality reduction facilitates the classification, the visualization, and the storage of high-dimensional data. A simple and widely used method is PCA, which finds the directions of greatest variance in the data set and represents each data point by its coordinates along each of these directions. A new deep network model has been proposed to transform the high-dimensional data into a low-dimensional code (Hinton and Salakhutdinov, 2006). The adaptive multilayer network consisted of two subnetworks, an encoder and decoder. The encoder transformed high-dimensional data into a low-dimensional code. The code layer was then used as the input layer to the decoder network to reconstruct the original input pattern.

The two networks were trained together to minimize the discrepancy between the original data and its reconstruction. The required gradients were obtained using the chain rule to back-propagate error derivatives, first through the decoder network and then through the encoder network. In general, it is difficult to optimize the weights in a multilayer network with many hidden layers. Large initial weights typically lead to poor local minima; with small initial weights, the gradients in the early layers are tiny, making it impossible to train. But if the initial weights are close to a good solution, gradient descent back-propagation works well. A good initial network was obtained with unsupervised learning based on Restricted Boltzmann Machine (RBM) learning algorithm. First, the input layer of the

multilayer network was used as a visible layer of RBM, and the next layer served as a feature layer. After learning one layer of feature detectors, the weights were fixed and used for learning a second layer of feature detectors. This layer-by-layer learning was repeated many times. After pretraining multiple layers of feature detectors, the model was unfolded to produce the encoder and decoder networks that initially used the same weights. The global fine-tuning stage used back-propagation through the whole network to adjust the weights for optimal reconstruction.

They applied the algorithm to multiple tasks including handwritten digits visualization, grayscale images, and documents generalization. In all these tasks, the new algorithm outperformed different approaches based on PCA and other supervised algorithms.

1.34.10 Conclusions

We have discussed learning rules and learning algorithms designed for neural network models and described some problems that can be solved by neural networks with modifiable connections. Neural computation is a broad field that continues to grow; only a few selected studies have been used to illustrate general principles.

Although early modeling efforts focused mainly on traditional synaptic plasticity, such as LTP and LTD, relatively new homeostatic plasticity mechanisms are also being explored. Although synaptic plasticity was once presumed to be the primary neural mechanism of learning, recent models have incorporated changes of intrinsic properties of the neurons as well.

Most experimental studies of learning have studied the mechanisms of synaptic plasticity in reduced preparations. Recently the focus has shifted to relating the changes in the synapses with behavioral learning. For example, inhibitory avoidance learning in rats produced the same changes in hippocampal glutamate receptors as induction of LTP with HFS (Whitlock et al., 2006). Because the learning-induced synaptic potentiation occluded HFS-induced LTP, they concluded that inhibitory avoidance training induced LTP in hippocampus.

Theoretical approaches can integrate local mechanisms with whole system behavior. Even after locating particular sites where changes occur, it is still not clear to what degree those changes are directly related to the learning. Building a computational model that integrates learning mechanisms allows one to evaluate the importance of different sites of plasticity. The observed plasticity for some sites may be secondary, or compensatory to the primary sites of learning (Lisberger and Sejnowski, 1992).

1.35 Connectionist Memory Models of Hippocampal Function

R. A. Koene and M. E. Hasselmo, Boston University, Boston, MA, USA

1.35.1 Introduction

Connectionist models of memory function distinguish themselves from other models of memory through their explicit analogy to memory function that may be supported by the anatomy of the neural substrate. Unlike semantic memory models, for example, connectionist models do not generally store explicit semantic pieces of information in individual memory locations. Instead, the expression of concepts in connectionist models relies on the simultaneous activity of a number of units that form a unique pattern. The structure that is needed to elicit such patterns of activity is provided by a corresponding unique arrangement of connection strengths between units. The network of units is therefore analogous to anatomical networks of neurons, and the connections in such models are analogous to the pathways, fibers, and synapses that form connections between neurons and groups of neurons.

The degree of functional similarity between connectionist units and connections and their biological counterparts varies greatly between different models. Connectionist models with abstract functions, such as the error back-propagating functions of Rumelhart units, tend to focus on general concepts of learning in networks with distributed storage resembling neural networks. At the other end of the spectrum, computational models that involve a greater degree of biophysical accuracy generally study neural activity that is comparable with electrophysiological data. It is the latter type of connectionist model that is our principal focus here, as those models are directly applicable to the study of neural activity in the hippocampal system.

We will consider connectionist models of the complex and comparatively well-studied memory binding functions of the medial temporal lobes. The anatomical regions included in the medial temporal lobes are the hippocampus (dentate gyrus, Cornu Ammonis fields CA1–CA3, and CA4, which is also called the hilus, and the subiculum) and the surrounding perirhinal, parahippocampal, and entorhinal cortices (*See* Chapter 1.33 for anatomical details).

Three significant forms of memory function are believed to depend on the function of hippocampal and entorhinal networks in particular: (1) context-dependent memory, which is retrieved by association with specific contextual cues; (2) episodic memory, in which specific associations between temporally ordered events are maintained; and (3) spatial memory, which aids spatial navigation through the retrieval of associated spatial features (*See* Chapters 1.14, 1.15, 1.21, 1.23, 1.33, 1.34). In the following text, we will review a number of theories and models that specifically attempt to model functions that have

been proposed to rely on neuronal network activity in the hippocampal and entorhinal regions of the medial temporal lobes.

Connectionist models developed to study different types of learning and memory are evaluated in the context of the computational neurophysiology that underlies function in networks of the entorhinal cortex and hippocampus. Hippocampal function supports specific memory-dependent behaviors in humans and animals. Data are therefore available with which models of the integral system can be tested. The hippocampal system is consequently a rich substrate for studies both at the scale of an individual network and at the scale of dynamic interactions between networks.

Neuropsychological data in human subjects show that lesions of the hippocampus selectively impair specific components of memory function. Hippocampal lesions impair the delayed free recall of information (Scoville and Milner, 1957; Penfield and Milner, 1958; Corkin, 1984). Such lesions have little effect on digit span (Corkin, 1984) or on the recency component of the serial position curve (Baddeley and Warrington, 1970). Neither semantic memory nor consolidated episodic memory appears affected by hippocampal lesions (Zola-Morgan et al., 1983, 1986). As a result of lesion data from nonhuman primates, the impairments seen in patients such as HM have been attributed in part to the removal of perirhinal cortex and parahippocampal gyrus (Suzuki et al., 1993). Lesions that are restricted to the subregions of the hippocampus may, however, cause severe memory impairments, as exhibited by patient RB (Zola-Morgan et al., 1986; Rempel-Clower et al., 1995). For example, in tests of the free recall of ten words from the middle of a 15-word list, patient RB recalls only 10% of the words, whereas controls recall about 40% (Graf et al., 1984). Similar striking differences between controls and patients with hippocampal lesions appear in tests of the free recall of information from a story, which is a common subtest of the Wechsler Memory Scale (Zola-Morgan et al., 1986). The human data support the specific significance of hippocampal subregions for the storage and retrieval of verbal information with context-dependent and episodic associations, as mentioned (*See* Chapters 1.02, 1.14, 1.15).

Memory function in a range of tasks can also be impaired by drug effects and by damage to the cholinergic innervation of regions in the medial temporal lobes. In humans, damage to cortical cholinergic innervation caused by anterior communicating artery aneurysms impairs performance in tests of the free recall of lists of words or information from paragraphs (Heilman and Sypert, 1977; Hodges and Carpenter, 1991), causes enhanced interference in an AB, AC paradigm (van der Linden et al., 1993), and also results in considerable confabulation in memory tasks (DeLuca, 1993). In nonhuman primates, lesions of the fornix, which cuts off most of the cholinergic innervation of the hippocampus, have been shown to impair formation of snapshot memories (Gaffan and Harrison, 1989). In addition to the extensive behavioral data suggesting some role for the hippocampus in human memory function, there is a wealth of data on the anatomy and physiology of this structure, and extensive theoretical work on the function of individual subregions. Here we review simulations of encoding and retrieval of item representations within networks that represent components of the full hippocampal circuit. The connectionist models discussed deal with sequential encoding, delayed free recall, and pattern recognition. In the context of hippocampal learning and memory, we review the published modeling results of many investigators, and in particular the integrative qualities of several system models that include our own work.

1.35.2 Connectionist Modeling of Hippocampal Episodic Memory

The study of memory in neural network models is typically approached in one of two ways: Either a fixed pattern of network connectivity is applied, so that simulations can focus on aspects of the retrieval of information (Hopfield, 1982; Treves and Rolls, 1994), or connectionist models use a protocol of repeated presentations of stimuli, so that they can simulate the training of connection weights by explicitly computing an error during a behavioral task (Schmajuk and DiCarlo, 1992; Gluck and Myers, 1993; Myers and Gluck, 1994). By contrast, recent simulations of hippocampal network activity use Hebbian learning (Jensen and Lisman, 1996; Hasselmo and Wyble, 1997; Koene et al., 2003) and often do not impose learning and recall stages externally (Hasselmo and Wyble, 1997; Koene et al., 2003). Instead, these models explicitly simulate the effect of cholinergic modulation of specific pathways and oscillatory activity at theta rhythm. Electrophysiological evidence suggests that such modulation elicits specific periods of selective

suppression of synaptic transmission and of modulated susceptibility to long-term potentiation (LTP) (Hyman et al., 2003). Conditions favor the retrieval of patterns of activity in associative memory when synaptic transmission is cholinergically suppressed (Huerta and Lisman, 1993; Hasselmo, 1995). Conversely, encoding and self-organization are favored in the absence of synaptic suppression and when LTP is facilitated.

In models of hippocampal memory function that simulate neural activity in terms of values for the firing rate, Hebbian learning rules are justified by experimental evidence of firing rate protocols that elicit LTP (McNaughton et al., 1978; Levy and Steward, 1979; Kelso et al., 1986; Wigstrom et al., 1986; *See* Chapter 1.33). Similarly, experimental evidence by Bi and Poo (1998) supports the hypothesis that spike-timing-dependent potentiation (STDP) of synapses is an effect that implements the Hebbian learning rule. Computational equivalents of STDP are applied in integrate-and-fire neural network models of hippocampal function (Jensen et al., 1996; Koene et al., 2003), also known as spiking neuron models (Gerstner, 1998a,b; Gerstner and Kistler, 2002).

In many cases, a theory of hippocampal function focuses exclusively on the function of a specific subregion of the hippocampus. Such theories commonly do not take into account how interactions between the subregions of the hippocampal system affect behavior in specific tasks. This is not a trivial matter, since hippocampal function is characterized by a dynamic interaction between the activity in its various subregions. It is likely that hippocampus-mediated behavior is not simply a consequence of the gathering of communicated results from isolated regional functions, but is instead elicited and modified through interaction and feedback. A number of reviews have previously summarized subregion-specific theories (Levy, 1989; Eichenbaum and Buckingham, 1990; O'Reilly and McClelland, 1994; Treves and Rolls, 1994).

Our models of learning and memory in the hippocampal system explicitly integrate the simulated functions of multiple regions (Hasselmo and Wyble, 1997; Hasselmo et al., 2002b; Koene et al., 2003; Hasselmo and Eichenbaum, 2005). A similar approach has been taken by other investigators, such as Jensen and Lisman (1996). The structure of these integrated system models of hippocampal function was motivated by experimental data about the anatomy and physiology of the hippocampal formation, and by previous theoretical work on the function of different hippocampal subregions (Marr, 1971; Valentino and Dingledine, 1981; McNaughton and Morris, 1987; Dutar and Nicoll, 1988; Levy, 1989; Eichenbaum and Buckingham, 1990; Levy et al., 1990, 1995; Ratcliff et al., 1990; McNaughton, 1991; Treves and Rolls, 1992, 1994; O'Reilly and McClelland, 1994; Rolls, 1995; Hasselmo et al., 1996, 1998). These models contrast with most earlier simulations in that they do not simulate individual effects and ideas in isolation. Instead, they combine the functions of different regions into a detailed, self-regulated model, generally including network representations of three or more subregions of the hippocampus along with the adjacent entorhinal cortex. Some of these new models address specific human memory tasks, such as free recall and recognition, and the effect of drugs on memory function during such tasks, which was not done in earlier simulations of the full hippocampal network (Rolls et al., 1997). Others address the combination of spatial memory and episodic memory or context-dependent memory tasks involved in rodent spatial navigation behavior. The anatomy of the hippocampal formation and structure of the model are summarized in **Figure 1**.

The hippocampus extends along the ventromedial border of the temporal lobe and receives convergent multimodal input from a wide range of neocortical association areas, most of which project to the hippocampus via neurons of the entorhinal cortex. The hippocampus consists of two interdigitated structures: the dentate gyrus (DG) and cornu ammonis (CA), of which regions CA1 and CA3 feature prominently in many models. Researchers often refer to the classical trisynaptic circuitry of the hippocampus, which consists of a feed-forward flow of information between the different structures (Amaral and Witter, 1989). As shown in **Figure 1**, entorhinal cortex layer II projects via the perforant path to the dentate gyrus. The DG projects via the mossy fibers to region CA3; region CA3 contains extensive excitatory recurrent collaterals (the longitudinal association fibers) and also projects on to region CA1 via the Schaffer collaterals. Region CA1 projects back directly and via the subiculum to entorhinal cortex layer IV. In addition to the trisynaptic circuit, there are also direct projections from entorhinal cortex layers II and III to regions CA3 and CA1 of the hippocampus.

In the recent integrated system models (Hasselmo and Wyble, 1997; Hasselmo and Eichenbaum, 2005),

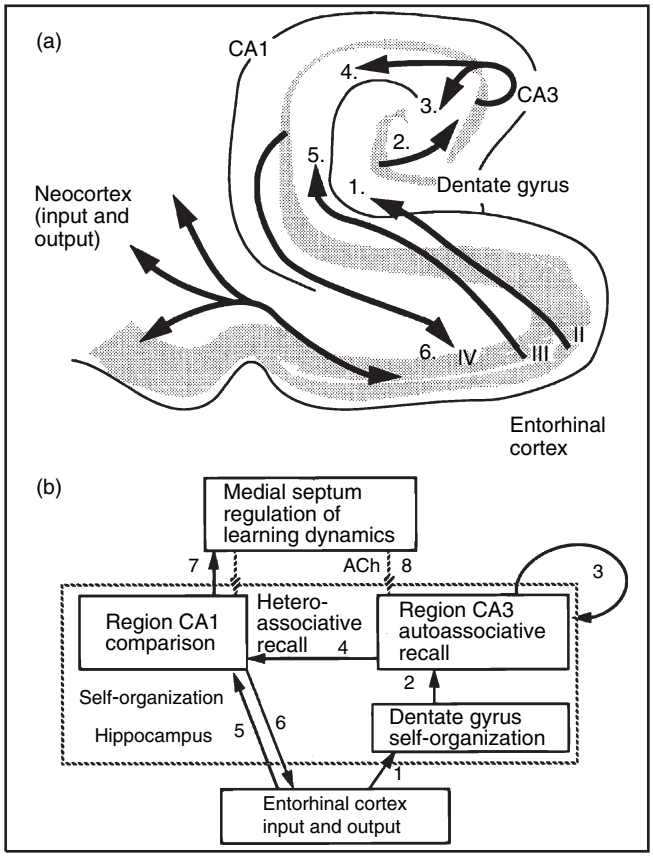

Figure 1 (a) Anatomical connectivity of the hippocampal formation. Connections between the hippocampus and multimodal association cortices pass through the entorhinal cortex. (1) Fibers of the perforant path connect layers II and III of the entorhinal cortex with the dentate gyrus. (2) The dentate gyrus projects to subregion CA3 via the mossy fibers. (3) Longitudinal association fibers connect pyramidal cells within subregion CA3. (4) The Schaffer collaterals connect subregion CA3 with subregion CA1. (5) Perforant path connections also enter subregion CA1 from the entorhinal cortex. (6) Projections back from subregion CA1 enter layer IV of the entorhinal cortex, either directly or via the subiculum. Subregion CA1 can influence activity in the medial septum either directly or via connections with the lateral septum. The medial septum (and the vertical limb of the diagonal band of Broca) provides cholinergic modulation to all hippocampal subregions. (b) Proposed function of individual anatomical subregions in the model by Hasselmo and Wyble (1997). The entorhinal cortex provides input from neocortical structures and transmits output back to neocortical structures. (1) Perforant path synapses undergo rapid self-organization to form new representations of patterns presented sequentially to the entorhinal cortex. (2) Mossy fibers pass the sparse new representation on to subregion CA1 for autoassociative storage. (3) Excitatory feedback in subregion CA3 mediates autoassociative storage and recall of these representations. (4) Schaffer collaterals mediate heteroassociative storage and recall of associations between activity in subregion CA3 and the self-organized representations formed by entorhinal input to subregion CA1. (5) Perforant path inputs to subregion CA1 undergo self-organization, forming new representations of entorhinal cortex input for comparison with recall from subregion CA3. (6) Feedback from subregion CA1 stores associations between activity in CA1 and in entorhinal cortex, allowing representations in subregion CA1 to activate the associated activity patterns in entorhinal cortex layer IV. (7) Output from subregion CA1 regulates cholinergic modulation, allowing a mismatch between recall and input to increase acetylcholine (ACh) and a match between recall and input to decrease ACh. (8) ACh from the medial septum sets appropriate dynamics for learning of new information in the model.

the network representations of individual subregions have the following functions:

1. Entorhinal cortex layer II (ECII). Network activity elicited by input to this model region represents the activity induced in entorhinal cortex in response to experimental stimuli. For example, the presentation of specific words in a behavioral experiment, as well as the shared experimental context, elicits representative patterns of activity in ECII.

2. Dentate gyrus (DG). The network model of this structure forms self-organized representations of each input pattern in ECII. The overlap between stored item and temporal context-specific representations in DG is reduced compared with the corresponding sequence of patterns of activity in ECII. The resulting patterns of output activity in DG target neurons in region CA3.

3. Region CA3. This modeled region encodes and retrieves associations between the shared experimental context (e.g., episode) and the individual items (e.g., words). The CA3 network activity provides the driving force for memory function in the model.

4. Region CA1. This modeled network structure compares the direct input from entorhinal cortex with the output of region CA3. In Hasselmo and Wyble (1997), the output of region CA1 regulates levels of acetylcholine on the basis of how well CA3 retrieval matches direct input. In Hasselmo and Eichenbaum (2005), the convergence of spreading activity in the entorhinal cortex and of episodic retrieval activity in region CA3 generates spiking activity in CA1 that identifies prior temporal context-specific events needed to make a decision at a choice-point in a delayed spatial alternation task.

5. Medial septum. The model network of this region in Hasselmo and Wyble (1997) sets the level of acetylcholine in all the other regions. In our integrated system model of hippocampal function, modulation by acetylcholine influences synaptic modification, synaptic transmission, depolarization, and adaptation.

6. Entorhinal cortex layer IV (ECIV). This modeled region stores associations between the full input patterns and the compressed representations from region CA1, allowing full retrieval of patterns. In prior work by one of the authors (Koene, 2001), this decoding stage emphasized learned connectivity from region CA1 to subiculum and ECIV.

Other connectionist approaches modeling these individual functions are described in the following text.

A number of subregion-specific models have focused on the significance of the perforant path synapses that link the output of entorhinal cortex to the DG (Marr, 1971; McNaughton and Morris, 1987; Eichenbaum and Buckingham, 1990; Treves and Rolls, 1994). It is a common hypothesis that the perforant path synapses encode representations of the patterns of afferent input activity that are manifested by sparse or nonoverlapping, distributed patterns of activity in the DG. Such sparse representations are especially useful to a hippocampal function for the encoding of episodic memory after a single occurrence of a sequence of individual patterns of input activity, in which the individual patterns of simultaneous activity are familiar. This is also called one-shot episodic learning. Recent theory and modeling have begun to address the questions of when and how such sparse representations may be generated and modified in tasks that involve multiple stimulus episodes in which specific patterns of activity may interfere (Koene, 2001; Koene and Hasselmo, 2006). In the section titled 'Dentate gyrus: Generating representations that minimize interference,' we address the issue of 'catastrophic interference' (McCloskey and Cohen, 1989) and the ways in which models of hippocampal memory function deal with that concern.

The Schaffer collateral fibers are another important hippocampal synaptic pathway. Those fibers transfer the output activity of subregion CA3 to subregion CA1. A common hypothesis is that the Schaffer collateral fibers mediate heteroassociative memory function (McNaughton, 1991; Treves, 1995). If this is so, then activity in CA1 may be predicted to a significant degree by the activity in CA3 (Levy, 1989). The involvement of the Schaffer collateral fibers in heteroassociative memory function has been explored in modeling studies with differing hypotheses about their precise role in the process. Possible self-regulation of learning and recall was studied in models specifically of the Schaffer collaterals (Hasselmo and Schnell, 1994), as well as in more inclusive models of the hippocampal network (Hasselmo and Stern, 1996; Hasselmo et al., 1996, 1998). In another set of hippocampal network models, the bulk of heteroassociative memory function was assumed to occur within the CA3 network, and the involvement of the Schaffer collateral fibers was constrained to delivering the activity of heteroassociative memory function to neurons in region CA1 (Jensen and Lisman, 1996; Koene et al., 2003).

The desire to pinpoint the hippocampal structure in which heteroassociative memory function is enabled has frequently focused on the possible function of the third set of significant fibers in the hippocampus, the longitudinal association fibers (or

recurrent fibers) within region CA3. One common hypothesis is that the longitudinal association fibers within region CA3 mediate autoassociative memory function (Marr, 1971; McNaughton and Morris, 1987; Eichenbaum and Buckingham, 1990; Treves and Rolls, 1992; Lisman, 1999). The other common hypothesis is that these association fibers mediate episodic memory by encoding temporal sequences of spiking patterns at the synapses of fibers that connect pyramidal neurons within region CA3 (Levy, 1989; Minai and Levy, 1994; Levy et al., 1995; Jensen and Lisman, 1996; Hasselmo and Eichenbaum, 2005). Models that focused exclusively on the recurrent CA3 network have studied autoassociative learning and retrieval (Hasselmo et al., 1995; Levy et al., 1995). More recently, models of autoassociative function mediated by such a recurrent network have been incorporated into more general (hierarchical) models of the integral hippocampal system (Hasselmo and Stern, 1996; Hasselmo et al., 1996, 2002b; Jensen and Lisman, 1996; Koene et al., 2003; Hasselmo and Eichenbaum, 2005; Koene and Hasselmo, 2007b).

The integral system models of hippocampal and entorhinal memory function tend to include a (sub)-set of modeled subregions, most commonly including networks of entorhinal cortex and hippocampal subregions CA3 and CA1. Each subregion is generally represented by local network circuitry. Those networks receive input and deliver output through connections that represent a subset of the known anatomical pathways in the medial temporal lobes. For example, the Hasselmo and Wyble (1997) model of cholinergically modulated learning and recall includes networks representing ECII, ECIII, DG, hippocampal subregions CA3 and CA1, and ECIV.

This system model is depicted in **Figure 2**. A similarly complex model of episodic recall by Lisman et al. (2005) includes networks that represent hippocampal subregion CA3 and that separately represent the mossy and granule cell layers of the DG. In recent models of temporal context-dependent episodic memory in the hippocampus that were used to simulate behavioral experiments with rodents in spatial tasks, modeling involved the specification of networks representing layer II and III of the entorhinal cortex, the DG, and hippocampal subregions CA3 and CA1, as well as the interactions mediated by fiber pathways between the modeled subregions (Hasselmo and Eichenbaum, 2005; Koene and Hasselmo, 2007b).

1.35.3 Encoding and Retrieval of Items within a Context Cue Presented in Layer II of Entorhinal Cortex

Our understanding of the physiology and of the biophysics of neurons in ECII has improved greatly in recent years (Klink and Alonso, 1997; Fransén et al., 2002), as have the available data about the task-specific responses of neurons from electrophysiology performed in ECII (Hafting et al., 2005). It is now known that both the pyramidal and stellate cell types in ECII can exhibit rhythmic activity during specific tasks and can sustain persistent repeated firing following specific stimulation protocols. Klink and Alonso (1997) showed that an after-depolarizing response exhibited by pyramidal cells in ECII can sustain rhythmic spiking once action potentials are elicited by a short period of depolarization or by synaptic input. These characteristic neural responses in ECII resemble earlier findings about neurons in the prefrontal cortex (Andrade, 1991). The apparent possibility that synaptic input can elicit intrinsic spiking without relying on excitatory fiber loops or synfire chains (Abeles et al., 1993) gave rise to a novel mechanistic hypothesis for short-term spike buffering introduced by Lisman and Idiart (1995). Since then, models of working memory that are based on intrinsic neuron dynamics have been investigated and used as networks specially suited to the rapid acquisition and ordered maintenance of sequences or temporal cues of patterns of spikes (Jensen et al., 1996; Koene and Hasselmo, 2007a). A buffered sequence of spike patterns can be repeatedly delivered to the hippocampus for episodic encoding (Jensen and Lisman, 1996; Koene et al., 2003).

In vivo electrophysiology during spatial tasks has shown that neurons in medial ECII respond in a spatial-location-specific manner that has some resemblance with the place cell activity commonly attributed to hippocampal pyramidal cells (Fyhn et al., 2004), although the place fields associated with location-specific activity in ECII can be large and overlapping with multiple peak response locations. Responses of stellate cells in rat layer II of dorsocaudal medial entorhinal cortex also appear to be rhythmic and directly related to location in a spatial task, but in contrast to the activity of the pyramidal cells, Hafting et al. (2005) found that the place-specific responses of the stellate cells in ECII change in spike frequency with distance from spatial grid points of maximum spike frequency. Active grid

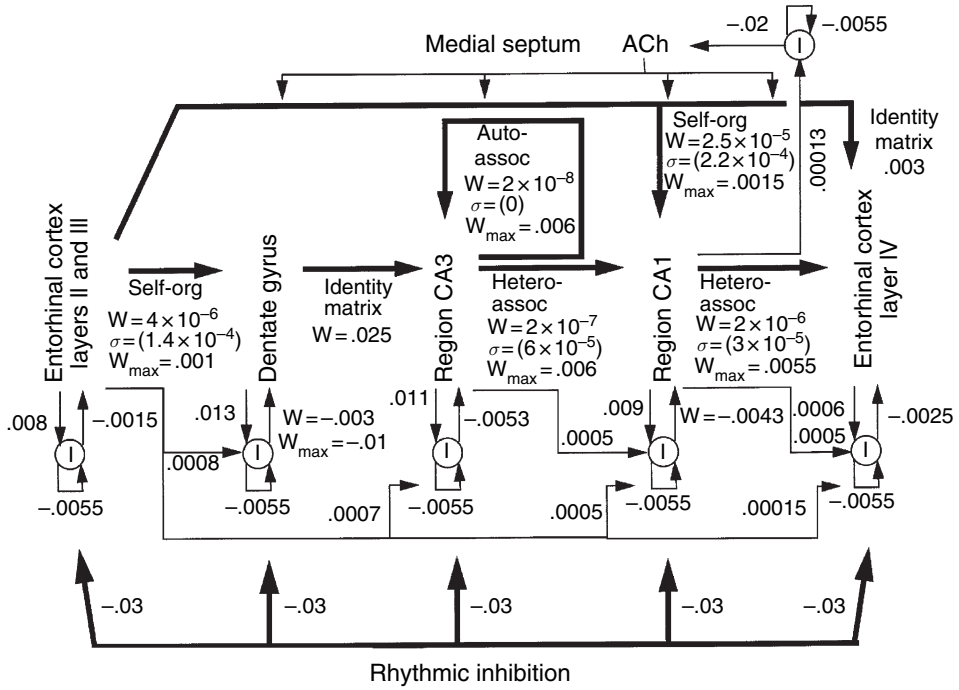

Figure 2 Strength of individual connections within the network simulation of the hippocampal formation in Hasselmo and Wyble (1997). When a single number is specified, this is the homogeneous strength of a set of nonmodifiable connections. When three numbers are specified, these are the mean initial strength, the standard deviation of the initial strength, and the maximum possible strength of a set of modifiable connections. Each modeled layer of entorhinal cortex contained 40 excitatory units, while the other hippocampal subregions each contained ten excitatory context units and 50 excitatory item units. Excitatory connections between regions represent the perforant path projecting from layer III of entorhinal cortex to dentate gyrus, layer III of entorhinal cortex to subregion CA1, the mossy fibers from dentate gyrus to CA3, the recurrent longitudinal association fibers in subregion CA3, the Schaffer collaterals from CA3 to CA1, and projection back from subregion CA1 to layer IV of entorhinal cortex. In each region the pyramidal cells are fully connected with an inhibitory interneuron (marked I) by excitatory connections of the strength shown. The inhibitory interneuron sends back inhibitory connections of the strength shown. In the dentate gyrus and subregion CA1, these inhibitory connections had random initial strength and were modifiable.

points of a particular stellate cell appear throughout an extended spatial field, and the grid points form equilateral triangles. The spatial frequency that is defined by the distance between grid points of an active ECII stellate cell increases when recording from cells in the dorsal medial ECII toward cells in the ventral medial ECII. The possibility that combinations of the rate-coded activity of multiple grid cells can act as a coordinate system that determines a precise spatial location has led to the development of models of path integration that incorporate this stellate activity in ECII as part of the information into the hippocampal system (O'Keefe and Burgess, 2005).

Other connectionist modeling of the memory function of ECII emphasizes encoding of representative patterns for use in hippocampal memory function. In Hasselmo and Wyble (1997), context-dependent encoding of specific word stimuli is assumed to occur in ECII. The corresponding connectionist network model that does this encoding was tested with regard to its performance in subsequent recognition or free recall of the words. In the simulations, both individual words and experimental contexts were represented by binary patterns of activity that were presented to the ECII and ECIII networks of the model. The binary patterns of activity used were strongly overlapping and were chosen randomly. The assumption that underlies the use of separate item and context representation is that a persevering context, provided by input due to (1) environmental features present during trials, (2) features of the presentation medium, and (3) the presence of the experimenter, results in cortical activity that is largely nonoverlapping with item input activity. Each individual word belonged to a specific

list, and the representative patterns of words from the same list were always given in association with the same consistent representation of context. During the presentation of a pattern of activity, which was maintained for 400 time steps of the simulation, the network activity caused by the input propagated to all other subregions of the modeled hippocampal system. In this manner and by manipulation of the model functions, the effects of scopolamine (Ghoneim and Mewaldt, 1975) could be described. A similar representation of stimuli has been used in previous connectionist models of free recall (Metcalfe and Murdock, 1981; Metcalfe Eich, 1982; Gillund and Shiffrin, 1984).

Free recall and recognition test different aspects of memory retrieval. A common means to elicit recognition retrieval in connectionist models is to present partial input patterns. By contrast, free recall tests require that subjects recall items from a list without being given item-specific cues. In the integral hippocampal system model of Hasselmo and Wyble (1997), either type of retrieval could be elicited by providing the corresponding appropriate input to the modeled entorhinal networks. To simulate free recall, only the activity pattern representing a context cue was presented to layers II and III of model entorhinal cortex. The resulting entorhinal activity evoked context-specific activity in the model networks of DG and of hippocampal subregion CA3. In the associative CA3 network, the context cue elicited activity that represents individual items. If one of the item patterns of activity produced in CA3 matched a pattern of activity that was elicited in ECIV in response to the context cue, then successful recall was achieved.

To test the recognition of events in an episode or items from a list in a connectionist model, it is necessary to explicitly avoid presenting a cue that is a partial representation of one learned item. In tests of recognition with human subjects, the subjects are given lists that contain words from a learned list, as well as distractor words. They are instructed to identify words that were encountered during the encoding phase of the experiment. A similar protocol can be simulated in connectionist models. For example, in the model of Hasselmo and Wyble (1997), this was simulated by presenting to layers II and III of the model entorhinal cortex a sequence containing some known and some unknown item patterns. In simulations, the propagation of activity allowed the known item patterns to elicit the retrieval of a corresponding context pattern in the CA3 network. A recognition process of this sort was first proposed by Hollingworth (1913), which led Tulving and Norman (Norman, 1968; Tulving, 1975) to hypothesize that recognition was the inverse function of recall.

Another issue that concerns the presentation of input at entorhinal cortex layers of a hippocampal system model is the relationship between presentation frequency and recognition, the effect of familiarity. This issue was addressed by several connectionist models (Metcalfe and Murdock, 1981; Gillund and Shiffrin, 1984; Hintzman, 1988; Chappell and Humphreys, 1994) and was restated in the integral system model of Hasselmo and Wyble (1997). There and in similar system models, the effect that cue familiarity has on simulated recognition performance may be observed in terms of the temporal delay before a context or item pattern is reactivated by retrieval. This method has been suggested for studies of temporal delays in ECIV.

The potential roles of the entorhinal cortex in models of learning and memory, as the perforant path input to the integrative processing in the hippocampus, are likely to inspire a major part of the modeling and experimental efforts in coming years. In addition to the sustained and specialized rhythmic responses supported by pyramidal and stellate cells in ECII, novel types of intrinsic spiking responses are now known to occur in ECIII and ECV. In layer III, induced sustained spiking may be maintained until deactivated by an equivalent stimulus, regardless of intervening hyperpolarization (Fransén et al., 2006b). In layer V, successive instances of induced depolarization produce a graded increase in the frequency of a sustained spiking response, while following instances of hyperpolarization cause a graded decrease of the sustained spike frequency (Fransén et al., 2006a). Each of these characteristic responses implies a nonsynaptic neural memory function that can play a specialized role in learning and memory.

1.35.4 Dentate Gyrus: Generating Representations That Minimize Interference

Recent models of learning and memory in the hippocampal system propose that the neurons of the DG may self-organize to form novel and sparse (nonoverlapping) ensembles that are associated with a unique temporal context (Hasselmo and Eichenbaum, 2005). In this case, such a temporal context is

identified as a sequence of input activity that originates in the entorhinal cortex, as well as through associations that were established with episodic sequences of patterns of activity in region CA3 of the hippocampus. The unique representations of successive temporal contexts that may be generated in DG could establish associations between those representations within the DG that reflect a specific temporal order. Such associations within the DG may be established through synaptic modification in the fibers that connect the mossy and granule cell layers of DG (Lisman, 1999; Lisman et al., 2005).

Unique coding for temporal context in DG may provide a route of direct access through which input to the DG can cue the retrieval of episodic memory stored by the hippocampus. A process by which unique representations may be generated by coincidental activity has been postulated in earlier studies (Koene, 2001). In connectionist models, a temporal context may be represented as a continually changing sequence of input activity. Presentation of such a sequence to the hippocampus may be aided by a first-in, first-out buffer in ECII, thereby providing a sliding window in which activity is repeatedly presented in order (Koene and Hasselmo, 2007a). The representation of temporal context has been described formally in terms of context drift and its potential significance with respect to the recency and contiguity effects in human recall performance (Howard and Kahana, 2002; Howard et al., in press). Recent unpublished data by J. Manns, obtained by recording in subregion CA1, provides supporting electrophysiological evidence of a mechanism that supports contiguity of context representations.

Connectionist networks, unlike human brains, are prone to a type of forgetting called 'catastrophic interference,' which is not gradual as during normal forgetting observed in experiments with humans (Barnes and Underwood, 1959). When new data interfere catastrophically with existing stored memory in connectionist networks, the earlier memory can be erased rapidly and completely by the interference effects. Attractor neural network models can avoid catastrophic interference by using a protocol of interleaved learning. During interleaved learning, items of a list are presented multiple times in randomized order (McClelland et al., 1995; Hasselmo, 1999).

In humans, interleaved learning may indeed occur during a gradual process of transfer from the hippocampus and memory consolidation in neocortical regions of the brain. For such consolidation to be possible, new information that is generally believed to be processed as part of hippocampal function must first be acquired and encoded in the hippocampal system. During this initial encoding, interleaved learning is not generally feasible, since animals and humans cannot exert absolute control over the environment from which stimuli appear. It will often be impossible or undesirable (as in the case of dangerous events) to repeat stimuli or to randomize their order during repeated presentations (as in the case of causal events). One-shot encoding of episodes is possible without risking catastrophic interference if nonoverlapping representations are involved, as in the case of the unique coding that was hypothesized in DG, as described in preceding paragraphs. A number of spiking neuron models (integrate-and-fire models) of hippocampal function use encoding with sparse patterns in portions of modeled hippocampal network hierarchy to avoid catastrophic interference. In those models, the separated patterns of activity can be maintained in a short-term buffer to repeat ordered presentations that elicit activity in the hippocampus and encode episodic associations (Jensen et al., 1996; Jensen and Lisman, 1996; Koene, 2001; Koene et al., 2003; Hasselmo and Eichenbaum, 2005).

This supposed function of the DG has been described in some connectionist models as a competitive network. There, it is proposed that the divergent connections from entorhinal cortex to DG distribute overlapping input patterns into sparse nonoverlapping representations that reduce interference (McNaughton, 1991; Treves and Rolls, 1994). A detailed analysis of the modification of perforant path synapses by O'Reilly and McClelland (1994) showed that modification can enhance pattern separation, but that study did not explicitly focus on the sequential presentation of different input patterns. A modification of perforant path synapses was explicitly considered when sequences of input were presented in the Hasselmo and Wyble (1997) model. The excitatory perforant path connections from layer II of model entorhinal cortex to the DG network consequently achieved self-organization: random initial connection strengths from ECII to DG resulted in the initial activation of a subset of DG neurons; the connections from active ECII neurons to activated DG neurons were strengthened; the connections from inactive ECII neurons were weakened by synaptic decay in response to the postsynaptic activity; connections from active ECII neurons to inactive DG neurons were weakened due to presynaptically regulated synaptic decay. The effect of these model

mechanisms corresponded to experimental evidence, which has shown that strengthening of perforant path synapses depends on pre- and postsynaptic activity (McNaughton et al., 1978; Levy and Steward, 1979), while weakening of connections has been similarly demonstrated (Levy and Steward, 1979). In Hasselmo and Wyble (1997), the model mechanism was able to establish selective patterns of connectivity between active neurons in the ECII network and neurons in the DG network. The process produced sparsified, less overlapping representations for each of the item patterns that were presented in trial sequences.

The model in Hasselmo and Wyble (1997) did require a novel mechanism to prevent previously established representations from dominating the learning elicited by new pattern input. The novel mechanism involved strengthening the connections from active inhibitory interneurons in DG to active neurons in DG (Hasselmo et al., 1996, 1998). Such inhibitory synaptic enhancement has been demonstrated in other regions of the hippocampus (Haas and Rose, 1984; Morishita and Sastry, 1991; Grunze et al., 1996). The resulting suppression of neurons that participated in previously encountered representations insured that different patterns of activity were elicited in DG by subsequent patterns of entorhinal cortex activity.

The connectionist proposal that DG rapidly establishes new memory patterns to represent changing input leads to neural network models that rely of different rates of learning in DG networks and in networks that represent a hippocampal subregion such as CA3. In Hasselmo and Wyble (1997), this need was met by assuming different thresholds for synaptic modification in the two regions. In more recent models, the comparative ease with which spiking has been shown to occur in cells of the dentate granule layer is explicitly taken into consideration, so that the resulting simulations further suggest that comparatively rapid encoding takes place at synapses in the DG (Lisman et al., 2005; Koene and Hasselmo, 2007b).

1.35.5 CA3: Forming Attractors and Associations between Attractors during Rhythmic Oscillation at Theta Frequency

The hippocampus is essential to the ability of humans to easily acquire new episodic memory. One-shot learning is known to occur, in which known stimuli are presented only once in a specific order. One-shot episodic learning may depend critically on a combination of subregion-specific learning functions. In DG, nonoverlapping and therefore noninterfering representations can be made of activity that originates in and may be buffered in the entorhinal cortex. In subregion CA3, associative memory may be encoded by the LTP of the synapses of excitatory recurrent fibers (the longitudinal fibers of subregion CA3). Jensen and Lisman (1996) have demonstrated successful simulations with a model that combines these elements and achieves one-shot learning of novel episodes that are composed of known item patterns. In that integrate-and-fire network model, item representations are patterns of simultaneous spikes, and individual patterns are separated by competitive recurrent inhibition due to the activation of a network of interneurons after each pattern of item spikes. Lisman and Idiart (1995) theorized that the separation of spike patterns by such inhibition may explain the appearance of gamma frequency in the power spectrum during working memory tasks.

A model of episodic acquisition similar to that of Jensen and Lisman (1996) incorporates novel insights about the modulatory effect of theta rhythm in the hippocampus (Hasselmo et al., 2002a; *See* Chapter 1.37). During each cycle of the simulated theta rhythm in this model, the phase of maximum neuronal membrane depolarization in region CA3 coincides with a suppression of the strength of afferent input transmission. Conditions during that phase favor associative retrieval via the recurrent fibers in subregion CA3. Conversely, conditions at the opposite phase of the theta rhythm encourage the receipt and encoding of novel associations in accordance with afferent input. During that opposite phase of rhythmic modulation, recurrent synaptic transmission is suppressed, and LTP of those synapses is more readily elicited (Hyman et al., 2003).

The theory of differential functional modulation during different phase intervals of the theta rhythm that is observed during hippocampal memory tasks inspired the development of a new category of models of hippocampal episodic memory (Hasselmo et al., 2002b,c; Cannon et al., 2003). In these models, memory encoding and memory retrieval alternate within each cycle of the theta rhythm. Complex integral system models include both the proposed neural network mechanism of buffered (Lisman and Idiart, 1995; Koene and Hasselmo, 2007a) one-shot episodic learning (Jensen et al., 1996; Jensen and Lisman, 1996) and the proposed biophysical model

mechanism of alternating encoding and retrieval conditions. These system models with integrate-and-fire neurons react dynamically to feedback from the environment in response to actions taken and, therefore, perform successfully in tasks during which the need for memory encoding or memory retrieval may not be easily predicted or may be required in a concurrent or ongoing manner (Hasselmo et al., 2002b; Koene et al., 2003). During phase-locked conditions favorable to memory encoding, buffered sequences of spike patterns cause synaptic modification at recurrent excitatory fibers in model subregion CA3 and in model ECIII. During phase-locked conditions favorable to memory retrieval, activity spreads along strengthened connections within the recurrent networks, thereby retrieving representative spike patterns that provide information about known feature associations and heteroassociative information about encountered episodes.

The allocation of network roles in terms of stored association type is a continuing source of debate. For example, in models by Hasselmo et al. (2002b) and by Koene et al. (2003), feature (or place) associations were stored in a network representing subregion CA3, and heteroassociative storage occurred in a network representing ECIII. In later models by Hasselmo and Eichenbaum (2005) and by Koene and Hasselmo (2007b), the roles of the two recurrent networks were reversed. In either case, it was assumed that a convergence of streams of spreading activity in the two recurrent networks elicited spike activity at pyramidal neurons in hippocampal subregion CA1. The spiking of neurons in subregion CA1 can inform actions to be taken to successfully perform a specific task. The models of rhythmically alternating encoding and retrieval, and of activity that is gated by converging streams of spreading activity during retrieval, were applied together by Koene et al. (2003) to successfully simulate the performance of rat spatial navigation and by McGaughy et al. (2005) to simulate conditioned responses in a delayed nonmatch to sample task.

A number of connectionist models have proposed that hippocampal subregion CA3 provides autoassociative memory function, based on the extensive and strong excitatory recurrent connectivity in that neural network (McNaughton and Morris, 1987; Levy, 1989; Eichenbaum and Buckingham, 1990; Treves and Rolls, 1992; Hasselmo et al., 1995; Hasselmo and Stern, 1996). In contrast to the biophysical and structural complexity of the models described in preceding paragraphs, neural network models with excitatory recurrent connections that focus on the principles of attractor networks have been used extensively to model memory function (Little and Shaw, 1975; Anderson et al., 1977; Hopfield, 1982; Anderson, 1983; Ruppin and Yeshurun, 1991; Chappell and Humphreys, 1994; Hasselmo et al., 1995; *See* Chapters 1.33, 1.34). Those networks have the characteristics of fixed-point attractor models, due to recurrent connections with specific patterns of connection strengths. When network activity settles into final stable states, those stable states represent stored memories. Each final stable state may be reached by a different state of initial activity.

From a computational perspective, fixed-point attractors present an appealing model of human memory function, since the final memory states can exhibit robustness to variation in the input cues. Therefore, attractor dynamics are particularly useful for models that are used to simulate free recall. In tests of free recall, the input cues are relatively weak, and associations with an experimental context are shared by a number of items in the same list. Given initial activity that reflects these item and context input characteristics, free recall performance is simulated when attractor dynamics lead from the initial state to a final stable state that is a known representation in the trial context. It is worth noting that attractor dynamics in a more biophysically detailed model of hippocampal subregion CA3 may mediate the retrieval of autoassociative memory, even if network activity does not settle into persisting fixed-point attractors. The dynamics of activity in subregion CA3 may nonetheless be dominated by the approach to an attractor, during the interval defined by a single oscillation at gamma frequency, or during complex spike activity.

As perpetuated in recent system models (Hasselmo and Eichenbaum, 2005; Koene and Hasselmo, 2007b), the hypothesized role in Hasselmo and Wyble (1997) for the memory function of subregion CA3 was that of an attractor network that specialized in the formation of robust episodic representations of items and context. These associations were learned by modifying excitatory recurrent connection strengths, so that attractor states were encoded. The encoding of weaker associative links between context and item attractors was also assumed. Free recall and recognition were primarily achieved through the attractor dynamics. During encoding, the activity of a sufficiently active unit in model DG propagates through an identity matrix of connections that represent mossy fibers to activate individual CA3 units. In the presence

of cholinergic suppression, the pattern of activity in the model is determined primarily by this afferent input, instead of being subject to strong recurrent excitation. Consequently, the connections between neurons that were activated by input from the DG are selectively strengthened, which results in increased activity in model subregion CA3 and a greater output of activity to subregion CA1.

Earlier studies have explored the stability of the CA3 network when modeled with a number of different patterns of connectivity (Minai and Levy, 1994). In comparatively abstract neural network models, the possibility of an exponential explosion of excitatory activity is prevented by assuming that total activity is normalized (Treves and Rolls, 1992). In continuous-firing-rate models, a similar limitation of network activity is achieved through the use of feedback inhibition (Hasselmo et al., 1995; Hasselmo and Wyble, 1997). The same method may be applied in spiking neuron models.

In the Hasselmo and Wyble (1997) integral system model, increased activity in subregion CA1 causes a decrease in simulated cholinergic modulation throughout the model network, which in turn causes greater recurrent excitation in subregion CA3. Therefore, it is possible to enter a stable fixed-point attractor pattern that represents a stored context or item, if a pattern of cue activity is presented. An emerging item or context attractor state can (a) drive ensuing activity into an associated item or context attractor state, and (b) drive output activity in region CA1 and ECIV. Attractor states are terminated in the model by neural adaptation and by the rhythmic inhibition through interneuron activity, which is a model mechanism of hippocampal theta rhythm (Bland and Colom, 1993).

With the model mechanisms in Hasselmo and Wyble (1997), free recall is simulated when a cue elicits a context attractor state in model subregion CA3. The activity spreads into a number of weakly associated item attractor states in CA3. As the activity of item attractor states grows, they compete by inhibiting each other. At most one winning attractor state persists, which represents the free recall of an item. That attractor state is eventually terminated by cyclic inhibition, so that the context attractor can evoke the attractor state of another associated item. Inhibitory oscillations have been shown to provide a potent means of competitive neural network learning (Norman, 2006).

Recognition is simulated when input of an individual learned item pattern of activity in model ECII elicits the corresponding item attractor state in subregion CA3. When a familiar item attractor state is reached, that attractor elicits associated context attractor activity. Such context attractor activity does not appear for novel items.

1.35.6 CA1: Comparing and Gating of Input from Region CA3 and Entorhinal Cortex

There are two common functional hypotheses concerning the arrangement of synapses in the important Schaffer collateral fiber path from hippocampal subregion CA3 to subregion CA1. The first supposes that the Schaffer collaterals undergo a process of self-organization (Treves and Rolls, 1994). The second supposes that the Schaffer collaterals provide a heteroassociative memory function (McNaughton, 1991). The two are not mutually exclusive, and the relative amount of these two functions depends upon how strongly the Schaffer collaterals influence activity in subregion CA1.

If the Schaffer collaterals dominate postsynaptic activity in region CA1 during learning, then they will predominantly undergo self-organization. This must be assumed if no mechanism for the modulation of synaptic transmission is incorporated in models. However, in models that include the cholinergic suppression of synaptic transmission at the Schaffer collaterals, the perforant path input can more strongly influence CA1 activity during learning, thereby allowing heteroassociative memory function. The heteroassociative memory function may be necessary if it is assumed that one of the functions of subregion CA1 is to provide a comparison between the recall activity generated by subregion CA3 and episodes of direct input transferred from entorhinal cortex, as has been proposed by some researchers (Levy, 1989; Eichenbaum and Buckingham, 1990; Lisman, 1999).

Experimental results have shown that the strength of input from entorhinal cortex to subregion CA1 is insufficient to achieve significant activation in subregion CA1, unless supported by converging input from hippocampal subregion CA3. The Schaffer collateral input from CA3 therefore gates the activation of neurons in subregion CA1. In this regard, recent integral system models of the hippocampal system, such as the model of Hasselmo and Eichenbaum (2005) and the model of Koene and Hasselmo (2007b), implement an explicit mechanism of

convergence and gating of activity in CA1 by Schaffer collateral input.

The model of Hasselmo and Wyble (1997) proposes that, during sequential self-organization in DG, similar self-organization also takes place in subregion CA1, resulting in a similar modification of excitatory and inhibitory connections. The possibility of long-term changes of inhibitory potentials is supported by considerable data obtained by recording in subregion CA1 (Grunze et al., 1996). During encoding of a novel pattern, random initial connection strengths of the activated Schaffer collateral fibers elicits a distributed pattern of activity in subregion CA1. This postsynaptic activity can interact with the presynaptic activity of input from perforant path fibers to form a new self-organized representation. Hasselmo and Wyble supposed that during recall, even though the perforant path input initially has a greater influence on the activity of subregion CA1, those patterns of Schaffer collateral activity that represent familiar stimuli are a sufficient match to perforant path input, so that the output of CA1 elicits a reduction of the cholinergic modulation. One consequence of this is the removal of cholinergic suppression of synaptic transmission through the Schaffer collateral fibers. Then, the input to CA1 through Schaffer collaterals comes to dominate activity there. The mode suggests that it is through such a mechanism that the output activity of hippocampal subregion CA3 can drive the neural activity in subregion CA1 to produce a pattern of activity that is associated with memory retrieved in CA3.

1.35.7 Medial Septum: Feedback Regulation of Cholinergic Modulation and Selective Emphasis of Encoding or Retrieval

In the regulatory system of cholinergic modulation that was supposed in the models discussed in preceding paragraphs, the propagation of hippocampal activity through the medial septum has been explicitly associated with the feedback regulation and consequent selective emphasis of memory encoding or memory retrieval processes. In recent simulation studies, the proposed selection mechanism has been further refined to include ongoing alternation of preferential encoding and retrieval in separate phase intervals of each cycle of theta rhythm. Rhythmic modulation of hippocampal networks at theta frequency establishes opposing periods of relative depolarization and relative hyperpolarization of the neural membrane.

In Hasselmo et al. (2002a), this network-wide modulation of membrane potentials is combined with the aforementioned phase-locked selective suppression of recurrent or afferent fiber transmission during distinct intervals of the theta rhythm. Also included was an explicit mechanism of the theta-phase specific effectiveness of LTP in the hippocampus (Hyman et al., 2003). The sum of the theta-modulated transmission and plasticity effects may enable alternation between conditions that favor encoding and conditions that favor retrieval during each theta cycle. This model of ongoing encoding and retrieval has been applied successfully to simulated spatial navigation tasks (Hasselmo et al., 2002b; Koene et al., 2003) and to delayed nonmatch to sample tasks (McGaughy et al., 2005), as well as to a biophysical implementation of reinforcement learning in prefrontal cortex (Koene and Hasselmo, 2005).

According to Hasselmo and Wyble (1997), the level of output activity elicited in subregion CA1 is a direct determinant of activity in the medial septum. That in turn determines the degree of cholinergic modulation that is applied to all modeled subregions through connections from the medial septum. The cholinergic modulation was deemed responsible for all cellular effects of acetylcholine, namely: (1) selective suppression of synaptic transmission at connections from neurons in CA3 through recurrent connections to other neurons in CA3, and at connections from neurons in CA3 to neurons in CA1, as well as at connections from neurons in CA1 to neurons in the entorhinal cortex; (2) network-wide depolarization of all neurons; (3) suppression of adaptation in the response of excitatory neurons; and (4) enhancement of synaptic plasticity (Hyman et al., 2003). In the model implementation, default levels of cholinergic modulation were high, and changes were effected by the active inhibition of cholinergic input. This inhibition was hypothesized to occur due to the activation of interneurons in the medial septum by output activity from subregion CA1.

In summary therefore, when both the output activity from model subregion CA3 to CA1 and the activity delivered to CA1 via the perforant path generate a match and elicit consequent activity in the CA1 network, then the output activity from CA1 feeds back into the hippocampal system in the form of a decrease of cholinergic modulation via the medial septum, which was proposed to effectively

switch the modeled hippocampal networks from encoding to retrieval dynamics. This proposed switching system has a slower time course than the rhythmic alternation of modulation that was proposed in Hasselmo et al. (2002a) and subsequent published models.

1.35.8 The Translation of Representations in Layer IV of Entorhinal Cortex and Feedback to the Neocortex

ECIV receives direct input from ECII. For this reason, layer IV may be considered an ideal network in which activity represents the output of the hippocampal system during simulations of tests of free recall and of recognition (Hasselmo and Wyble, 1997). Simulated activity elicited in ECII is transmitted directly to ECIV, propagation that is done through an identity matrix of connections in the model. During the initial learning of a novel pattern, it is that input which dominates activity in layer IV of model entorhinal cortex. After all, feedback from subregion CA1 is suppressed by cholinergic modulation during this time. Associations between the patterns of activity in ECIV and the activity of episodic representations in subregion CA1 are encoded.

During simulated retrieval, partial input cues given to the ECII network result in inactive or incomplete item pattern activity in ECIV. Those patterns of activity can be completed only once output activity spreads from subregion CA1 to ECIV, which can reconstitute previously encoded item or context information. Transmission through the feedback connections from subregion CA1 to ECIV is not suppressed during retrieval. Consequently, recognition tests could be simulated and evaluated with the model by measuring whether activity in the ECIV network generated a known context pattern when individual familiar or novel item patterns were presented (Norman and O'Reilly, 2003).

1.35.9 The Hippocampal Model of Temporal Context-Dependent Episodic Memory

Insights gained in work with earlier integral system models, such as in the models of Hasselmo and Wyble (1997), Jensen and Lisman (1996), and Koene et al. (2003), and through the application of those models to simulated tasks that depend on the specific functions of each layer of the entorhinal cortex and subregions in the hippocampus, led those researchers to formulate novel hierarchical models. Recent models in Hasselmo and Eichenbaum (2005) and in Lisman et al. (2005) incorporate proposed functions of context-dependent episodic memory that enable complex behavioral performance in tasks such as delayed spatial alternation. Each of these models takes into consideration associative encoding on the recurrent fibers of two networks. In the case of the Hasselmo and Eichenbaum (2005) model, these networks are subregion CA3 and ECIII. In the case of the Lisman et al. (2005) model, they are subregion CA3 and the recurrent network that is formed by the reciprocal synaptic fibers between the mossy and granule cell layers of the DG. Associative encoding on the recurrent fibers in DG was also taken into account for the unique sparse encoding in DG of the models of Hasselmo and Eichenbaum (2005) and Koene and Hasselmo (2007b), although the implementation of the network was more abstract in those models.

The Hasselmo and Eichenbaum (2005) model has been applied to simulated tasks in which performance depends on the ability to concurrently encode and retrieve temporal context-dependent episodic memory. In these simulations, input activity that is elicited by stimuli in a simulated environment causes activity in a layer II network of model entorhinal cortex. In an integrate-and-fire implementation of the model hypotheses (Koene and Hasselmo, 2007b), the ECII network acts as a working memory of short sequences of sequences of spike patterns that are sustained by persistent firing characteristics of the pyramidal neurons in ECII (Koene and Hasselmo, 2007a). Several studies have addressed the possible mechanisms by which executive mechanisms and attention may gate input to working memory (Grossberg and Stone, 1986; O'Reilly and Frank, 2005). The output of the ECII network provides repeated episodes of spiking activity to the model ECIII, as well as to model subregion CA3 and model DG.

Hasselmo and Eichenbaum have proposed that the synapses of recurrent fibers in ECIII encode associations between items distinguished by specific features, such as associations between the place cells of adjacent place fields in spatial navigation tasks. In this model, the associative network properties of the DG are used to generate unique temporal context representations that are associated with a buffered

episodic cue of activity in the ECII network. The third associative network, model subregion CA3, was assigned a heteroassociative role, storing episodic memories of the sequences of activity propagated from the output of ECII. During encoding, the modification of synapses at fibers from DG to CA3 creates associations between the unique temporal context-specific representations in DG and the episodic memory traces stored in subregion CA3. In this manner, activating a representation stored in the DG provides a direct way to elicit the retrieval of a specific instance of episodic memory that was stored in the hippocampus.

A significant characteristic of episodic encoding in the CA3 network of the models of Hasselmo and Eichenbaum (2005) and Koene and Hasselmo (2007b) is that episodic order is reversed in the encoded associations at recurrent fibers. Thus, during episodic retrieval in the model CA3 network, the sequence of retrieved activity can trace events in reverse, resembling reversal of activity shown during *in vivo* electrophysiology in linear track experiments (Foster and Wilson, 2006) and during spatial alternation behavior in multiple T-mazes (Johnson and Redish, 2006).

Activity in the model subregion CA1 was elicited by the convergence of spreading activity elicited during retrieval in the ECIII and CA3 recurrent networks. Simulation results with the model showed that it could successfully simulate performance in delayed spatial alternation tasks. The activity of neurons in the model subregion CA1 could be decoded to represent specific spatial locations and, in the stem of a T-maze, exhibited the selective activity and spiking behavior of experimentally observed 'splitter cells' (Hasselmo and Eichenbaum, 2005; Koene and Hasselmo, 2007b). In a spatial alternation task, splitter cells that respond to motion in the same head direction and in the same location of the stem of a T-maze fire selectively, depending on whether an animal must turn left or right at the top of the stem in order to perform a specific run of the alternation task successfully.

With the development of several hierarchical models that include the interacting functions of multiple subregions of the hippocampal system, it has become possible to simulate full-network activity and thereby to study the interactions between the subregions. Early full-network simulations focused either on behavioral phenomena (Schmajuk and DiCarlo, 1992; Gluck and Myers, 1993) or on hippocampal physiology (Rolls, 1995; Hasselmo and Stern, 1996), but the recent models explicitly simulate a combination of system behavior and biophysical detail. That combination of modeling levels has already led to new insights about mechanisms necessitated by the interaction and improved physiological realism of individual subregion networks. Full-network simulations in Hasselmo and Wyble (1997) indicated the need for inclusion of additional hippocampal subregions, so that nonoverlapping representations could be generated (DG), and so that encoding and retrieval conditions could be regulated within the simulations (a comparison function in CA1, plus medial septum). Entorhinal regions were included to decode self-organized representations in the hippocampus and allow the study of the interaction of input and output with neocortical regions. A set of simulations by Jensen et al. (1996) and by Jensen and Lisman (1996) showed how a succession of hippocampal network stages could generate incrementally more complex associative information, from short buffered sequences to auto-associative item representations and sequence representations of episodic memory, and emphasized how the characteristic physiology of *N*-methyl-D-aspartate (NMDA) receptors in the subregions involved could selectively mediate the different associative functions. Simulations by Koene et al. (2003) clearly demonstrate the involvement of synchronization by theta rhythm throughout the hippocampal system during active task behavior, while simulations by Hasselmo and Eichenbaum (2005) demonstrate the functional significance of spreading retrieval activity in regions CA3 and ECIII that converge in region CA1.

In Hasselmo and Wyble (1997), simulations with the neural network model were able to replicate list length and list strength effects seen in the human data.

The list strength effect appears during free recall, where list strength is the ratio of recall performance between strong items (items presented several times) and weak items (items presented once). There was no effect of list strength on performance during recognition. In the model, items interfere only when simultaneously active, such as when competing during free recall. As more items compete, simulated recall becomes more difficult, with a greater threshold for retrieval in subregion CA3.

This difference in the experimental human data, between free recall and recognition performance, was not replicated by earlier composite models, in which each item contributes to the variance of the entire

system. In such models, the variance deteriorates recognition accuracy just as it deteriorates recall accuracy (Ratcliff et al., 1990). The list strength effect has been achieved differently by a model of Chappell and Humphreys (1994), in which the activity of units is controlled by intrinsic dynamics. The list length effect, which is seen during recognition, and the list strength effect are achieved by the same process in composite models. In contrast, the list length effect appears in the Hasselmo and Wyble (1997) model when the chance that a distractor item matches one of the list of items learned by DG is great enough to cause an erroneous recognition. This effect is due to increasing intrusions with longer lists, rather than due to increasing variance assumed in the composite models.

Simulations in full-network, hierarchical models of hippocampal function may also be compared to data on the effect of hippocampal lesions. Removal of a model's ability to rapidly encode episodic memory after a single presentation can simulate anterograde amnesia and partial retrograde amnesia, as experienced by patients such as HM (Scoville and Milner, 1957). Temporally graded, partial retrograde amnesia (McClelland et al., 1995) may result if episodic memories encoded with the hippocampal system are involved in a gradual formation of representations in the neocortex (Buzsáki, 1989; Treves and Rolls, 1994; Hasselmo et al., 1998). A transfer of data back from the hippocampus to deep entorhinal cortex during periods of decreased cholinergic modulation is supported by physiological data (Chrobak and Buzsáki, 1994). Compared to the more abstract and fundamental models of human memory (Gluck and Myers, 1993; Myers and Gluck, 1994), full-network simulations clarify the link between the model and specific anatomical or physiological features of the hippocampal system.

The internal representation of item activity in recent models of hippocampal function, though established through a biologically plausible rationale, has similarities with earlier and nonconnectionist models of human memory. Entorhinal activity resembles coding in composite trace models, where the individual features that compose items elicit subsets of an item representation (Metcalfe and Murdock, 1981; Murdock, 1982). By contrast, after sparse nonoverlapping encoding in DG, representations have more in common with those used in separate trace models (Gillund and Shiffrin, 1984; Hintzman, 1988). For example, the storage of representations in CA3 in (Hasselmo and Wyble, 1997) resembles that used in the search of associative memory model (Gillund and Shiffrin, 1984), where a matrix of weights between 0 and 1 stores the relative values of associations between different items, but using attractor dynamics for retrieval. To cue retrieval, a number of hippocampal models use context (Hasselmo and Wyble, 1997; Hasselmo and Eichenbaum, 2005; Koene and Hasselmo, 2007b). Such cuing resembles the retrieval mechanism used in convolution-correlation models Metcalfe and Murdock (1981).

During retrieval, a procedure of cleanup, error correction, or pattern completion is used by many models of human memory, from the more abstract approaches (Hintzman, 1988) to those in which dynamic interactions allow activity to spread through different regions (Hasselmo and Wyble, 1997; Hasselmo and Eichenbaum, 2005). In the Lisman (1999) model, the combination of perforant path and Schaffer collateral input to CA1 allows error or novelty detection, while dynamic pattern completion during the retrieval of spiking patterns in episodic recall is enabled by recurrent activation through the reciprocal loop from CA3 to the granule and mossy cell layers of DG and back to CA3. In the Hasselmo and Wyble (1997) model, competition between different patterns in model subregion CA3 must result in a clear winner before the output of CA3 is propagated to subregion CA1 and to the model ECIV, since the model specifies that activity in CA1 can be elicited only by complete retrieved patterns.

In the model of temporal context-dependent episodic memory of Hasselmo and Eichenbaum (2005) and its variant based on integrate-and-fire neurons (Koene and Hasselmo, 2007b), spiking in CA1 can be elicited only when there is a convergence between spreading activity representing the retrieval of feature associations in entorhinal cortex and spreading activity in CA3 that represents retrieved episodic memory in the temporal context. In their implementation of cleanup, those latest models incorporate competition between items retrieved by auto- and heteroassociative attractor processes, as well as the gating of perforant path input by Schaffer collateral input, which had been demonstrated in prior full-network models (Lisman, 1999; Koene et al., 2003). In addition to this, the integrate-and-fire neuron implementation of the model (Koene and Hasselmo, 2007b) of temporal context-dependent episodic memory does not depend on a specific complete pattern size, but instead depends on activity that occurs at specific phases of the cycles of theta rhythm.

Some models of free recall (Metcalfe and Murdock, 1981; Gillund and Shiffrin, 1984) prevent the reactivation of previous responses through a sort of repetitive cued recall, in which previously recalled items provide cues that move recall more efficiently from item to item. In contrast, the cues presented for free recall in the Hasselmo and Wyble (1997) model remain constant during recall. Instead, that model uses adaptation based on previous activation to effectively remove a pattern, once activated, from the pool of possible responses. The adaptation properties of the model have been used to simulate functional magnetic resonance imaging data that showed a decrease in hippocampal activation during the viewing of a single repeated stimulus when compared to the activation during the viewing of different novel stimuli (Stern et al., 1996; Stern and Hasselmo, 1997).

Simulations with neural network models that include mechanisms of interactions between networks with specific characteristics, such as those described in the preceding text, can be used to make specific and testable predictions. For example, in the case of the Hasselmo and Wyble (1997) neural network model, by blocking simulated cholinergic effects, it was possible to make clear and specific predictions of the effects of scopolamine on human memory function. The selectivity of the effects predicted corresponded to effects demonstrated in psychopharmacological experiments (Ghoneim and Mewaldt, 1975, 1977; Peterson, 1977; Mewaldt and Ghoneim, 1979). Specifically, encoding of new words was impaired, but retrieval of words in a free recall test was not, and the recognition of words was not impaired. The connectionist model therefore pointed out a direct link between physiological effects at the level of neurons and synapses and the behavioral effects of drug administration in a human experiment. This example demonstrates how the use of connectionist simulations to link cellular physiology with behavior may be used to constrain models of memory function in accordance with experimental data in neurophysiology and molecular biology.

1.36 Theory of Reward Systems

S. B. Ostlund, N. E. Winterbauer, and B. W. Balleine, University of California, Los Angeles, CA, USA

1.36.1 Introduction

Except, perhaps, for the unabashed moralist, knowledge alone does not determine choice of action, i.e., knowing that "action A leads to X and action B leads to Y" does not 'entail' choosing A or B. What enables choice, given this information, is some nonarbitrary means of establishing the relative merits of achieving X or Y. We argue that it is the reward system that provides this means. From this perspective, although the reward system is an extension of the general motivational processes of animals, its function is limited to actions over which animals can exert control and that are instrumental to achieving some goal or other, i.e., to goal-directed instrumental actions. Of course, although most aspects of an animal's behavioral repertoire can be described in goal-directed terms, many of these activities are not goal-directed at all and are reflexive responses elicited by stimuli or relations between stimuli. Establishing criteria for discerning goal-directed and non-goal-directed actions is a necessary step, therefore, in limiting our discussion of the reward system. In this chapter, we consider first the criteria for defining an action as goal-directed and then use that definition to describe the nature and function of the reward system in establishing primary rewarding events, like foods and fluids, both with respect to encoding reward value and to retrieving that value in order to choose between competing courses of action.

This research has established that the value of reward is determined by the quality of the emotional response associated with an event, the latter dependent on current motivational state, i.e., value essentially maps onto the relationship between the specific sensory features of an event and the particular, pleasant or unpleasant, emotional feedback generated when that event is contacted. This issue is taken up in more detail in the section titled 'Reward processes,' where we examine one of the main predictions of this account, that, in the context of secondary rewards, any event associated with a pleasant emotional reaction will support the performance of goal-directed actions. These are sensory events that acquire reward value through association with primary rewards (commonly mislabeled conditioned reinforcers). The procedures used to establish secondary rewards are identical to those commonly used to establish Pavlovian conditioned responses to a stimulus, raising the possibility that the functioning of the reward system can be reduced to the motivational processes that support Pavlovian conditioning. In the section titled 'Secondary reward' we examine this possibility and conclude, based on the extensive evidence standing against this claim, that Pavlovian conditioned responses (CRs) and

goal-directed actions are controlled by fundamentally distinct incentive processes.

1.36.2 Reward Processes

1.36.2.1 Goal-Directed Actions and Behavioral Control

The critical distinction between reflexive and goal-directed actions is that the latter are controlled by a causal relationship to their consequences, whereas the former are not. There are many illustrations of this distinction but perhaps the most apposite is Sheffield's (1965) analysis based on the salivary response of dogs. Salivation was the conditioned and unconditioned reflex studied by Pavlov (1927). Nevertheless, from a goal-directed perspective, it is possible that dogs control this response in order to facilitate digestion or to improve the taste of food. Sheffield arranged a standard pairing between conditioned and unconditioned stimuli, in this case presentation of a tone followed by food delivery, but with a twist: If the dog salivated during the tone the food was not delivered on that trial. This arrangement maintains a Pavlovian relationship between the tone and food but abolishes any instrumental contingency between salivation and food. He reasoned that, if the salivation was goal-directed then this omission contingency should ensure that they stop salivating; indeed having never had the opportunity to learn that salivating improved the rewarding impact of the food by enhancing its flavor or improving its ingestion, they should never acquire salivation to the tone in the first place. Sheffield found that it was clearly the Pavlovian relationship controlling performance; during the course of over 800 tone-food pairings the dogs acquired and maintained salivation to the tone even though this resulted in them losing most of the food they could otherwise have obtained.

Salivation may be the exception of course, but in numerous studies over the last 40 years it has been established in a range of species that Pavlovian conditioned responses do not adjust to this kind of contingency, i.e., one in which performance of the conditioned response leads to the omission of the unconditioned stimulus. Rats acquire conditioned approach responses during a conditioned stimulus (CS) when doing so omits the food (Holland, 1979), pigeons peck at keys (Williams and Williams, 1969), chicks chase food away (Hershberger, 1986), and so on. In all of these studies, the evidence confirms that the performance of the Pavlovian CR does not depend on the relationship between the CR and the US. (*See* Chapter 1.03).

In contrast, experiments assessing the performance of actions acquired during instrumental conditioning have found evidence that these responses do indeed depend on the contingency between action and outcome. Take, for example, instrumental lever pressing. Rats will acquire lever pressing for food quickly and without explicit shaping. Putting this response on an omission contingency, in which responding leads to the omission of an otherwise freely delivered food, rapidly reduces the performance of that response, more rapidly than simply delivering the outcome in an unpaired manner (Davis and Bitterman, 1971; Dickinson et al., 1998; *See* Chapter 1.06). Furthermore, numerous studies have demonstrated the exquisite sensitivity of the performance of instrumental lever pressing to changes in the net probability of outcome delivery given the action (i.e., the difference between probability of an outcome given a response and the probability of the outcome given no response). These changes can be highly selective; degrading one action–outcome contingency by delivering the outcome associated with that action noncontingently often has no effect on the performance of other actions (Colwill and Rescorla, 1986; Dickinson and Mulatero, 1989; Balleine and Dickinson, 1998a).

1.36.2.2 The Effect of Changes in Reward Value

Generally, therefore, goal-directed actions are those that, unlike Pavlovian CRs, are sensitive to the causal relation between the performance of the action and its specific outcome. It is important to note, however, that lever press responses can be controlled by two kinds of association. The first is the relationship between action and outcome described earlier. After extensive instrumental training, however, performance of an action can become habitual, elicited by various situational cues connected with the action through a process of sensorimotor association (Adams, 1981; Dickinson, 1985, 1994). Although the formation of these associations diminishes sensitivity to omission (Dickinson et al., 1998), it does not necessarily abolish it and, although this test distinguishes actions from Pavlovian conditioned reflexes, it does not provide an adequate assessment in itself to distinguish goal-directed actions from habits. Fortunately, there is a clear distinction between the functions of the instrumental outcome in the two

forms of learning. Whereas the outcome serves as the second term of the action–outcome association that supports the acquisition and performance of goal-directed actions, it serves merely to strengthen or to reinforce the stimulus–response (S–R) associations that form habits. As such, the outcome forms no part of the associative structure that supports habitual performance. Based on this analysis, therefore, and combined with an assessment of sensitivity to changes in the instrumental contingency, the standard test of whether an action is goal-directed or not involves an assessment of the sensitivity of performance to a posttraining change in the reward value of the outcome. From an S–R perspective, when conducted posttraining, i.e., after a substantial S–R association has been established, a change in outcome value should be expected to have little if any effect on the subsequent tendency to perform the action. If an action is goal-directed, however, the change in value should potently alter performance.

Consider the case in which a hungry rat is trained to press a lever for a particular type of food pellet. According to a goal-directed account, it is the reward value of the food pellets that motivates performance. Consequently, if having trained the rat to perform this action, the reward value of the food pellets is reduced in some way, we should expect this devaluation to affect performance, i.e., the rat should be less inclined to press the lever after the devaluation. Given this scenario, the question at issue is whether the devaluation affects performance via the animal's knowledge of the contingency between lever pressing and the food pellets. In the first appropriately controlled study along these lines, Adams and Dickinson (1981) assessed this by training rats with two types of food pellets, sugar and grain, with only one type being delivered by lever pressing. The other type of pellet was presented independently of any instrumental action. Thus, any particular rat might have to work for sugar pellets by lever pressing, while receiving free deliveries of grain pellets every so often. The issue was whether the animals would reduce lever pressing more after the devaluation of the response-contingent pellets, the sugar pellets in our example, than after devaluation of the free pellets, the grain ones. Such an outcome could only occur if the effect of the devaluation was mediated by the instrumental contingency between lever pressing and the sugar pellets.

In this study, the pellets were devalued using conditioned taste aversion procedures; it is well established that a food aversion can be conditioned by inducing gastric illness, for example by the injection of lithium chloride (LiCl), shortly after the animal has consumed the food (Bernstein, 1999). In the Adams and Dickinson study, having trained the rats to lever press, half had a taste aversion conditioned to the sugar and half to the grain pellets. During aversion conditioning, the levers were withdrawn and the animals were given a series of sessions in each of which they were allowed to eat one type of pellet. The animals in the devaluation group received a LiCl injection after sessions in which they received the pellets that had been contingent on lever pressing during training but not following sessions with the free pellets. The control group, by contrast, had the aversion conditioned to the free pellets rather than the response-contingent ones. Although such food aversions can be established with a single pairing of consumption with illness when the food is novel, the treatment had to be repeated a number of times to suppress consumption in the present study. This is because the pellets were already familiar to the rats, having been presented during instrumental training.

After inducing these aversions, Adams and Dickinson were now in a position to ask whether devaluing the pellets that acted as the reward for lever pressing during training had a greater impact on performance than devaluing the freely delivered pellets. This result would be expected if the motivational properties of rewards are mediated by their instrumental relation to the action. In fact, this is just what Adams and Dickinson found: when subsequently given access to the lever again, the devaluation group pressed significantly less than the control group. Note that this test was conducted in extinction, during which neither type of pellet was presented, for if the pellets had been presented during testing, the reluctance of the devaluation group to press the lever could be explained simply in terms of the direct suppressive effect of presenting this aversive consequence. By testing in extinction, however, different performance in the two groups must have reflected integration of knowledge of the consequences of lever pressing acquired during training with the current reward value of the pellets. This suggestion was further confirmed by Colwill and Rescorla (1986) using a choice test. They trained hungry rats to perform two instrumental actions, lever pressing and chain pulling, with one action earning access to food pellets and the other earning access to a sucrose solution. The rats were then given several trials in which they were allowed to consume one of the outcomes with the levers and chains

withdrawn and were then made ill by an injection of LiCl. All animals were then given a choice extinction test on the levers and chains again conducted in extinction, i.e., in the absence of either of the outcomes. Although S–R accounts should predict no effect of this treatment, Colwill and Rescorla found that animals performed less of the action whose training outcome was subsequently paired with LiCl than the other action, indicating that the rats had indeed encoded the consequences of their actions.

The importance of these demonstrations of the outcome devaluation effect lies in the fact that, together, they provide strong evidence that animals encode the specific features of the consequences or outcome of their instrumental actions. Furthermore, these studies show that instrumental performance is not only determined by the encoding of the action–outcome relation but also by the current reward value of the outcome. In recent years, considerable attention has been paid to the processes that contribute to the encoding of reward value, and the advances that have been made have come largely from asking how outcome devaluation works to change instrumental performance: How does taste aversion work to modify the rats' evaluation of the outcome and so change the course of its instrumental performance?

1.36.2.3 Incentive Learning and the Encoding of Reward Value

Perhaps the simplest account of the way taste aversion learning works to devalue the instrumental outcome can be derived from accounts of aversive conditioning generally according to which pairing the instrumental outcome with illness changes the evaluation of the outcome through the formation of a predictive association between the food or fluid and the aversive state induced by illness. The result of an effective pairing of the outcome with illness is, therefore, that the animal learns that the outcome now signals that aversive consequence. From this perspective, the outcome devaluation effect is the product of a practical inference process through which a previously encoded action–outcome relation is combined with learning that the outcome signals an aversive consequence to reduce subsequent performance of the action.

In contrast, Garcia (1989) introduced a more complex account according to which the change in the evaluation of the outcome induced by taste aversion learning is not due to changing what the outcome predicts but due to changes in how it tastes. Garcia related the change in taste to negative feedback from a system sensitive to illness that he identified as inducing a disgust or distaste reaction. It is important to see that this view implies that taste aversion learning involves not one learning process but two: (1) an effective pairing of the outcome with illness initially enables a connection between the sensory properties of the outcome and processes sensitive to illness; (2) this association is activated when the outcome is subsequently contacted to generate a distaste reaction and allow the animal to associate the outcome representation with disgust or distaste. This account predicts that, to induce outcome devaluation, it is not sufficient merely to pair the outcome with an injection of LiCl. Rather, a change in value is not induced until the second process is engaged when the outcome is again contacted.

The procedures employed to induce instrumental outcome devaluation, such as that described by Adams and Dickinson (1981), do not differentiate between these two accounts of taste aversion learning because the conditioning of an aversion to the outcome is usually conducted using multiple pairings of the outcome with illness. Clearly the pairings themselves would be sufficient to establish a signaling relation between the outcome and an aversive consequence. But the fact that the animals were allowed to contact the outcome on subsequent pairings could have provided the opportunity for the animals to associate the outcome representation with distaste. If a substantial aversion to the outcome could be conditioned with a single pairing of the outcome with illness, however, then these accounts of outcome devaluation make divergent predictions: On the signaling account, a devaluation effect should emerge, providing that an effective pairing between the taste and illness was produced; on Garcia's (1989) account it should not emerge until the rats have been reexposed to the devalued outcome. In a test of these divergent predictions, Balleine and Dickinson (1991) trained thirsty rats to lever press for water. After acquisition, the outcome was switched to sugar solution for a single session, after which the rats were given an injection of LiCl either immediately or after a delay (the latter treatment, as an unpaired control, should have induced relatively little aversion to the sucrose on either account). The critical question was whether, in the absence of further contact with the sucrose, the rats in the immediately poisoned group

would display reduced performance on the lever relative to the delayed group.

To assess the influence of reexposure to the sucrose, half of each of the immediate and delayed groups were allowed merely to taste the sucrose, whereas the remainder were given water before two tests were conducted on the levers. The first test was conducted in extinction to assess the effects of devaluation and reexposure on the tendency to press. A second, punishment test was then conducted in which responding on the lever again delivered the sucrose, which allowed us to assess the strength of the aversion to sucrose. If a substantial aversion to the sucrose was conditioned in the immediately poisoned groups, then not only should a reliable punishment effect have emerged in the second test, but, on the signaling account, responding should also have been reduced in the extinction test in all of the immediately poisoned rats. In contrast, in Garcia's account, responding in the extinction test should be reduced in those immediately poisoned rats given reexposure to the sucrose. In fact, in this and in several other experiments along similar lines, Balleine and Dickinson (1991) and Balleine (1992) found consistent evidence for Garcia's account; although a single pairing between sucrose and illness invariably produced a reliable punishment effect in immediately poisoned rats, a devaluation effect only emerged in the critical extinction test if reexposure to the sucrose was given prior to the test.

These results suggest that outcome devaluation depends upon the interaction of two learning processes. The first process involves the conditioning of an association between the outcome and processes that are activated by the induction of illness by LiCl. The failure of this learning process to directly affect instrumental performance suggests that it is not, alone, sufficient to induce outcome devaluation. Rather, it appears to be necessary for feedback from this first learning process to become explicitly associated with the specific sensory features of the outcome itself for a change in the reward value of the instrumental outcome to occur and for performance to change. Indeed, considerable evidence now suggests that this second learning process critically determines the encoding of the rewarding properties of the instrumental outcome, a process referred to as incentive learning (Dickinson and Balleine, 1994, 1995).

The reason for emphasizing the role of incentive learning in instrumental outcome-devaluation effects is that it also appears to be the process by which other primary motivational states, such as hunger and thirst, encode the reward value of other goals such as foods and fluids. It is well established that the motivational state of rats is a major determinant of their instrumental performance; not surprisingly, hungry animals work more vigorously for a food reward than sated ones. But what current evidence suggests is that this is because a food-deprived state induces an animal to assign a higher incentive value to nutritive outcomes when they are contacted in that state and that this high rating of the incentive value of the outcome is then reflected in a more vigorous rate of performance. Although this suggestion stands contrary to general drive theories of motivation that suppose that increments in motivation elicit their effects on performance by increases in general activation (Hull, 1943), there are good empirical grounds for arguing that motivational states do not directly control performance (Dickinson and Balleine, 1994, 2002; Balleine, 2001). Balleine (1992) trained groups of undeprived rats to lever press for a food reward. After training, half of the rats were shifted to a food deprivation schedule, whereas the remainder were maintained undeprived before both groups were given an extinction test on the levers. Balleine found that performance of the groups on test did not differ even though the shift in motivational state was clearly effective. In a subsequent test where the animals could again earn the food pellets, the food-deprived rats pressed at a substantially higher rate than the undeprived rats. Although motivational state clearly did not exert any direct control over performance, as was found in taste aversion conditioning, the motivational state could control performance if the rats were given the opportunity for incentive learning by allowing them consummatory contact with the instrumental outcome in the test motivational state prior to the test. To demonstrate this, Balleine (1992) trained two further groups of rats to lever press when undeprived. Both groups were given prior exposure to the instrumental outcome when food-deprived before the test in which one group was tested undeprived and the other food-deprived. Now a clear difference in performance was found in that the rats tested when food-deprived and allowed to consume the instrumental outcome when food-deprived prior to test pressed at a higher rate than the other three groups that in turn did not differ. Balleine (1992) was able to confirm that this incentive learning effect depended upon the instrumental contingency. He trained undeprived rats to perform two actions, lever pressing and chain pulling,

with one action earning access to food pellets and the other to a maltodextrin solution. All rats were then given a choice extinction test on the levers and chains. Prior to the test, however, the animals were given six sessions in which they were allowed to consume one instrumental outcome when food deprived and, on alternate days, the other outcome in the training, i.e., undeprived, state. On test, Balleine found that animals performed more of the action that, in training, had delivered the outcome reexposed in the food-deprived state prior to the test than the other action.

It should be noted that this role for incentive learning in instrumental performance following a shift in motivational state is not confined to posttraining increases in food deprivation. The same pattern of results was also found for the opposite shift, i.e., where rats were trained to lever press for food pellets when food-deprived and then tested when undeprived. In this case, rats only reduced their performance when food deprivation was reduced if they were allowed to consume the instrumental outcome when undeprived prior to the test (Balleine, 1992; Balleine and Dickinson, 1994). Finally, the generality of this role of incentive learning in instrumental performance has been confirmed for a number of different motivational systems and in a number of devaluation paradigms. For example, in addition to taste aversion learning, incentive learning has been found to mediate (1) specific satiety-induced outcome devaluation effects (Balleine and Dickinson, 1998b); (2) shifts from water deprivation to satiety (Lopez et al., 1992); (3) changes in outcome value mediated by drug states (Balleine et al., 1994, 1995a); and changes in the value of (4) thermoregulatory rewards (Hendersen and Graham, 1979) and (5) sexual rewards (Everitt and Stacey, 1987; Woodson and Balleine, 2002) (see Dickinson and Balleine, 1994, 2002; Balleine, 2001, for reviews). In all of these cases, it is clear that animals have to learn about changes in the incentive value of an instrumental outcome through consummatory contact with that outcome before this change will affect performance.

1.36.2.4 Incentive Learning as an Emotional Process

Traditional neobehaviorist learning theories argued that CRs, what were called fractional anticipatory goal responses, could exert a motivating effect on instrumental performance (Hull, 1943, 1952; Spence, 1956). Largely due to the subsequent work of Konorski (1967) and Mowrer (1960), however, it is now widely accepted that these effects reflect the conditioning of an affective state that can exert a direct modulatory influence over consummatory responses and, through a change in the emotional responses elicited during ingestion, on instrumental performance (Rescorla and Solomon, 1967; Dickinson, 1989). Recent research investigating the microstructure of orofacial taste reactivity responses in rats to various tastes has provided evidence, not only of specific ingestion and rejection responses to sweet and bitter tastes, but also that the ingestive taste reactivity responses are increased in hungry rats to tastes previously paired with nutrients (Myers and Sclafani, 2001). Likewise, rejection-related taste reactivity responses are increased to tastes previously paired with illness (Berridge et al., 1981). With respect to incentive learning, this approach suggests that, during this form of consummatory exposure, activation of the outcome representation activates its associated motivational system, which, through activation of attendant affective processes, generates feedback in the form of an emotional response. This process is illustrated in **Figure 1**. On this account, incentive learning depends on two processes: a feedback process: (**Figure 1 (a), (b)**) and a feedforward process (**Figure 1 (c)**). Presenting the instrumental outcome in some motivational state or other provides the opportunity for the formation of an association between the outcome representation and the motivation system (**Figure 1(a)**) that acts to open a feedback loop (**Figure 1(b)**). When the outcome is subsequently contacted, activation of the outcome representation acts to produce specific motivational activity that results directly in activity in affective structures productive of an emotional response. Incentive learning

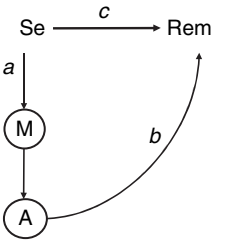

Figure 1 The structure of incentive learning. (a) Sensory features of the instrumental outcome (Se) are associated with a motivational process (M). (b) Through connections with affective structures (A) this connection provides feedback in the form of an emotional response (Rem). (c) Incentive learning reflects the association between Se and Rem based on their contiguous activity.

(Figure 1(c)), then, is the formation of a feedforward association between the outcome representation and an emotional response.

Taste aversion-induced outcome devaluation effects provide a good example of this process. In this case, this perspective argues that a taste is first associated with activation of a disgust system induced by LiCl. After this pairing, reexposure to the taste can drive the disgust system to activate the aversive affective system to generate an aversive emotional response. It is the contiguous pairing of the taste and the emotional response that, from this perspective, drives the reduction in reward value induced by reexposure. Notice that, if pairing a taste with illness conditions an association between the taste and disgust, then blocking the activity of the disgust system at the time of conditioning using an antiemetic, i.e., a drug that prevents or relieves illness or nausea, should be predicted to attenuate the formation of that association with the effect that, in the test sessions, rats should prefer a taste poisoned under the antiemetic to some other poisoned taste. But furthermore, if the expression of a previously conditioned aversion, and the consequent change in reward value, depends upon the ability of the taste representation to access the disgust system via an established connection, blocking the activity of the disgust system with an antiemetic during reexposure should be predicted to block the incentive learning effect; see Figure 2.

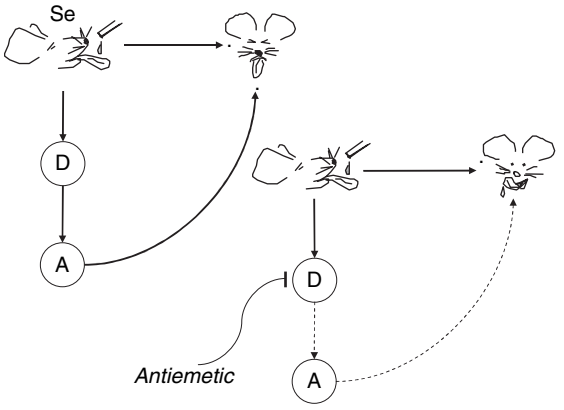

Figure 2 Incentive learning and taste aversion-induced outcome devaluation. The left panel shows the effect of reexposure to a poisoned outcome; the association between the taste (Se) and disgust (D) induced by pairing the taste with illness provokes feedback in the form of a disgust response, allowing the rat to learn about the change in value of the outcome. The right panel shows the predicted effect of an antiemetic on incentive learning. By blocking activity in the disgust system, the antiemetic should reduce the unpleasant emotional feedback and hence the change in value produced during reexposure to the taste. A, affective structures.

In accord with this suggestion, Limebeer and Parker (2000) reported that the antiemetic ondansetron blocked the expression of the aversive taste reactivity responses induced by a taste previously paired with illness. Furthermore, we have assessed this prediction by assessing the influence of ondansetron on reexposure to a poisoned taste on instrumental choice performance (Balleine et al., 1995b). In this experiment, thirsty rats were trained in a single session to perform two actions, lever pressing and chain pulling, with one action delivering a sucrose solution and the other a saline solution on a concurrent schedule. Immediately after this training session, all of the rats were given an injection of LiCl. Over the next 2 days the rats were given brief periods of reexposure to both the sucrose and the saline solutions. Prior to one reexposure session, rats were injected with ondansetron in an attempt to block the emotional effects of reexposure, whereas prior to the other session they were injected with vehicle. The next day, the rats were given a choice extinction test on the lever and chain. If reexposure devalues the instrumental outcome via the ability of the outcome representation to access the disgust system, blocking the activity of that system with ondansetron should attenuate the effects of reexposure such that, on test, the action that, in training, delivered the outcome subsequently reexposed under ondansetron should be performed more than the other action. This is, in fact, exactly what was found (Balleine et al, 1995a). The attenuation of incentive learning by ondansetron provides, therefore, strong confirmation of the suggestion that incentive learning depends critically upon negative feedback generated by an association between the outcome representation and a disgust system.

1.36.2.5 Retrieving Reward Value

Given the role of incentive learning in the encoding of reward, it is interesting to consider how the value conferred by this process is retrieved to determine choice performance. Because the choice tests are often conducted many days after incentive learning, in extinction the rat is forced to rely on their memory of specific action–outcome associations and the current relative value of the instrumental outcomes. So how is value encoded for retrieval during this test?

A currently influential theory, the somatic marker hypothesis (Damasio, 1994), proposes that value is retrieved through the operation of the same processes through which it was encoded. According to this view, decisions based on the value of specific goals are determined by reexperiencing the emotional effects associated with contact with that goal. With regard to outcome devaluation effects, for example, the theory could not be more explicit:

> When a bad outcome connected with a given response option comes to mind, however fleetingly, you experience an unpleasant gut feeling . . . that forces attention on the negative outcome to which the given action may lead, and functions as an automated alarm signal which says: Beware of danger ahead if you choose the option that leads to this outcome. The signal may lead you to reject, *immediately*, the negative course of action and thus make you choose between other alternatives (Damasio, 1994: 173).

An alternative theory proposes that reward values, once determined through incentive learning, are encoded abstractly (e.g., X is good or Y is bad and so on) and, as such, from this perspective they are not dependent on the original emotional effects induced by contact with the goal during the encoding of incentive value for their retrieval (see Balleine and Dickinson, 1998a; Balleine, 2005, for further discussion).

We have conducted several distinct series of experiments to test these two hypotheses and, in all of these, the data suggest that after incentive learning, incentive values are encoded abstractly and do not involve the original emotional processes that established those values during their retrieval (Balleine and Dickinson, 1994; Balleine et al., 1994, 1995a,b). One test of these two accounts was derived from consideration of the role of associations between the outcome representation and the disgust system in outcome devaluation described in the previous section. If the impact of outcome devaluation on performance is carried by emotional feedback induced by activation of the disgust system by the outcome representation, then, according to the somatic marker hypothesis, reducing the ability of the outcome representation to activate the disgust system during retrieval of incentive value on test by administering ondansetron prior to the test should be predicted to attenuate the effects of outcome devaluation on performance. This experiment replicated the procedures used in the experiment described earlier (Balleine et al., 1995b) except that, prior to the choice extinction test, half of the animals were injected with ondansetron, whereas the remainder were injected with vehicle. Based on the previous study, it was anticipated that the group given the injection of vehicle prior to the test would perform more of the action that, in training, had delivered the outcome reexposed under ondansetron. More importantly, if activation of the disgust system critically mediates the retrieval of incentive value during the test, as the somatic marker hypothesis suggests, then any difference found in the vehicle group should be attenuated in the group injected with ondansetron on test.

The results of this experiment were very clear; contrary to predictions of the somatic marker hypothesis, the injection of ondansetron on test had no impact whatsoever on performance in the choice extinction test. Whether injected with vehicle or ondansetron prior to the test, the action that, in training, delivered the outcome reexposed under ondansetron was performed more than the other action and to a similar degree. This finding suggests that, although activity in the disgust system determines the effects of incentive learning, the disgust system does not play a role once incentive learning has occurred, i.e., the retrieval of incentive value is not based on the same process through which it was encoded. In line with the proposal that reward value is encoded abstractly or symbolically and in contradiction to predictions from the somatic marker hypothesis position, in this and other similar studies we have found that the processes that determine the encoding of reward value are not required during the retrieval of that value during free choice tests in order for animals to select a course of action.

1.36.3 Secondary Reward

The suggestion that the reward process supporting instrumental conditioning is derived from an association between the sensory features of an event and an emotional response, together with the evidence for the abstract encoding of reward value, provides an immediate explanation as to how events not directly associated with primary motivational systems can serve as the goals of instrumental actions; from this perspective, any stimulus associated with an emotional response should be able to serve as a goal and so support the performance of goal-directed actions. In the past, the seemingly arbitrary nature of goals has been explained in terms of a process called

conditioned reinforcement (Skinner, 1938). Within that literature, this process was proposed as the means by which arbitrary things, like colored pieces of paper, could serve as reinforcers supporting the development of new response tendencies through the acquisition of various stimulus-response associations. It is our view that the term conditioned reinforcement is a misnomer; it implies that the actions that they support are no more than habits. Of course, most human actions are acquired and maintained by goals that are associated with primary rewards and so have only an indirect connection to primary motivational systems and as such are more likely to be goal-directed actions than habits. We propose that the process that determines the acquisition of these goals be referred to, therefore, as secondary reward (SdR). Nevertheless, it is clear that the goal-directed status of these actions is something that stands in need of direct assessment.

There is, in addition, a further implication of this account. Although one should anticipate that secondary rewards will be the more potent, what this account of incentive learning portends is that, if the emotional response associated with an event determines whether it can serve as a goal, essentially any event can serve as the goal of an action providing it induces a positive change in emotional tone. In this section we describe research indicating that both stimuli associated with already established rewards and salient sensory events can serve as goals, allowing animals to acquire new responses based on the relationship of actions to these, sometimes weakly but nevertheless apparently rewarding, consequences.

1.36.3.1 Sensory Versus Secondary Reward

As mentioned, the older literature dealing with the phenomenon of conditioned reinforcement proposed that when neutral stimuli were associated with reinforcing ones, they could become conditioned reinforcers. A problem widely neglected within this literature, however, is the fact that apparently neutral stimuli turn out to be very difficult to come by. Indeed, the vast majority of experimentally utilized stimuli are demonstrably not neutral with respect to their ability to support instrumental responding even prior to any pairing with primary reward (Kish, 1966). The capacity of environmental stimuli, or more correctly, of change in the state of environmental stimuli to support instrumental behavior can, however, be well enough handled by the current claim that reward value is controlled by the emotional response associated with that event providing it is accepted that change in environmental stimuli provides a sufficiently positive change in that response. From this perspective, therefore, events that are sufficiently mild to induce a positive change provide a source of sensory reward (SeR), whether it is derived from generalization or perhaps by another source of motivation, such as a form of preparatory state produced by general affective arousal (Konorski, 1967) or perhaps, as has occasionally been proposed in the past, by a primary motivational process such as curiosity (Berlyne, 1960).

In order to use secondary reward as a tool to establish the way apparently arbitrary events can become the goals of instrumental action, it is important first to compare the influence of secondary and sensory rewards on the performance of actions. The question is, which secondary reward procedure should one employ to do so? The central position of this notion in Hull's conception of learning (Hull, 1943) and Skinner's utilization of it to explain the origin of human actions without apparent reinforcement (Skinner, 1938) drove considerable research during the middle part of the last century intended to establish or to disprove its applicability to the conditioning process. The most commonly used procedure to analyze SdR has been in chain schedules of instrumental reinforcement, where both instrumental training with the SdR and the pairing of the event with reward presumed to support that conditioned reinforcer occurred within a common sequence of behavior. Zimmerman (1969), for instance, gave rats the opportunity to press one lever in order to obtain the presentation of a stimulus light on a fixed interval. Once that stimulus was presented, a response on a second lever would result in the delivery of food. The stimulus light, via its forward pairings with the food, should have accrued associative strength over the course of performance. Because, however, responding on the first component of the chain also activated the second manipulandum in the chain, it is difficult to assert that the animal was responding for the stimulus rather than the opportunity to respond on that second manipulandum. Chain schedules, therefore, typically require some further intervention in order to partition the sources of support for instrumental responding. In this case, Zimmerman took advantage of the fact that the pattern of responding on fixed interval and variable interval schedules differs to assess whether the light was controlling performance on the first lever as a secondary reward.

To do this, he put the rewarding impacts of the light and food into competition with each other on the first lever. In a test phase, the light was presented as a result of responding on the first lever on a variable interval schedule, whereas the food was presented on the fixed interval schedule that had previously delivered the light and the second lever was shifted to an extinction schedule. Zimmerman found that the pattern of responding on the first lever shifted from that typical of a fixed interval schedule to that typical of a variable interval schedule, a finding consistent with the development of conditioned reinforcing properties by the stimulus light.

Although commonly employed, the difficulty of ruling out alternative interpretations of the source of instrumental performance on chain schedules leaves something to be desired. Since the second response, as in Zimmerman's study (1969), often becomes superfluous in the critical phase testing for the presence of SdR, it follows that it may not be necessary at all. Extinction studies of SdR reify this possibility, by utilizing a training phase where an instrumental action is paired with a stimulus that is immediately followed by the delivery of a reward. Because of the presence of the reward during training, the second, third, and higher components of the instrumental chain used to provide further conditioned stimuli and eventual primary reinforcement in chain studies of SdR are eliminated from the outset. A test phase is again required to detect the role of the SdR in the maintenance of that instrumental behavior. If the SdR plays no role in the maintenance of instrumental responding, then with or without its presence at an extinction test phase, animals should extinguish at the same rate. Instead, researchers usually find that animals extinguish much more slowly when the instrumental response leads to the delivery of the putative conditioned reinforcer than when it leads to no stimulus consequences (Bugelski, 1938).

Although these studies appear to confirm the basic effect, the most direct way to demonstrate and compare the secondary or sensory reward value of some event or other is to assess its ability to serve as the goal during the acquisition of a new action. If stimuli acquire the ability to reward instrumental actions in the course of pairing them with a primary reward, then it follows that one should be able to demonstrate the acquisition of instrumental actions that have as their sole outcome the delivery of a stimulus with a history of this pairing. This logic has been frequently employed in the detection of SdR, and procedures employing it have generally been referred to as acquisition of a new response, or simply, acquisition tests of SdR. Especially attractive is the absence of confounding effects of primary reward during training that could interfere with SdR interpretations of instrumental behaviors (Wike, 1966). Numerous experiments along these lines have been conducted by giving prior stimulus–outcome associations followed by training on a lever that delivers that stimulus. Work by Trevor Robbins and colleagues has demonstrated particularly clear acquisition of lever-press performance when that lever delivered a stimulus that was previously associated with food relative to an inactive lever that the rats could press but that had no scheduled consequences (Taylor and Robbins, 1984; Robbins et al., 1989).

We have conducted a similar experiment to those of Robbins using two different versions of their procedure, firstly to replicate their basic result but also to examine the effects of using a different control condition in which one lever delivered a stimulus that had previously been paired with food and the other lever delivered a familiar stimulus but that had not been paired with any rewarding consequence; a sensory reinforcement control (SeR). The results of this study are presented in **Figure 3**. As is clear from this figure, a good conditioned reinforcement effect was observed in both conditions: responding on the lever delivering the SdR was greater than on the inactive lever (left panel) and greater on the lever delivering the SdR than on the lever delivering the SeR. It is also clear, however, that the net size of the SdR effect is really much smaller than one might be led to believe from the difference between the active and inactive levers.

1.36.3.2 Do Secondary Rewards Reward, Reinstate, or Reinforce?

Describing events associated with primary reward as SdRs suggests that the responses that animals learn to gain access to SdRs are goal-directed. This is, however, a matter of dispute. It has often been argued in the past that, rather than developing reward value, the stimulus acquires the ability to drive instrumental responding in an S–R fashion, i.e., rather than acting as a goal in and of itself, it acts to reinforce the connection between situational cues and the response. That the conditioned reinforcing stimulus itself might not be the object of an instrumental action, but rather an elicitor of that action, is an explanation that has seen some theoretical and experimental exploration. Bugelski (1956), for instance, reinterpreted his

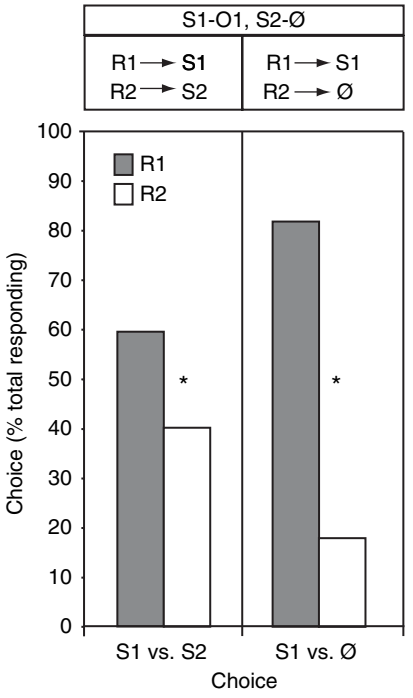

Figure 3 An assessment of secondary reward conducted in a choice test on two levers. Rats were first given pairings between one stimulus (S1) and a rewarding outcome (O1), whereas another stimulus was presented unpaired (S2). Some rats were then allowed to press two levers. In one group, one lever delivered S1 and the other S2 (left panel) in the other group, one lever delivered S1 and the other nothing (Ø). It is clear that both tasks revealed a secondary rewarding effect of S1 on performance. However, the effect is somewhat exaggerated by the choice between S1 and Ø. When sensory reward is taken into consideration, as it is in the choice between S1 and S2, the net secondary reward effect is significantly smaller.

earlier extinction test-conditioned reinforcement data (Bugelski, 1938) using this framework and found that it provided a satisfactory account of the results. During acquisition training, the SdR not only follows the instrumental response as a consequence, but on all trials except the first bears a forward predictive relationship with later occurrences of that response. It is at least possible that during acquisition the instrumental action is reinforced solely by the primary reinforcer, whereas the SdR becomes associated with the response itself. In extinction, it is argued, the conditioned reinforcer then acts, following the first response, to delay extinction through this conditioned ability to evoke or reinstate subsequent instrumental responses.

Wyckoff (1959) attempted to produce a quantitative model of SdR effects emphasizing the eliciting function, or cue properties, of the conditioned reinforcer. This model was based on the results of an experiment reported by Wyckoff et al. (1958) in which rats were given conditioning trials where a buzzer was followed by the delivery of water. Following this training, experimental rats were given the opportunity to press a lever in order to secure the delivery of the buzzer without water, and control rats were placed on an omission schedule, where the buzzer was delivered if they refrained from pressing the lever. Performance between the two groups was not reliably different, which led Wyckoff et al. to conclude that the buzzer functioned primarily not to reward lever pressing, in which case the experimental group should have pressed significantly more than the control animals, but to elicit lever pressing. This result, however, has not been replicated, suggesting that some feature of the experimental design, or a simple lack of power, prevented Wyckoff et al. from observing cue-independent conditioned reinforcing effects. Indeed, Ward (1960) conducted a formally very similar experiment, substituting food reward for water and the random delivery of the cue in the control group for the omission schedule, and demonstrated a reliably greater level of responding in experimental animals than in control animals.

An important source of evidence against the response elicitation account of SdR effects comes from an experimental series performed by Crowder and his colleagues. They employed a yoked control procedure in several different paradigms to demonstrate the existence of secondary reward above and beyond the effects of stimulus-based response elicitation. In all experiments, the experimental animals performed an instrumental action that was followed by the delivery of SdR. At the same time as that delivery, the yoked controls received noncontingent presentation of that same stimulus. If the stimulus elicited or reinstated further responding, it should have done so equally in both groups. Instead, in the extinction test paradigm (Crowder et al., 1959a), the acquisition of a new response paradigm (Crowder et al., 1959b), and in reacquisition (Crowder et al., 1959c) and retention SdR paradigms (Crowder et al., 1959d), they found superior performance in the experimental subjects whose actions were correlated with the delivery of the SdR. Although these results are not completely immune to criticism derived from the analysis of systematic sources of error in the

yoked group (Church, 1964), they indicate the relatively small degree of support that elicitation or reinstatement accounts provide for instrumental responding in SdR paradigms.

One published study has attempted to assess whether lever pressing for the SdR is goal-directed by devaluing the primary reward previously associated with the SdR (Parkinson et al., 2005). In this study rats were given pairings of a light stimulus paired with sugar after which the sugar was paired with illness. Although this reduced responding to the sucrose, it did not affect the ability of the light to serve as a secondary reward for lever pressing; lever pressing was acquired and maintained to a comparable degree whether the sucrose had been devalued or not. The authors concluded that, as the lever pressing appeared to be independent of the value of the primary reward, performance acquired through SdR should be considered habitual. But what was not confirmed in this study, however, was whether the devaluation of the sucrose was successful in modifying the reward value of the light. Indeed, as the SdR value depends on the association of the light with the emotional response elicited by the sucrose, rather than by the sucrose itself (see **Figure 4**), it seems unlikely that SdR could be undermined in this way. Rather, what this account predicts is that devaluation of the SdR could only be induced by counterconditioning, i.e., pairing the light previously paired with sucrose with a noxious consequence, such as foot shock. Would lever pressing still have been maintained after this treatment? To date no studies along these lines have been conducted, although there is plenty of evidence from studies of conditioned punishment to conclude that at least the sensory

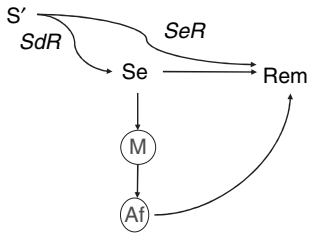

Figure 4 Sensory reward (SeR) is derived from the emotional effects (Rem) of stimulus change that can be produced by the presentation of even quite neutral stimuli (such as S′). Secondary reward (SdR) is derived from the pairing of S′ with an excitatory sensory event (Se in this diagram) previously established as a primary reward and through its association with an emotional response generated by its connection with both motivational (M) and affective (Af) processes (see **Figure 1**).

rewarding component of stimuli is abolished by this means of devaluation (Killcross et al., 1997).

Other studies from our laboratory have, however, confirmed that actions acquired for a secondary reward are essentially goal-directed. As discussed with respect to primary reward, one of the criteria for defining an action as goal-directed is that it is sensitive to the causal relationship between the action and reward. In this experiment, rats were first given pairings between two distinct visual cues with one cue paired with sucrose and the other with food pellets. After this training, the rats were trained to press two levers, each associated with a different visual cue. In these sessions, one of the visual cues was also presented noncontingently; as such the noncontingent cue was the same as that presented contingent on pressing one lever but different from that presented for pressing the other lever. As such the specific R-SdR contingency was maintained on one lever but was degraded on the other. The results of this study are presented in **Figure 5**. As is clear from this figure, the rats were sensitive to the specific lever press–SdR contingency, reducing performance on the action delivering the same SdR as that delivered noncontingently relative to the other action. This result is not consistent with either the reinforcing or reinstating functions of SdRs (Winterbauer, 2006).

An important aspect of the establishment of a secondary reward is its pairing with primary reward. The procedures that establish SdRs are, in fact, identical to those used to establish Pavlovian CRs to a stimulus. The possibility that stimuli require something more than Pavlovian conditioning to become conditioned reinforcers has been entertained; Skinner (1938) proposed, for example, in a thesis later considered in detail in the work of Keller and Schoenfeld (1950), that only stimuli that act to set the occasion for responding to other Pavlovian stimuli could serve as SdRs. Again, as Wike (1966) suggested, although occasion setters may make better SdRs, there seems to be no requirement that all conditioned reinforcers be occasion setters. Work in our laboratory has largely confirmed this view, in that we show perfectly reasonable SdR effects without special modifications to the Pavlovian conditioning phase (Winterbauer, 2006). But this raises an important issue: if SdR can be established using Pavlovian procedures, are the processes underlying reward and those underlying Pavlovian incentive motivation all one and the same? Or is this no more than a superficial, procedural similarity?

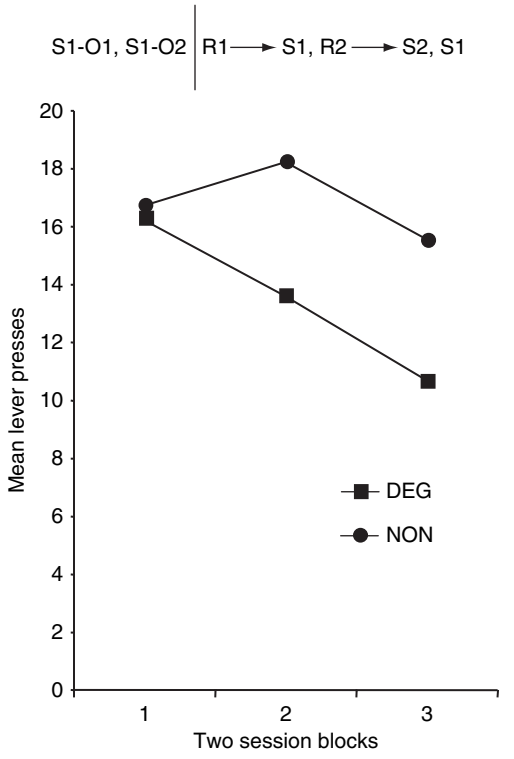

Figure 5 Contingency degradation in instrumental conditioning using secondary rewards. After establishing two stimuli (S1 and S2) as secondary rewards by pairing them with primary rewards, rats were trained to perform two lever-press responses (R1 and R2) with one earning S1 and the other S2. Noncontiguous presentations of one secondary reward (e.g., S1) degraded the response–outcome contingency (DEG) and caused a significant reduction in responding on the lever delivering S1 (DEG) relative to that delivering S2 (NON).

1.36.4 Reward and the Anticipation of Reward

The preceding sections have reviewed the considerable evidence suggesting that the influence of changes in reward value on goal-directed instrumental actions is an important determinant of action selection and of instrumental performance generally. Other factors can clearly influence performance, however. One of the most obvious, and perhaps best-documented, influences on action selection is that produced by stimuli 'associated' with reward. Advertising has a clear influence on action selection; if it did not the advertising industry would be a vacuous waste of time and of advertisers' money. Of course, advertisers are hoping that the stimuli that they associate with a particular product will provide the basis for quite specific changes in choice performance and, of course, by and large they do. It is important to recognize, however, that, despite a superficial similarity in some of the procedures used to establish the reward value of particular events, notably SdRs, there is substantial evidence suggesting that the influence of cues associated with reward on goal-directed instrumental actions is not mediated by the reward system. In this section, we describe this evidence as it has emerged from analyses of the relationship between Pavlovian and instrumental conditioning, particularly those proposing that the motivational processes engaged by reward and by the anticipation of reward are the same or, at the very least, interact with one another.

1.36.4.1 Pavlovian-Instrumental Interactions

In fact, some of the earliest evidence that the representation of the instrumental outcome takes part in action selection was found by studying how Pavlovian and instrumental learning processes interact. For instance, Trapold (1970) trained rats on a biconditional discrimination in which, on any given trial, subjects were allowed to choose between two actions (left and right lever press). Trials were initiated by the presentation of one of two discriminative stimuli (tone and clicker), signaling which of the actions would be rewarded (e.g., S1 → R1 and S2 → R2). The novel feature of this experiment, however, was that these cues also signaled the identity of the outcome that could be earned on that trial. Whereas the control groups earned either food pellets (food control) or sucrose solution (sucrose control) on both actions (e.g., S1 → R1 → O1 and S2 → R1 → O1), the experimental group was rewarded with one outcome (O1; e.g., pellets) for performing one action and a different outcome (O2; e.g., sucrose) for performing the other action (e.g., S1 → R1 → O1 and S2 → R2 → O2). Consequently, the experimental group differed from the control groups in that, for the former, each discriminative stimulus signaled not only a different response but also a different outcome. Interestingly, Trapold (1970) found that the experimental group acquired more rapidly than either control group despite the fact that the S–R arrangements needed to solve the discrimination were the same across conditions.

This phenomenon, known as the differential outcomes effect, provides clear evidence that reward expectations can be used to guide action selection.

Moreover, the representation mediating this effect appears to consist of richly detailed information about the sensory properties of the reward. In Trapold's (1970) study, the sucrose solution and grain-based pellets used to differentially reward the two actions were both nutritive outcomes and so should have held a similar incentive value for hungry rats. Since this motivational variable does not appear to have been used to discriminate between actions, rats probably relied instead on the sensory features (e.g., texture, odor, taste) of the anticipated outcome. There is even evidence that this effect can be obtained using outcomes that differ in one motivationally irrelevant sensory feature. Fedorchak and Bolles (1986) trained thirsty rats on a biconditional lever press discrimination task in which each correct response was rewarded with water. For two groups, the delivery of water was occasionally paired with a flashing light; whereas the light exclusively followed just one of the two S–R arrangements in the differential outcomes group, it followed both responses with an equal probability in the nondifferential control group. For a third group, the light was never paired with water. Once again, the group that received differential outcomes acquired more rapidly than the other two groups, demonstrating that the expectancy of a sensory event extraneous to outcome itself could be used to guide action selection.

How does differential outcomes training provide an advantage in discriminating between two actions? Clearly, it must have something to do with the Pavlovian contingencies embedded in the task (see **Figure 6**, top panel). It has long been argued that Pavlovian learning plays an important role in the control of instrumental performance (Rescorla and Solomon, 1967). Although we will discuss alternative accounts shortly, let us first consider the model Trapold and Overmier (1972) devised to explain the differential outcomes effect and similar findings (see **Figure 6**, middle panel). Their model was built within the general framework of traditional S–R theory (Hull, 1943), and so instrumental learning was assumed to involve the gradual recruitment of S–R associations through a conventional reinforcement process. However, Trapold and Overmier (1972) proposed that reward deliveries engage a second, Pavlovian learning process capable of supporting the acquisition of stimulus–reward associations. It was argued that through such learning, stimuli acquired the capacity to elicit a reward expectancy comprising the sensory features of that event. The final step in their argument was in allowing this reward

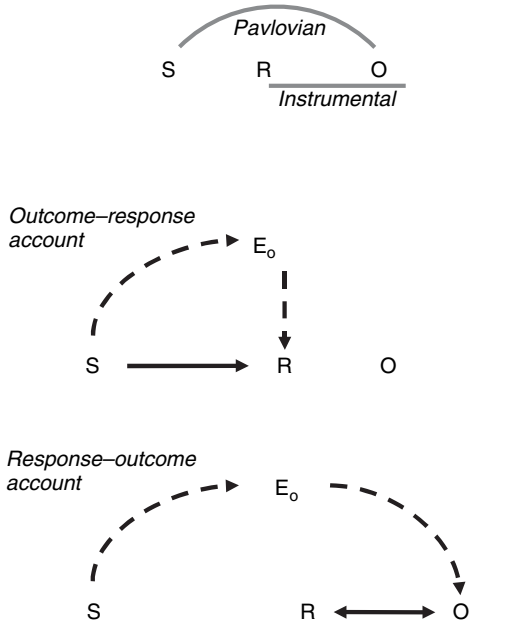

Figure 6 Schematic diagrams illustrating the associative structure proposed to underlie instrumental conditioning on various accounts. As shown in the top panel, the introduction of an instrumental (R–O) contingency is typically accompanied by an imbedded Pavlovian (S–O) contingency, arising from incidental pairings between contextual cues and reward. Two-process accounts of action selection have proposed that Pavlovian learning results in the generation of an outcome expectancy (E_o), which may guide performance by entering into association with the instrumental response (middle panel), or by retrieving any response that had earned the expected outcome (bottom panel).

expectancy to enter into S–R associations like any other sensorial event in the training environment, i.e., the expectation of reward was assumed to acquire discriminative control over performance. According to this analysis, the experimental group in Trapold's (1970) study was provided with an additional source of stimulus support for action selection; the correct choice was signaled by both an auditory cue and an expectation of the reward that could be earned on that trial.

The differential outcomes effect provides strong evidence that the Pavlovian learning can influence instrumental performance through a highly specific representation of the mediating outcome. Further evidence for this claim comes from studies of the so-called Pavlovian-instrumental transfer effect. For instance, Kruse et al. (1983) first trained rats using a biconditional procedure quite similar to that used in differential outcomes studies (e.g., Trapold, 1970;

Fedorchak and Bolles, 1986), such that each stimulus (clicker and tone) signaled both the response (left or right lever) that would be rewarded and the identity of its outcome (pellets or sucrose solution). During a separate Pavlovian training phase, the group of interest to our current discussion received pairings between a stimulus (pause in the background white noise) and one of the two outcomes (either pellets or sucrose). In a subsequent test phase, Kruse et al. (1983) found that presentations of this stimulus facilitated instrumental performance in an outcome-dependent manner; rats preferentially increased their performance of the action that had shared a common outcome with that cue, relative to the other action. Importantly, this test was conducted in extinction, indicating that this effect relied entirely on information acquired during earlier training phases.

Following Kruse et al. (1983), there have been numerous demonstrations of outcome-specific transfer (Colwill and Rescorla, 1988), even using actions that had been acquired through free operant training (Colwill and Motzkin, 1994; Delamater, 1995; Holland, 2004). The latter finding is important because it reveals that Pavlovian learning can influence action selection even under conditions in which anticipating reward provides no obvious advantage in obtaining reward. According to Trapold and Overmier (1972), the transfer effect emerges because the Pavlovian outcome expectancy selectively retrieves the response it signaled during training through the activation of an outcome–response association (see **Figure 6**, top panel). This account applies equally well to the free operant situation. Note that in any instrumental conditioning study there exists an embedded Pavlovian relationship between contextual cues and the reward delivery. In this case, cues that best predict reward should come to elicit an expectancy of reward capable of entering into association with the response.

Of course, the two-process account of Trapold and Overmier (1972) does not provide the only explanation for the influence of Pavlovian reward expectancies over instrumental performance. For instance, several two-process theories have been proposed that assume instrumental learning involves encoding some approximation of the action–outcome contingency arranged by the experimenter (Bolles, 1972; Asratyan, 1974). According to this view, Pavlovian outcome expectancies guide action selection by retrieving the action that had actually earned that outcome during training (see **Figure 6**, bottom panel).

1.36.4.2 The Two-Process Account of Reward Value

How is Pavlovian-instrumental transfer relevant to our interpretation of instrumental performance as an instance of goal-directed action? Recall that in order to be considered goal-directed, a behavior must be performed because of its expected consequences; performance should depend on the subject's capacity to (1) anticipate the outcome of the action (i.e., action–outcome learning) and (2) evaluate the incentive properties of that outcome (i.e., incentive learning). Two-process theories, however, tend to attribute incentive effects, such as the sensitivity of instrumental performance to outcome devaluation, to the Pavlovian process (Rescorla and Solomon, 1967). These accounts typically assume that Pavlovian learning provides the motivational support for instrumental performance. Even Trapold and Overmier (1972), who took an expressly associative approach, entertained the possibility that incentive manipulations have their effect by disrupting the capacity of the Pavlovian outcome expectancy to mediate response selection (e.g., through generalization decrement). Others have taken a more explicitly motivational position. Bolles (1972), for instance, proposed that Pavlovian and instrumental processes interact based on their shared outcome expectancies, but that this interaction is gated by the incentive value of mediating outcome. The two-process approach, therefore, provides a compelling explanation for the influence of reward value over performance. According to this account, instrumental responding is depressed following outcome devaluation, not because of a reduction in the reward value of the outcome and knowledge of the underlying response–outcome contingency, but because this treatment diminishes the Pavlovian support for performance.

The claim that Pavlovian learning plays a part in action selection is beyond doubt. The critical question, however, is whether these processes are responsible for the influence of reward value over performance. If so, it would be necessary to abandon the goal-directed interpretation of instrumental performance altogether. Note that since the two-process account uses the Pavlovian–instrumental interaction responsible for transfer to explain the sensitivity of performance to outcome devaluation, it predicts that these two apparently distinct forms of action selection should share a common associative structure. One way to evaluate this prediction, therefore, is to assess whether the associations guiding

transfer and outcome devaluation are acquired at roughly the same rate. For instance, it has been repeatedly shown that, while sensitivity to outcome devaluation emerges with rather limited training (Holland, 2004; Yin et al., 2005), depending on training parameters used (e.g., number of action–outcome contingencies), this effect is either maintained (Colwill and Rescorla, 1985a) or attenuated (Adams, 1981; Holland, 2004) with training that is more extensive. Alternatively, recent evidence suggests that Pavlovian-instrumental transfer increases in magnitude with more extensive instrumental training (Holland, 2004).

It should also be possible to evaluate the two-process account by analyzing the content of the associations that mediate transfer and outcome devaluation. However, it is important to remember that individual two-process theories do not agree on what that content should be. Trapold and Overmier (1972), for instance, argued that the response becomes associated with an expectancy of reward generated by prevailing stimuli, resulting in an outcome–response association. As we have mentioned, others (e.g., Asratyan, 1974; Bolles, 1972) have proposed that the response becomes associated with the outcome it actually produces during training, in the form of a response–outcome association. Two-process theories, therefore, can be distinguished by determining whether the association responsible for action selection reflects the actual response–outcome contingency, or whether it is, instead, the product of the incidental stimulus–outcome contingency present during training. However, investigating the relative contribution of these two contingencies to instrumental learning is no trivial task. In any typical instrumental conditioning study, the outcome earned by the response is also predicted by the prevailing situational cues (i.e., the anticipated and earned outcomes are the same). Thus, one approach to the problem is to create a training situation in which this in not the case.

Several studies have used this basic strategy to assess the associative structure underlying transfer and outcome devaluation. For instance, Colwill (1994) reported evidence of outcome selective transfer with responses that had been concurrently trained on distinct action–outcome contingencies. Similarly, Colwill and Rescorla (1985b) reported that rats display an outcome-specific devaluation effect after concurrent training of this kind. Since rats given concurrent training are allowed to alternate freely between responses, the context should be associated equally with both outcomes, thereby preventing the development of specific outcome–response associations. The specificity of transfer and outcome devaluation despite this treatment, therefore, seems to suggest that both effects can be supported by response–outcome learning.

Rescorla and Colwill (1989) and Rescorla (1992) have attempted more directly to compare the relative contribution of outcome–response and response–outcome associations to these effects. For instance, Rescorla and Colwill (1989) investigated this issue by first pretraining rats on a common nose-poke response with four distinct stimuli; two stimuli (S1 and S3) signaled a pellet reward and two others (S2 and S4) signaled a sucrose solution. Next, they were given discrimination training on two responses (R1 and R2), such that one response, say R1, earned pellets and the other response, R2, earned sucrose. However, each response was also signaled by a stimulus that had previously been paired with the alternative outcome (i.e., $S2 \rightarrow R1 \rightarrow O1$ and $S1 \rightarrow R2 \rightarrow O2$). According to Trapold and Overmier's (1972) two-process account, this should have resulted in the formation of, for example, a sucrose–R1 association, even though R1 had actually been followed by pellets. During the transfer test, rats were allowed to perform each response in extinction while S3 and S4 were occasionally presented. In contrast to the predictions of the outcome–response view, it was found that stimulus presentations selectively facilitated performance based on the identity of the outcome that 'followed' a response during training (e.g., S3 increased R1 relative to R2). Furthermore, in a separate experiment, Rescorla and Colwill (1989) used the same strategy to investigate the structure underlying outcome devaluation performance. They found that, as with transfer, the sensitivity of instrumental performance to reward value was dominated by response–outcome learning; performance was suppressed by devaluing the outcome that the action had actually earned during training, not the outcome that was signaled by the discriminative stimulus (e.g., devaluing O1 decreased R1 relative to R2).

There is, however, reason to question whether these experiments provide a fair test of the outcome–response account. This basic approach, of course, depends entirely on the experimenter's capacity to create a situation in which the expectation of reward differs from the reward that is obtained by responding. In Rescorla and Colwill's (1989) study, for instance, each discriminative stimulus was pretrained so that it would signal a different outcome

from the one that would be earned on that trial. Since this phase of the experiment was conducted over 4 days, however, it is possible that rats were able to learn the new stimulus–outcome relationships (e.g., S1 → O2), nullifying the effects of pretraining. Rescorla (1992) addressed this issue in an experiment otherwise quite similar to the first (Rescorla and Colwill, 1989), except that, during the discrimination phase, each stimulus continued to be paired with the outcome that it predicted during initial pretraining, while at the same time signaling that responding could earn the opposite outcome. These additional Pavlovian trials were added to encourage the persistence of the initial stimulus–outcome learning, thereby providing greater opportunity for any potential outcome–response associations to form during the instrumental discrimination training. Using this new procedure, Rescorla (1992) once again found no evidence that outcome–response associations play a part in outcome devaluation performance. However, the results of transfer testing were less straightforward. He observed that stimulus presentations tended to increase the performance of both responses, although this effect was larger for the response that had 'earned' the outcome signaled by the transfer stimulus than it was for the response that had been trained in 'anticipation' of that outcome. Thus, while these findings suggest that both outcome devaluation and transfer are dominated by response–outcome learning, they also indicate that outcome–response associations may play some, albeit limited, role in the latter.

This conclusion does not help the two-process account of reward value. According to this account, the processes underlying transfer and outcome devaluation should be identical. Perhaps more importantly, however, these studies illustrate the difficulty in attempting to dissociate the contributions of Pavlovian and instrumental learning to performance. Indeed, even in these studies it is possible that the subjects were able to confound the experimenter's intentions and acquire appropriate stimulus–outcome associations during instrumental training based on the relationship between the features of the individual response manipulanda and the outcome earned by those responses. For instance, rats trained to press a lever for pellets and pull a chain for sucrose solution may come to associate the lever itself with pellets and the chain with sucrose. Such learning would ensure that the rat anticipated the reward that they would actually obtain for performing the response, even in the presence of a context that signaled both rewards (e.g., Colwill and Rescorla, 1985b; Colwill, 1994) or a Pavlovian cue that signaled a different reward (e.g., Rescorla and Colwill, 1989; Rescorla, 1992).

This problem can be avoided, however, by training distinct action–outcome contingencies on a common response manipulandum. For instance, Dickinson et al. (1996) trained rats to push a vertically positioned pole to the left and right for different outcomes; for half the rats, left pushes earned food pellets and right pushes earned a maltodextrin solution, whereas the other half was trained with the opposite arrangement. Rats were then sated on one of the two outcomes in order to selectively reduce its reward value. Immediately after this treatment, they were given an extinction test in which the pole was available and could be pushed freely in either direction without consequence. Dickinson et al. (1996) found that, despite having both actions trained on a common manipulandum, the rats were able to use response–outcome training relationships to guide their action selection according to outcome value; rats were less likely to push the pole in the direction that had earned the now devalued outcome, relative to the other direction. This finding is incompatible with the two-process account, which predicts that outcome-selective devaluation should never emerge in the absence of differential stimulus–outcome contingencies. Instead, it provides strong support for the view that instrumental performance is goal-directed and that its sensitivity to reward value depends on response–outcome learning.

One final method for evaluation of the two-process account of reward value involves assessing the interaction between transfer and outcome devaluation. If these phenomena rely on the same underlying structure, then the capacity of a Pavlovian cue to facilitate performance should depend on the value of the mediating outcome representation. Colwill and Rescorla (1990) directly investigated the role of incentive value in outcome selective transfer. Rats were initially given biconditional discrimination training using differential outcomes, such that one stimulus (S1) signaled that pellets could be earned on one response (R1) and the other stimulus (S2) signaled that sucrose could be earned on a different response (R2). Subsequently, they were given free operant training on two new responses (R3 and R4), such that each earned a unique outcome (either pellets or sucrose). One outcome was then devalued through

conditioned taste aversion and then a transfer test was conducted in extinction, with both R3 and R4 available. Although rats were, in general, less likely to perform the response that had earned the devalued outcome than the other response, both responses were selectively facilitated by presentations of the stimulus with which they shared a common outcome. Moreover, the magnitude of this transfer effect, measured in the difference from baseline performance, was comparable across responses. This basic finding, that devaluing an outcome fails to diminish its capacity to mediate Pavlovian-instrumental transfer, has since been replicated in a number of studies (Rescorla, 1994; Holland, 2004).

Altogether, there appears to be scant support for the two-process account of reward value. The associative processes supporting outcome devaluation and transfer appear to be acquired at different rates and encode somewhat different content. Furthermore, instrumental responses remain sensitive to outcome devaluation under conditions that cannot support differential stimulus–outcome learning. Finally, the Pavlovian-instrumental interaction responsible for transfer does not appear to depend on the reward value of the retrieved outcome. Instead, these findings strengthen the goal-directed view of instrumental action and, while demonstrating that reward anticipation influences action selection, it is also clear that this effect is not mediated by the reward system.

1.36.5 Summary and Conclusions

We have argued that the reward system is a specialization that developed in the service of goal-directed action allowing animals to encode the relative values of specific environmental events. These values provide the basis for choice, allowing animals to decide on a course of action based not only on knowledge or information as to the consequences of an action but on the basis of the value of those consequences.

Encoding the reward value of a particular event involves the formation of an association between the specific sensory representation of that event and an emotional response. In the case of primary rewards, the emotional response is directly determined by the activity of specific motivational and affective processes engaged during consummatory contact with the outcome. Thus, by virtue of their biologically active properties (e.g., nutrient, fluidic, pheromonal), rewarding events (food, fluid, sex objects, and so on) are readily able to activate these underlying systems that modify emotional responses as one of the consequences of that activation. Basing the evaluation of primary rewards on emotional responses is adaptive if those responses are determined by the operation of these basic motivational and affective systems, which is essential if the animal's choice between alternative courses of action is to remain, by and large, adaptive too. In the case of secondary rewards, the emotional response is, of course, determined by the primary reward with which it is paired. By basing the transfer of value from primary to secondary rewards on an emotional response, the selection of actions, even when they are directed toward achieving apparently quite arbitrary goals, can be understood as being constrained by primary motivational processes through their influence on emotional responses.

Finally, we addressed the distinction between the role the reward system plays in assigning reward value and the processes controlling the anticipation of reward. These are quite distinct aspects of behavioral control; although cues that signal forthcoming rewards can provide information that can be used by the goal-directed system, they do not depend, ultimately, on the reward system to play that role. As such, the influence of reward-related cues on action selection does not replace or explain away the functions of the reward system in this regard. Rather, the distinct processes mediating the effects of reward and of the anticipation of reward provides the basis for understanding the role that cognitive processes generally play in goal-directed action. Because it constrains the event relations to which an animal is exposed, there has been a long tradition of using Pavlovian conditioning to model the cognitive control of behavior. The fact that, ultimately, this system is concerned with the production of reflexive responses would, however, appear to render this approach perhaps a little too abstract. It makes more sense to study the role of cognition in a behavioral system within which information can act to influence performance. Based on the evidence reviewed here that animals are able to exert control over their instrumental actions, choose between actions based on the relative value of their consequences, and use predictive information to influence action selection, we suggest that instrumental conditioning provides the more precise model of this capacity.

1.37 Synchronous Oscillations and Memory Formation

W. Singer, Max Planck Institute for Brain Research, Frankfurt am Main, Germany

1.37.1 Introduction

It is commonly held that the neuronal mechanisms supporting the formation of memories consist of use-dependent long-term modifications of synaptic transmission. In order to explain the formation of new associations, Donald Hebb had postulated that connections among neurons should strengthen if the coupled neurons are repeatedly active in temporal contiguity (Hebb, 1949). This prediction has been confirmed by the seminal discovery of long-term potentiation (LTP) in the hippocampus by Bliss and Lomo (1973). They had found that tetanic stimulation of excitatory pathways led to a long-lasting enhancement of the efficacy of the synapses between the activated fibers and the respective postsynaptic target cells. Later it had been shown that this increase in synaptic efficacy occurred only if the postsynaptic cells were actually responding with action potentials to the tetanic stimuli, thus fulfilling the criterion of contingent pre- and postsynaptic activation. If postsynaptic cells were prevented from responding, modifications either did not occur or had opposite polarity, i.e., they consisted of a reduction of synaptic efficacy. This phenomenon has become known as long-term depression (LTD). It is now well established that both modifications depend on a surge of calcium in the subsynaptic space of the postsynaptic dendrites and that the polarity of the modifications depends on the rate of rise and the amplitude of this calcium increase (Bröcher et al., 1992b; Hansel et al., 1996, 1997). Fast and strong increases lead to LTP, while slow and smaller increases trigger LTD. Moreover, the source of the calcium increase is of importance. Calcium entering through *N*-methyl-D-aspartate (NMDA) receptor-associated channels favors the induction of LTP, whereas calcium entering through voltage-dependent calcium channels is more likely to trigger LTD. However, both modifications can be obtained merely by raising intracellular calcium concentrations through the liberation of caged calcium in a concentration-dependent manner (Neveu and Zucker, 1996). A vast number of studies have subsequently been performed in order to elucidate the molecular cascades mediating these use-dependent changes in synaptic transmission which involve both changes in transmitter release and postsynaptic susceptibility. This has led to a deep understanding of the extremely complex regulatory processes that translate neuronal activity into lasting changes of synaptic transmission (*See* Chapters 1.33, 1.34, 1.35).

It had long been held that the polarity of use-dependent synaptic gain changes depended merely on the extent to which pre- and postsynaptic activity was correlated in time as initially proposed by Hebb. The evidence that activation of NMDA receptors was one of the decisive variables in determining the polarity of synaptic gain changes agreed with this notion because these channels open and become permeable for calcium ions only if the excitatory transmitter glutamate is bound to the receptor and if the postsynaptic cell is sufficiently depolarized to remove the magnesium block that makes the channel impermeable at hyperpolarized membrane potential levels (Artola and Singer, 1987; Kleinschmidt et al., 1987; Bear et al., 1990). Thus, LTP would occur in all cases where presynaptic afferents are sufficiently active while the postsynaptic cells are sufficiently depolarized (Artola et al., 1990). Since the level of depolarization of the postsynaptic neuron not only depends on the level of activity of the pathways under consideration, but also on all the other excitatory and inhibitory inputs, this mechanism can also elegantly account for the cooperativity of synaptic modifications. Even weak inputs can increase their gain if at the same time strong inputs are active to assure sufficient depolarization of the postsynaptic membrane to remove the magnesium

block. Likewise, concomitant activation of inhibitory inputs can prevent NMDA receptor activation at levels of presynaptic activity that would normally induce LTP. In this case, the outcome is usually LTD (Artola et al., 1990).

In conclusion, this mechanism is ideally suited to strengthening excitatory interactions among pairs of cells that are frequently activated in temporal contiguity, and because of cooperativity, it strengthens excitatory inputs converging on a common target cell if these inputs are frequently active in temporal contiguity. Conversely, modifications of opposite polarity occur if the respective activation patterns are anti-correlated. In this conceptual framework, the crucial variable that determines the occurrence and the polarity of synaptic gain changes is the discharge rate of the pre- and postsynaptic elements and the temporal coherence of fluctuations in discharge rate. The precise timing of individual spikes appeared irrelevant in this context.

1.37.2 Spike Timing Synaptic Plasticity

This notion has changed considerably over the last few years because of three initially independent lines of research that converged in the conclusion that the precise timing of spikes matters both in signal processing and synaptic plasticity (Gray and Singer, 1989; Gray et al., 1989; Markram et al., 1997). In experiments based on paired recordings from coupled neurons in slices, it was deduced that the polarity of synaptic gain changes depended crucially on the temporal relation between excitatory postsynaptic potentials (EPSPs) and postsynaptic action potentials. It was discovered that somatic action potentials can propagate backward into the dendrites because of activation of voltage-dependent dendritic sodium channels and electrotonic propagation and that contingency of this back-propagating action potential with a simultaneously generated EPSP could be sufficient to remove the magnesium block of the NMDA channels and in certain cases even allow for the generation of a dendritic calcium spike, thus allowing for a sufficient increase in postsynaptic calcium to induce LTP (Stuart and Häusser, 2001). By varying the timing between the EPSP and the back-propagating spike, in this case elicited by somatic current injection, it was revealed that the timing between individual EPSPs and back-propagating spikes was critical both for the induction of long-term modifications and the determination of their polarity. No changes occurred when the interval between the EPSP and the back-propagating spike was longer than about 50 ms. When the EPSP preceded the back-propagating action potential, the probability of obtaining LTP increased with decreasing delays and then there was a sharp transition toward LTD as soon as the EPSP occurred after the back-propagating spike. This discovery of spike timing-dependent plasticity (STDP) had two important implications: First, it showed that the precise timing of spikes matters in determining the occurrence and polarity of synaptic gain changes. Second, the mechanism subserving synaptic modifications not only evaluates simple covariations between pre- and postsynaptic firing rates, but also evaluates causal relations. It increases the gain of excitatory connections whose activity can be causally related to the activation of the postsynaptic neuron and it weakens connections whose activity could not have contributed to the postsynaptic response (Markram et al., 1997; but see Stiefel et al., 2005).

At about the same time, evidence was obtained suggesting that the precise timing of individual spikes is relevant in signal processing. In vivo recordings from higher visual areas, the auditory and the somatic sensory cortex, revealed that the discharge latencies of individual neurons could signal the temporal structure of stimuli with an extreme precision in the millisecond range, suggesting that precise timing of discharges can be preserved despite numerous intervening synaptic transmission steps (Buracas et al., 1998; Reinagel and Reid, 2002). Simulation studies, partly based on the concept of synfire chains proposed by Moshe Abeles (1991), confirmed that conventional integrate-and-fire neurons are capable of transmitting temporal information with the required precision (Mainen and Sejnowski, 1995; Diesmann et al., 1999).

Parallel to these discoveries, evidence has been obtained in the visual system for the existence of mechanisms capable of adjusting the timing of individual spikes, again with millisecond precision independently of external stimuli (Gray and Singer, 1989; Gray et al., 1989; Engel et al., 2001; Fries et al., 2001a). Using multielectrode recording techniques, it was shown that neurons in the visual cortex engage in oscillatory firing patterns in the range of the gamma frequency band and that these periodic discharges are synchronized with a precision in the millisecond range. This synchronization was observed not only between neurons located within the same cortical area, but also between cells in different cortical areas

and even among cells in corresponding areas of the two hemispheres (Roelfsema et al., 1997; Singer, 1999). While synchronization probability reflected to some extent the layout of corticocortical association connections (Löwel and Singer, 1992), it soon turned out that this was the result of a highly dynamic self-organizing process that enables rapid reorganization of synchronized cell assemblies as a function of stimulus configuration, central state, and attentional mechanisms (for review, see Singer, 1999; Engel et al., 2001). Initially, this precise synchronization of discharges of spatially distributed neurons was seen mainly in the context of low-level visual processes such as feature binding and figure ground segregation. Later it became clear that it is a ubiquitous phenomenon in most structures of the nervous system (Castelo-Branco et al., 1998; Brecht et al., 1999) and with all likelihood serves a large number of different functions that all have to do with the coordination and selective routing of activity in the context of distributed processing (Womelsdorf et al., 2006). Synchronized discharges have a stronger impact on target neurons than temporally dispersed inputs and this effect means that synchrony can be used as a complementary mechanism to rate increases in order to raise the saliency of neuronal signals (Biederlack et al., 2006). The difference is that synchrony can enhance the saliency of discharge patterns on a spike-by-spike basis with very high temporal resolution.

Extensive experimental and theoretical studies have since demonstrated that the oscillatory patterning of neuronal activity is crucial for the adjustment of precise spike timing (König et al., 1995; Volgushev et al., 1998). Because of reciprocal coupling via chemical and electrical synapses, networks of inhibitory interneurons engage in oscillatory activity, the frequency of which is often characteristic for particular networks and conveys periodic inhibition to excitatory neurons, in the case of the neocortex and the hippocampus pyramidal cells (Whittington et al., 2001). The effect is that the timing of spikes generated by pyramidal cells does not solely depend on the timing of the arriving EPSPs. During the hyperpolarizing phase of the oscillation cycle, arriving EPSPs have only a small chance to drive action potentials in the postsynaptic neuron because of the initial shunting and then hyperpolarizing effect of the barrages of IPSPs. This limits spiking essentially to the depolarizing phase in the peak of the oscillation cycle, causing synchronization of discharges in cells oscillating in phase. Moreover, the precise timing of spikes generated during the depolarizing cycle does depend on the strength of the excitatory input (Fries et al., 2007). Strong excitatory input will elicit spikes earlier during the depolarizing cycle than a weak input. Thus, the phase relation between the time of occurrence of a spike and the peak of the oscillation cycle does reflect the amplitude of the excitatory drive that generated the spike. Through this mechanism, known as phase precession in the hippocampus for example, rate-coded amplitude values can be converted into a temporal code that is expressed in the timing of spikes relative to the oscillation cycle. As has been shown in numerous theoretical studies, such temporal codes are advantageous for fast processing because information on spike times can be transmitted and read out much more rapidly than information encoded in discharge rates because it does not require temporal integration, neither for transmission nor for readout (for review, see Fries et al., 2007).

There is thus a mechanism that can evaluate the precise temporal relations among individual spikes for the gating of synaptic plasticity, and there is a mechanism to adjust the precise timing of spikes during signal processing and to convert rate-coded information into timing relations. Both the classical Hebbian mechanism as well as STDP, which most certainly do coexist, evaluate temporal relations among activity patterns in order to convert correlations into synaptic gain changes. For these modifications to be meaningful, the signatures of relatedness used for engram formation must be exactly the same as those used for signal processing. Otherwise, correlations occurring spuriously during signal processing would lead to changes in synaptic coupling that are functionally meaningless. Because STDP does depend so critically on the precise timing of spikes and is susceptible to changes in timing relations on the order of the millisecond, relations between the distributed firing of neurons need to be defined and evaluated with similar precision during signal processing. However, this requires that neurons can act as coincidence detectors and distinguish between precisely synchronized and temporally dispersed input activity.

A third line of independent evidence also favors the notion that precise spike timing may play an important role in neuronal processing and memory formation. Data are accumulating which indicate that cortical circuits, synaptic properties, and the characteristics of neurons are optimized for the transmission and detection of coincident activity. A prominent feature of cortical connectivity is sparseness and as proposed by Abeles and confirmed later in extensive

simulation studies (Mainen and Sejnowski, 1995; König et al., 1996; Diesmann et al., 1999), such networks strongly favor transmission of synchronized activity over transmission of temporally dispersed activity. Likewise, the frequency adaptation of transmitter release and the adaptation of postsynaptic receptors attenuate transmission of frequency-coded information. These adaptive mechanisms favor transmission of singular synchronized events and tend to filter out discharge sequences occurring at high frequencies. Sensitivity to single but coincident EPSPs is further enhanced by cooperative mechanisms in the postsynaptic dendrites. The existence of voltage-dependent sodium and calcium channels in the dendrites and their ability to convert high-amplitude EPSPs such as result from coincident input into regenerative spikes greatly enhances the coincidence sensitivity of cortical neurons (Stuart and Häusser, 2001; Ariav et al., 2003). Finally, there is evidence that spike thresholds lower as the depolarizing slope preceding the spike becomes steeper. This also favors responses to coincident inputs as compared to temporally dispersed inputs. Last but not least, the membrane time constants of cortical neurons are shorter than previously assumed, especially when the neurons are in the up state: this is due to the reduced membrane resistance caused by the simultaneous bombardment by EPSPs and IPSPs in the up state.

Thus, several lines of evidence indicate that cortical networks that are thought to support memory formation by mechanisms of use-dependent synaptic plasticity are capable of exploiting precise temporal relations among the discharges of interconnected neurons for signal processing, the encoding of information, and the induction of corresponding gain changes.

However, if precise timing of discharges is achieved through an oscillatory modulation of neuronal excitability, especially when it comes to the coordination of timing relations over larger distances, and if synaptic gain changes depend essentially on STDP, a problem arises. If coupled neuron groups engage in oscillatory activity in the same frequency range but oscillate 180 degrees out of phase, one can anticipate situations in which EPSPs always arrive in the trough of the oscillation cycle and hence at equal distance to the preceding and the following peak of enhanced excitability where spikes tend to occur. Thus, EPSPs are preceded and followed by spikes at the same interval. In this case, different outcomes are predicted by the classical Hebbian correlation rule and STDP. If the pre- and postsynaptic neurons discharge at high frequencies, as would be the case, for example, if they are engaged in gamma oscillations, the classical Hebbian rule would predict LTP because of the contingency of high-frequency pre- and postsynaptic activation. The STDP rule cannot make a clear prediction because EPSPs are preceding and following spikes at about the same interval, which should lead to a cancellation of the antagonistic effects. This problem has recently been addressed in an in vitro study on slices of the visual cortex (Wespatat et al., 2004). The results indicated that inputs oscillating at the same frequency as the target cell (20 or 40 Hz) underwent LTP when they were in phase with the depolarizing peak of the oscillation cycle, whereby it was irrelevant whether the EPSPs arrived shortly before or after the action potentials, whereas the same input underwent LTD when it oscillated 180 degrees out of phase so that the EPSPs arrived during the hyperpolarizing troughs of the oscillation cycle of the postsynaptic neuron.

1.37.3 Evidence for Relations between Oscillatory Activity, Synaptic Plasticity, and Learning

Given that learning mechanisms evaluate temporal correlations among the activity patterns of coupled neurons and that the temporal patterning of neuronal activity is often structured by an oscillatory modulation, one expects to find close relations between memory processes and oscillatory activity. Although research on this issue is still at its very beginning, such evidence is indeed available.

Indirect evidence for a relation between synaptic plasticity and oscillatory patterning comes from studies relating oscillatory activity to central states and attentional mechanisms. While synaptic modifications can be induced with artificial stimulation conditions irrespective of the state of neuronal networks and even in fully deafferented slice preparations, there is consensus that under natural conditions learning-related modifications of synaptic gain occur only when the brain is in an activated state and when attentional mechanisms are functional. The reason is that synaptic modifications require the presence of an appropriate mix of neuromodulators such as acetylcholine, dopamine, and noradrenaline and that these modulators are available in the required concentrations only when the brain is in an awake and activated state. Another likely reason is that the induction of synaptic modifications requires a minimum of cooperativity, for example a sufficient amount of synchronized input activity, and that such cooperativity is only achieved in the

activated brain. These activated brain states favor the emergence of oscillatory activity in various frequency bands and the synchronization of the oscillations across structures that need to cooperate for memory processes. In this context, the most important frequency bands appear to be the theta, the beta, and the gamma. Gamma oscillations in the neocortex and the associated precise synchronization of neuronal discharges are greatly facilitated by the presence of acetylcholine and its action on muscarinic receptors (Munk et al., 1996; Herculano-Houzel et al., 1999). Acetylcholine also facilitates use-dependent synaptic modifications and it is likely that there is a relation between the two phenomena (Bröcher et al., 1992a; Wespatat et al., 2004). Likewise, attention facilitates gamma oscillations (Fries et al., 2001b) and favors learning (Bröcher et al., 1992; Wespatat et al., 2004). Preliminary evidence suggests that there may be a causal relation between the occurrence of synchronized oscillatory activity in the gamma-frequency band and the induction of synaptic plasticity. It is possible to modify the receptive fields of neurons in the visual cortex by appropriate visual stimulation even in anesthetized preparations if the brain is concomitantly activated by electrical stimulation of the mesencephalic reticular formation (unpublished observation). This stimulation increases the release of plasticity-enhancing neuromodulators and at the same time favors the occurrence of gamma oscillations in response to the applied stimuli. Post hoc analysis of the neuronal responses to the change-inducing light stimuli revealed that only those trials caused lasting changes in receptive field properties that were associated with a strong oscillatory modulation and synchronization of neuronal responses in the gamma band. A similar relation, albeit in the theta-frequency range, has been found in the hippocampus (Huerta and Lisman, 1995). Here, the so-called beta-burst stimulation that entrains the hippocampus in the characteristic theta rhythm of the structure turned out to be particularly effective for the induction of long-lasting synaptic modifications. Moreover, when the hippocampal circuits were engaged in spontaneous theta oscillations, the effectiveness of the stimuli applied for the induction of synaptic gain changes and the polarity of the resulting synaptic modifications depended critically on the phase relation between the ongoing theta activity and the change-inducing stimuli (Huerta and Lisman, 1995). A similar finding has been obtained in the somatosensory barrel cortex, where synchronous oscillatory activity occurs in conjunction with the whisking movements. Again, the efficacy of the change-inducing electrical stimuli depended critically on the timing of the stimuli relative to the whisking cycle. Finally, it was shown in experiments in which hippocampus theta was recorded while animals were exposed to classical conditioning paradigms that memory traces could be established only if the conditioning stimuli were given during a particular phase of the theta cycle. While these experiments only showed a relation between the timing of inducing stimuli relative to oscillatory activity, more direct evidence for an instrumental role of long-range synchronization of oscillations in memory processes has been obtained with multielectrode recordings from structures relevant for memory formation (Fell et al., 2001; Tallon-Baudry et al., 2001, 2004). In human subjects implanted with depth electrodes for the localization of epileptic foci, it was found that successful formation of episodic memories was accompanied by transient increases in gamma- and theta-oscillatory synchrony between the hippocampus and neighboring entorhinal cortex, structures known to be involved in memory formation. In trials in which memory formation was not successful, these changes in synchronization were not observed (Fell et al., 2001, 2003). Likewise, simultaneous recordings from limbic structures (amygdala and hippocampus) have shown that fear conditioning is associated with transient synchronization of oscillatory activity between the two structures (Seidenbecher et al., 2003; Narayanan et al., 2007). Electroencephalographic and magnetoencephalographic studies in healthy human subjects revealed that classical Pavlovian conditioning leads to a lasting enhancement of the synchronization of gamma oscillations between cortical areas encoding the conditioned and nonconditioned stimuli, respectively (Miltner et al., 1999).

The recall of memories also appears to be associated with enhanced oscillatory patterning of neuronal responses in the theta, beta, and gamma bands (Raghavachari et al., 2001; Tallon-Baudry et al., 2001; Rizzuto et al., 2003; Sederberg et al., 2003; Herrmann et al., 2004; Guderian and Duzel, 2005). Auditory stimuli that matched a previously stored template led to significantly more gamma band synchrony than those that did not match (Debener et al., 2003). Visual stimuli for which subjects have a long-term memory representation caused significantly greater gamma oscillations in the occipital cortex than similar stimuli that were not stored in long-term memory (Herrmann et al., 2004). A close relation between encoding and retrieval of memory contents and enhanced gamma oscillations has also been found in experiments on working memory (Tallon-Baudry et al., 1997; Strüber et al., 2000;

Tallon-Baudry et al., 2001, 2004). Here, the increase in oscillatory activity was particularly pronounced over parietal, central, and frontal regions of the brain. Finally, there appears to be a relation between the access to declarative memory and long-range synchronization of gamma oscillations (Melloni et al., 2007). In humans performing a delayed matching-to-sample task on stimuli that were only perceived in a subset of trials and gained access to consciousness and declarative recall, it was possible to demonstrate that only those stimuli that were consciously perceived and encoded in declarative memory evoked large-scale phase synchronization of gamma oscillations across distributed cortical networks. In addition, only those trials were associated with sustained, enhanced theta activity throughout the hold period. The latter finding agrees well with the growing evidence that large-scale synchronization in the theta frequency band is closely related to the encoding and recall of stimulus material in declarative memory. Successful recognition of known faces is associated with increased activity in a distributed network that includes prefrontal mediotemporal and visual areas in occipital cortex (Guderian and Duzel, 2005). Finally, invasive recordings in patients suggest that theta band oscillations are implicated in spatial navigation, working memory, and episodic memory (Raghavachari et al., 2001; Caplan et al., 2001, 2003; Rizzuto et al., 2003; Sederberg et al., 2007).

Last but not least, there is recent evidence from studies in human subjects that consolidation of memories during sleep is closely related to an oscillatory patterning of neuronal activity (Marshall et al., 2006).

1.37.4 Conclusion

So far, most of the evidence suggesting a relation between synchronized oscillatory activity in various frequency bands and memory formation is correlative in nature and does not allow one to conclude that synchronized oscillatory activity is a necessary prerequisite for the induction of memory-related synaptic gain changes. However, the evidence reviewed concerning the importance of precise temporal relations in memory processes and the pivotal role of oscillations for the establishment of precise temporal relations between neuronal activities provides strong support for the hypothesis that oscillations and the associated synchronization of spike discharges play a crucial role in the coordination of distributed neuronal processing on the one hand and engram formation on the other. This conclusion is further supported by the growing evidence that cognitive deficits, including impairments in short- and long-term memory such as occur in schizophrenia, Alzheimer's disease, and epilepsy, are associated with abnormal patterns of neuronal oscillations and reduced synchronization (for review, see Uhlhaas and Singer, 2006).

1.38 The Neuronal Workspace Model: Conscious Processing and Learning

J.-P. Changeux, URACNRS 2182, Collège de France and Institut Pasteur, Paris, France

S. Dehaene, Collège de France, Paris, France; and INSERM-CEA Cognitive Neuroimaging Unit, Neurospin Center, Gif-sur-Yvette, France

1.38.1 Introduction

Researchers in the field of computational biology have mostly focused their attention in the recent years on the sequences of eukaryotic genomes, on their annotation, and on the understanding of how these linear sources of information give rise to the three-dimensional organization of the body and, in

particular, of the brain. Ultimately, from the DNA sequences already stored *in silico* of the human genome, one should be able to compute the main features of the species-specific functional organization of our brain. Yet, the brain strikingly differs from the other organs of the body in several respects. First, the complexity of its cellular and supracellular organization is orders of magnitudes higher, and second, it is able to learn and store information from the outside world. Finally, its structure is under constant reorganization as a function of its internal physiological states of activity, either endogenously generated or evoked by signals from the outside world. These are a few of the many reasons why computational neuroscience has recently developed as a rather autonomous and fast-moving discipline. Its principal project is to understand the multiple modes of signal processing by the brain ultimately resulting in behavior and/or tacit mental events. It is also to build up formal models, expressed in terms of neuronal networks, that link the molecular, neuronal, physiological, and behavioral/mental data in a coherent, noncontradictory though minimal form (Changeux and Dehaene, 1989). Ultimately implemented as 'formal organisms' (Changeux et al., 1973), these neurocomputational models should altogether account for the available data and produce experimentally testable predictions at all those levels. Being minimal, they are not anticipated to give an exhaustive description of reality, but nevertheless to validate or invalidate theories and, if necessary, give rise to new ones, thus contributing to our understanding of how the human brain works.

If multiple attempts have been successfully done to model the relationships between the states of activity of neuronal networks and overt behaviors in simple systems (Grillner and Graybiel, 2006), a most fascinating intellectual challenge of today's neuroscience remains to understand the explicit processing of the mental events which invest our brain, in other words to establish a comprehensive theory of consciousness on the basis of the presently available scientific knowledge. As stated by Delacour (1997),

> Multiple explanations have already been suggested like such-and-such a sophisticated algorithm, the oscillation of the extracellular electrical field in the cortex, the probabilistic character of synaptic transmission, or some still mysterious property of 'quantum gravity.' These theories represent little advance over the pineal gland theory of René Descartes. (Delacour, 1997: 127)

The case of consciousness is indeed exceptional. First of all, a fundamental ambiguity exists in the use of the term which, depending on context and author, can equally refer to waking state, personal experience, mental processing, or the multifaceted concept of self. Second, its comprehensive description crosses multiple disciplines ranging from basic neuroscience to molecular biology, psychology, and philosophy which, in the present situation of the academic community, show considerable difficulties to interact and cooperate. Last, any plausible theory on consciousness has to refer to a phenomenal subjective experience reported through introspection that a long tradition, from positivism to behaviorism and, most of all, the current practices of bench work research in neuroscience or pharmacology, has banned from any serious form of scientific enquiry.

Nevertheless, in the past decades, the situation has significantly changed because of a 'renaissance' (Zeman, 2005) of empirical research on consciousness and the proposal of constructive and plausible mechanistic theories, which aim at accounting for the subjective experience of a unified or global 'space or scene,' where some kind of *synthesis* between past, present, and future takes place, where multimodal perceptions, emotions, and feelings (present), and evoked memories of prior experiences (past), together with anticipations of actions (future), become subjectively integrated in a continuously changing and dynamic flow of consciousness, "altogether one and multiple at any of its moments" (Fessard, 1954; Bogen, 1995; Edelman and Tononi, 2000; Crick and Koch, 2003; Dehaene and Changeux, 2004). Among these theories, Zeman (2005) distinguishes the following.

1.38.1.1 Information Processing Theories

Following the lead of William James in associating consciousness with selective attention and memory, Baars (1989) has proposed a psychological model which postulates that the content of consciousness is broadcasted to the whole brain through a 'global workspace' which recruits the operation of multiple unconscious and automatic processors. Yet, Baars proposed as the essential neural basis of his global workspace the ascending reticular formation, the nonspecific nuclei of the thalamus, and only casually mentioned that "it is possible that corticocortical connections should also be included."

Shallice (1988) has also suggested an integrative role of consciousness through a 'supervisory attentive system' which would control the activities of lower level psychological systems mediated by some kind of 'contention scheduling' system and has placed emphasis on parieto-prefrontal networks in relation with the supervisory system (see also Frith et al., 1999).

1.38.1.2 Neurobiological Theories

In their pioneering efforts to specify the neural correlates of consciousness, Crick and Koch (Crick, 1994; Crick and Koch, 1995, 2004) have successively emphasized the importance of gamma-band oscillations around 40 Hz as a correlate of conscious processing; then, successively, the role of connections to and from prefrontal cortex in conscious perception (though more recently they have defended the opposite view that prefrontal cortex works as an 'unconscious homunculus'); and last, the possible role of the claustrum in the integration of conscious percepts (Crick and Koch, 2005).

Edelman and Tononi (2000) and Tononi and Edelman (1998) have emphasized the role of information integration and of reentrant connections in establishing a shifting assembly or 'dynamic core' linking distributed cortical and thalamic neurons. Its representation content, at the same time diversified and unitary, could not be localized to single parts of the brain and would vary significantly among individuals, but yet would correspond to the content of phenomenal consciousness. Lumer et al. (1997a,b) have developed a formalism in their simulations focused on early visual processing, with reentrant connections but without establishing a link with the notion of consciousness and specifically with the dynamic core hypothesis.

The hypothesis of a conscious 'neuronal workspace' (Dehaene et al., 1998; Dehaene and Changeux, 2000; Dehaene and Naccache, 2001; Dehaene et al., 2003b) emphasizes the role of distributed neurons with long-distance connections, particularly dense in prefrontal, cingulate, and parietal regions, interconnecting multiple specialized processors and broadcasting signals at the brain scale in a spontaneous and sudden manner, forming a conscious 'global neuronal workspace.' This model is extensively presented and discussed in this chapter.

1.38.1.3 Social Theories

The philosopher Strawson (1974) has argued that the concept of one's own mind presupposes the concept of other minds. This, together with the notion that language is critical for human consciousness, has led to the notion that conscious experience would be more a social construction than a physiological or psychological phenomenon (Rose, 1999). Without contesting the importance of social relationships and in particular of language (see Edelman, 1989) in human consciousness, one may wonder, however, whether this is the adequate level of explanation for a comprehensive theory of consciousness, which should ultimately capture such basic phenomena as sleep and anesthesia, masking, or attentional blink (see following).

In this chapter we successively analyze: (1) the theoretical premises of the neuronal workspace hypothesis; (2) the formal representation of the neuronal workspace model; (3) simulations with the workspace model of states of consciousness and access to consciousness in cognitive tasks; and (4) the neuronal workspace model and the evolution of consciousness.

1.38.2 The Neuronal Workspace Hypothesis: Premises and Theoretical Statements

The views presented in this chapter developed from three sets of complementary data: anatomical, computational, and psychophysical.

1.38.2.1 Anatomical Data

Early observations by Cajal (1892) (see DeFelipe and Jones, 1988) underlined the 'special morphology' of the pyramidal cells from the cerebral cortex and suggested that they might be "the substratum of the highest nervous activities," calling them '*the psychic cells*.' Cajal mentioned their very numerous and complex dendritic cells and also noted that "the pyramidal cells from cortical layers II and III possess long axons with multiple collaterals." Cajal further distinguished in the white matter: projection fibers which enter the cerebral peduncle, callosal fibers which associate the two hemispheres, and fibers of association that "bring into relation . . . different territories and different lobes of the same hemisphere" (Cajal, 1892). He also noted that these fibers of association increase in number in humans and large

mammals, where they form "the main mass of the white matter." Recent investigations have confirmed the view that the corticocortical and callosal fibers primarily (though not exclusively) arise from layer II-III pyramids (Jones, 1984) (**Figure 1(d)**).

Furthermore, von Economo (1929), a follower of Brodman, distinguished in his "Cytoarchitectonics of the human cerebral cortex" five "fundamental types of cortical structure" (**Figures 1(a) and 1(b)**) and among them: the "frontal type 2 (which) . . . possesses large, well-formed, and well-arranged pyramidal cells in layers III and V" while in the "parietal type 3 (these cells) are smaller, more slender, and numerous . . . ." Von Economo also noted that the type 2 is "spread over the anterior two-thirds of the frontal lobe, over the superior parietal lobule . . ." as well as over the cingulate cortex, among other cortical areas and concludes that "type 2 and 3 isocortex . . . are the chief station for the commemorative and higher psychic functions."

Interestingly, recent quantitative analysis of the dendritic field morphology of layer III pyramidal neurons in the occipitofrontal cortical 'stream' revealed a continuous increase of complexity up to the prefrontal cortex within a given species (Elston and Rosa, 1997, 1998; DeFelipe and Farinas, 1992) (**Figure 1(c)**) and from lower species (owl monkey, marmoset) to humans (Elston, 2003). A correlative increase of the relative surface of the prefrontal cortex accompanies this increased complexity (see Changeux, 2004). Moreover, mapping of long-range connections in the monkey cerebral cortex revealed long-range connections linking, among others, the prefrontal cortex (area 46), the superior temporal sulcus, parietal area 7a, and the hippocampus together with the contralateral anterior and posterior cingulum, area 19, and the parahippocampal gyrus (Goldman-Rakic, 1988). These circuits were suggested to contribute to working memory (Goldman-Rakic, 1994) and

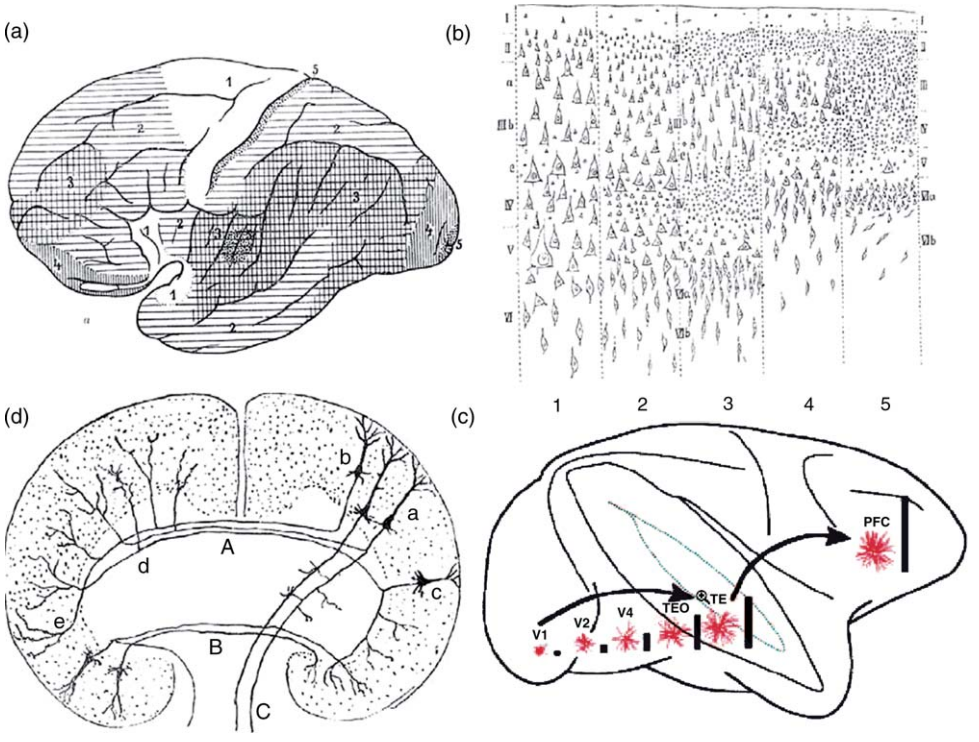

Figure 1 The anatomical basis of the neuronal workspace hypothesis. The pyramidal neurons with long corticocortical axons from layers 2–3 of the cerebral cortex (d) display increased complexity of the basal dendrites (and thus increased connectivity) from primary visual areas (V1) to prefrontal cortex (PFC) (here in the monkey (c)) and from primitive vertebrates to humans. These neurons are particularly abundant in what von Economo referred to as type 2 cortex (b), which primarily occupies the frontal, parietotemporal, and cingulate areas (a). Parts (a) and (b) from von Economo C (1929) *The Cytoarchitectonics of the Human Cerebral Cortex.* London: Oxford University Press; used with permission. (c) from Elston GN (2003) Cortex, cognition and the cell: New insights into the pyramidal neuron and prefrontal function. *Cereb. Cortex* 13: 1124–1138; used with permission from Oxford University Press. (d) from Cajal S (1892) El nuevo concepto de la histologia de los centros nerviosos. *Rev. Ciencias Med.*18: 457–476; used with permission.

proposed to contribute to the anatomical basis of the neuronal workspace model (Dehaene et al., 1998).

1.38.2.2 Computational Data

The present neurocomputational approach to conscious versus nonconscious processing originates from the design of neural network models that aimed at specifying the contribution of prefrontal cortex to increasingly higher cognitive tasks (Dehaene and Changeux, 1989, 1991, 1997; Dehaene et al., 1998). Successively, these models considered the issues of how a network could retain an active memory across the long delay of a delayed-response task (Dehaene and Changeux, 1989), how it could encode abstract rules that might be selected from external or internal rewards (Dehaene and Changeux, 1991), and finally how networks based on those principles could pass complex planning tasks such as the Tower of London test or the Stroop test (Dehaene and Changeux, 1997; Dehaene et al., 1998). The 'conscious *neuronal* workspace' model (Dehaene et al., 1998; Dehaene and Naccache, 2001; Dehaene et al., 2003b; Dehaene and Changeux, 2005) is the last development of these models which emphasize the role of distributed neurons with long-distance connections, particularly dense in prefrontal, cingulate, and parietal regions, which are capable of interconnecting multiple specialized processors and can broadcast signals at the brain scale in a spontaneous and sudden manner.

1.38.2.3 Cognitive Psychology, Neuropsychology, and Human Neuroimaging

A long psychophysical and neuropsychological tradition, dating back to Hughlings Jackson and perpetuated among others by Baddeley, Shallice, Mesulam, or Posner, has emphasized the hierarchical organization of the brain and separates lower automatized systems from increasingly higher and more autonomous supervisory executive systems. It has also been influenced by Fodor's distinction between the vertical 'modular faculties' and a distinct 'isotropic central and horizontal system' capable of sharing information across modules. Empirically, finally, it has taken advantage of a variety of experimental techniques, starting with behavioral analysis, neuropsychological observation in brain-lesioned patients, and most recently, human neuroimaging with functional magnetic resonance imaging (fMRI) and causal interference with transcranial magnetic stimulation (TMS).

It is beyond the scope of this chapter to discuss the variety of experimental contributions that are relevant to the ongoing science of consciousness (see, e.g., Laureys, 2005), but they can be briefly sketched as belonging to two main lines of research. The first line, starting with the pioneering research of Weiskrantz on blindsight and Marcel on subliminal priming, has investigated the extent of nonconscious processing in humans. In combination with fMRI, this research has uncovered that not only subcortical, but in fact a variety of specialized cortical systems were capable of activating in the absence of any conscious report of stimulus presence (for review, see Naccache and Dehaene, 2001; Naccache et al., 2005; Dehaene et al., 2006). The second line, exemplified by Posner's or Shallice's work, has studied the properties of a central executive or executive attention system, whose activity seems to index conscious top-down attention and control (Norman and Shallice, 1986; Amati and Shallice, 2007). Through the use of Baars's contrastive method, which consists of opposing two minimally different conditions, one of which is conscious and the other is not, it has been observed that executive control is deployed only following consciously perceived trials (e.g., Kunde, 2004) and is consistently associated with a sharp increase in dorsal and midline prefrontal as well as anterior cingulate and, in many cases, inferior or posterior parietal activation (see Gusnard and Raichle, 2001; Dosenbach et al., 2006).

1.38.2.4 The Model

Inspired by these observations, our theoretical work attempted to capture them within a minimal theoretical model. In the following, the headlines of the theoretical premises will be presented following the initial presentation of Dehaene et al. (1998), yet updated in a few of its formulations in the subsequent papers of Dehaene et al. (2003a) and Dehaene and Changeux (2005).

1.38.2.4.1 Two computational spaces

The neuronal workspace hypothesis distinguishes, in a first approach, two main computational spaces within the brain (**Figure 2**), each characterized by a distinct pattern of connectivity:

a. A processing network, composed of a set of parallel, distributed, and functionally specialized

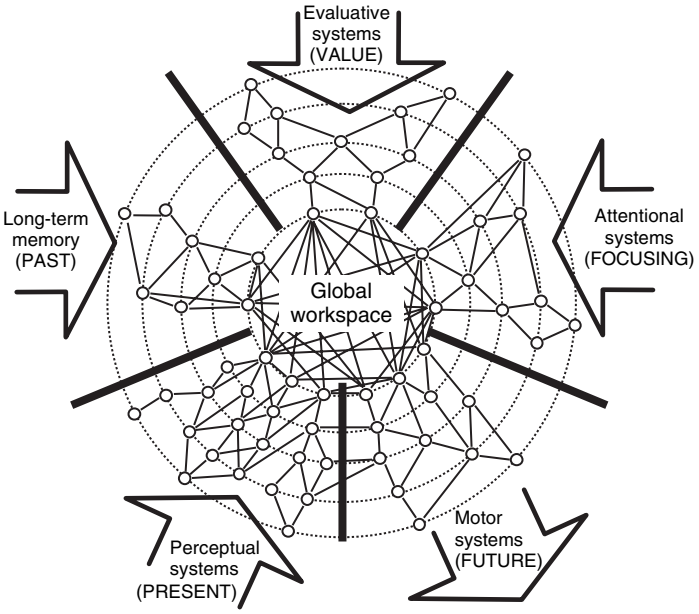

Figure 2 Schematic representation of the neuronal workspace hypothesis as initially proposed by Dehaene et al. (1998). The model distinguishes two computational spaces: (1) specialized processors, which are modular, encapsulated, and automatic, labeled here as perceptual systems, long-term memory (including autobiographic memory and self), and attentional and evaluative systems and (2) the global workspace, with long-range axon neurons broadcasting signals to multiple areas yielding subjective experience and reportability. From Dehaene S, Kerszberg M, and Changeux JP (1998) A neuronal model of a global workspace in effortful cognitive tasks. *Proc. Natl. Acad. Sci. USA* 95: 14529–14534; used with permission from the National Academy of Sciences.

processors (Baars, 1989) or modular subsystems (Shallice, 1988) subsumed by topologically distinct cortical domains with highly specific local or medium-range connections that encapsulate information relevant to its function. This specialized network processes information in a bottom-up manner (see Miyashita and Hayashi, 2000).

b. A global workspace, consisting of a distributed set of cortical neurons characterized by their ability to receive from and send back to homologous neurons in other cortical areas, horizontal projections through long-range excitatory axons (which may as well impinge on excitatory or inhibitory neurons). Such long-range corticocortical tangential connections include callosal connections and mostly originate from the pyramidal cells of layers 2 and 3. We therefore propose that the extent to which a given brain area contributes to the global workspace would be simply related to the fraction of its pyramidal neurons contributing to layers 2 and 3, which is particularly elevated in von Economo's type 2 (dorsolateral prefrontal) and type 3 (inferior parietal) cortical structures (von Economo, 1929). The pyramidal neurons from layers 2 and 3 establish, in addition, vertical and reciprocal connections with layer 5 neurons and thus corresponding thalamic nuclei. These connections contribute to both the stability and the dynamics of workspace activity, via, for instance, self-sustained circuits, but also mediate the direct access to and from the processing networks (Brecht et al., 2003). The global network neurons typically process information in a top-down manner.

1.38.2.4.2 Content of the global workspace

In the original formulation of the neuronal workspace hypothesis (Dehaene et al., 1998), five major categories of processors were distinguished which could be dynamically mobilized and multiply reconfigured (**Figure 2**).

a. *Perceptual circuits* give the workspace access to the present state of the external world. Empirically, perceptual circuits may include the primary and secondary sensory areas together with the object-oriented ventral and lateral areas of the temporal lobes in both visual (Mishkin and Ungerleider, 1982; Goodale et al., 1991; Fang and He, 2005) and auditory (Rauschecker and Tian, 2000) modalities as well as

the temporal and inferior parietal areas involved in language comprehension (including Wernicke's area) (Mesulam, 1998). Accordingly, the content of any external stimulus, attended object, or linguistic input can access the global workspace. Such access may take place stepwise through hierarchical stages of processing through primary and secondary sensory areas such as V1 and FEF (Lamme and Roelfsema, 2000) and then higher association areas of temporal, frontal, and cingulate cortex. In Dehaene et al. (2003a) and Dehaene and Changeux (2005) formulations, each area was further assumed to establish with the neighboring area bottom-up feedforward connections and top-down feedback projections, the top-down connections being slower, more numerous, and more diffuse (Felleman and van Essen, 1991; Salin and Bullier, 1995). Moreover, bottom-up connections were thought to impinge on glutamate α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors, whereas the top-down ones would primarily mobilize glutamate *N*-methyl-D-aspartate (NMDA) receptors (see Lumer et al., 1997).

b. *Motor programming circuits* allow the content of the workspace to be used to guide future motor behaviors and actions. A hierarchy of nested circuits implements motor intentions, from the highest level of abstract plans to individual actions, themselves composed of moves and gestures (Jeannerod and Jacob, 2005).

Empirically in humans, these circuits include premotor cortex, posterior parietal cortex, supplementary motor area, basal ganglia (notably the caudate nucleus), and cerebellum, as well as the high-level speech production circuits of the left inferior frontal lobe, including Broca's area. Connections of the workspace to motor and language circuits at the higher levels of this hierarchy endow any active representation in the workspace with the property of reportability (Weiskrantz, 1997; Dehaene et al., 2006), namely, the fact that it can be described or commented on using words or gestures.

c. *Long-term memory circuits* provide the workspace with an access to stored past percepts and events.

These long-term memory stores are likely distributed throughout the cortex according to their original content and modality; hippocampal and parahippocampal areas through reciprocal links with workspace neurons may play a special role in mediating the storage in and retrieval from these long-term stores.

d. *Evaluation circuits* (Dehaene and Changeux, 1989, 1991; Friston et al., 1994; Schultz et al., 1997) allow representations in the workspace to be selected according to a positive or negative value.

Empirically, the main anatomical systems in this respect include mesocortical noradrenergic, dopaminergic, serotoninergic, and cholinergic pathways together with the orbitofrontal cortex, anterior cingulate, hypothalamus, amygdala, and ventral striatum (see Everitt and Robbins, 2005). Autoevaluation systems develop from reciprocal projections allowing evaluation circuits to be internally activated by the current workspace content (Dehaene and Changeux, 1991) and, conversely, to selectively maintain or change workspace activity according to whether its value is predicted to be positive or negative (Dehaene and Changeux, 1991, 1995, 1997). These evaluation systems are the targets of drugs as instrumental reinforcers eventually resulting in drug self-administration or drug taking and mobilizing in particular medial prefrontal cortex and nucleus accumbens core (Everitt and Robbins, 2005; Christakou et al., 2004).

e. *Attention circuits* allow the workspace to mobilize its own circuits independently from the external world. Changes in workspace contents need not necessarily lead to changes in overt behavior, but may result in covert attention switches to selectively amplify or attenuate the signals from a subset of processor neurons.

Although all descending projections from workspace neurons to peripheral modular processors are important in this selective amplification process, a particular role is played by areas of the parietal lobe in visuospatial attention (Posner, 1994; Posner and Dehaene, 1994).

1.38.2.4.3 Global modulation of workspace activation

The state of activation of workspace neurons is assumed to be under the control of global vigilance signals from the ascending reticular activating system. Empirically they may include cholinergic nuclei in the upper brainstem and basal forebrain, noradrenergic nuclei (e.g., from the locus coeruleus), a histaminergic projection from the posterior hypothalamus, and dopaminergic and serotoninergic pathways arising from the brainstem (McCarley, 1999) together with recently identified orexin neurons from lateral hypothalamus (de Lecea et al., 1998; Harris et al., 2005). Much if not all of the influence exerted by these pathways is mediated by the thalamus and characterized by an increase in the excitability of the corticothalamic neurons.

Slow-wave sleep, on the other hand, coincides with a reduction of activity in the cholinergic, noradrenergic, and histaminergic nuclei, the anterior hypothalamus and basal forebrain being candidates for a critical role in sleep induction (Zeman, 2001). These signals are powerful enough to control major transitions between the awake state (workspace active) and slow-wave sleep (workspace inactive) states. Others provide graded inputs that modulate the amplitude of workspace activation, which is enhanced whenever novel, unpredicted, or emotionally relevant signals occur and, conversely, drops when the organism is involved in routine activity.

In the waking state the corticothalamic neurons are tonically depolarized by a blocking of hyperpolarizing potassium conductance (Steriade, 1999) (e.g., by acetylcholine acting on muscarinic receptors and norepinephrine on α_1-adrenergic receptors) switching them out of the slow-bursting mode and into fast gamma-band oscillations (Steriade et al., 1993; Llinas and Steriade, 2006). Similar effects can be obtained by electrical stimulation of the brainstem or by direct application of acetylcholine (McCormick and Bal, 1997). Moreover, mutations in the $\alpha 4$ and $\beta 2$-subunit genes of the nicotinic acetylcholine receptor cause autosomal dominant frontal lobe epilepsy (Steinlein, 2004), and deletion of the $\beta 2$-subunit is accompanied by a decrease of micro-arousals, which take place during slow-wave sleep (Léna et al., 2004).

As a consequence, the corticothalamic neurons show increased excitability: their signal-to-noise ratio is increased, and the response to sensory stimuli is facilitated. Their spontaneous activity is high and characterized by stochastic independence of time intervals between successive action potentials (Llinas and Paré, 1991; Steriade et al., 1993; Llinas and Steriade, 2006). By contrast, during slow-wave sleep, where consciousness is absent, signal-to-noise ratios to sensory responses are decreased, and most neurons tend to discharge in bursts synchronized over large populations, thus introducing distortions or blocking information transmission (Livingstone and Hubel, 1981).

In the resting awake state, the brain is the seat of an important baseline (Gusnard and Raichle, 2001; Raichle and Gusnard, 2005) or ongoing metabolic activity; a very large fraction of it (about 80%) being correlated with glutamate cycling and, hence, active synaptic signaling processes (Shulman and Rothman, 1998; Hyder et al., 2002; Raichle and Gusnard, 2002; Shulman et al., 2004). During slow-wave sleep, anesthesia, or coma, global cerebral glucose metabolism falls by about 20% (Heiss et al., 1985; Buchsbaum et al., 1989; Shulman et al., 2004), particularly in frontal and parietal cortices (Laureys, 2005; Laureys et al., 2006). Interestingly, optical imaging of visual cortex in anesthetized animals revealed structural states of activity which have a similar global organization as activity patterns evoked by external stimuli (Tsodyks et al., 1999; Kenet et al., 2003).

1.38.2.4.4 Spatiotemporal dynamics of workspace activity

From a theoretical point of view, the global workspace is considered the seat of a particular kind of brain-scale activity state characterized by the spontaneous activation, in a sudden, coherent, and exclusive manner, referred to as ignition (Dehaene and Changeux, 2005), of a subset of workspace neurons, the rest of workspace neurons being inhibited. The transition to this state of highly correlated activity is fast and characterized by an amplification of local neural activation and the subsequent activation of multiple distant areas. The entire workspace is globally interconnected in such a way that only one such workspace representation can be active at any given time (see Sigman and Dehaene, 2005, 2006). This all-or-none invasive property distinguishes it from peripheral processors in which, due to local patterns of connections, several representations with different formats may coexist.

A representation which has invaded the workspace may remain active in an autonomous manner and resist changes in peripheral activity (see Dehaene and Changeux, 1989, 1991). If it is negatively evaluated, or if attention fails, it may, however, be spontaneously and randomly replaced by another discrete combination of workspace neurons. Functionally, this neural property implements an active generator of diversity which constantly projects and tests hypotheses (or prerepresentations) on the outside world (Dehaene and Changeux, 1989, 1991, 1997). The dynamics of workspace neuron activity is thus characterized be a constant flow of individual coherent episodes of variable duration and their selection.

Although a variety of processor areas project to the interconnected set of neurons composing the global workspace, at any given time only a subset of inputs effectively accesses it. We postulate that this gating is implemented by descending modulatory projections from workspace neurons to more peripheral processor neurons. These projections may selectively amplify or extinguish the ascending inputs from processing neurons, thus mobilizing, at a given time, a specific set of

processors in the workspace while suppressing the contribution of others. In other words, the pattern of mobilized processor neurons defines the actual subjective content of conscious perception.

1.38.3 Formal Representation of the Neuronal Workspace Model

Since the initial formulation of Dehaene et al. (1998), the general architecture and dynamics of the neural network representing the global workspace and the relevant processors have been further specified in Dehaene et al. (2003a) and Dehaene and Changeux (2005). It is well understood that in any instance these computer simulations are partial and incomplete. Yet they are expected to point to the importance of particular components or features of these minimal architectures, thus leading to critical experimental tests. In our work, we found it useful to develop two quite distinct types of computer simulations. Some of them, referred to here as 'Type 1' models, were intended to describe an entire task-related cognitive architecture and thus focused more on global connectivity than on fine physiological details (e.g., Dehaene et al., 1998). Others, referred to as 'Type 2' models, were intended to capture some fine-grained physiological characteristics of neuronal firing trains and event-related potentials during conscious and subliminal perception. These simulations therefore necessarily incorporated considerably more physiological details of receptor types and cortical layers, but were not extended in a brain-scale architecture solving a precise task (e.g., Dehaene et al., 2003a; Dehaene and Changeux, 2005). Here, we describe their principles in turn.

1.38.3.1 Detailed Physiological Simulations of Access to the Conscious Workspace

In those Type 2 simulations, we intended to describe only part of the workspace (Dehaene and Changeux, 2005), but to do so with physiological details. The goal was to simulate the bottom-up/top-down interactions occurring between four hierarchically organized areas, the lowest of which was in contact with the external world while the highest was assumed to contact other workspace areas (not simulated).

1.38.3.1.1 Single-neuron model

The model (**Figure 3(a)**), adapted from Lumer et al. (1997a,b), was simulated at the level of single-compartment integrate-and-fire neurons whose membrane potential evolved according to semirealistic differential equations taking into account realistic temporal delays and AMPA, NMDA, and gamma-aminobutyric acid (GABA) currents. Neurons also received a diffuse neuromodulator input summarizing the known depolarizing effects of ascending activating systems, such as those from cholinergic, noradrenergic, and serotoninergic nuclei in the brainstem, basal forebrain, and hypothalamus (Steriade et al., 1993; Llinas and Steriade, 2006). This parameter was used to control the level of wakefulness (see following discussion).

1.38.3.1.2 Columnar structure

The neurons were organized into simulated thalamocortical columns comprising 80 excitatory and 40 inhibitory neurons and organized in a three-layered structure, schematizing supragranular, infragranular, and layer IV cortical neurons and a corresponding thalamic sector (**Figure 3(b)**). A fairly realistic scheme of connections was implemented, whereby thalamic excitatory neurons projected to layer IV (AMPA, 3 ms delay) and, with lesser strength, to infragranular neurons (AMPA, 3 ms). Layer IV excitatory neurons projected to supragranular neurons (AMPA, 2 ms). Supragranular excitatory neurons projected to infragranular neurons (AMPA, 2 ms). Finally, infragranular excitatory neurons projected to layer 4 (AMPA, 7 ms), to supragranular neurons (AMPA, 7 ms), and to the thalamus (AMPA, 8 ms). Those principles and parameter values capture the major properties of translaminar connections (Lumer et al., 1997a,b; Douglas and Martin, 2004), though they do not attempt to capture the possible functional roles of the different layers (see, e.g., Raizada and Grossberg, 2003).

1.38.3.1.3 Long-range connections

For corticocortical projections, supragranular excitatory neurons of each area projected to layer IV of the next area (AMPA, 3 ms). In agreement with physiological observations (Felleman and Van Essen, 1991; Salin and Bullier, 1995), top-down connections were slower, more numerous, and more diffuse. They connected the supra- and infragranular excitatory neurons of a given column to the supra- and infragranular layers of all areas of a lower hierarchical level. Strong top-down connections linked columns coding for the same stimulus, whereas weaker top-down connections projected to all columns of a lower area. Both were NMDA mediated, and transmission delays increased with cortical distance (delay $= 5 + 3\delta$ ms,

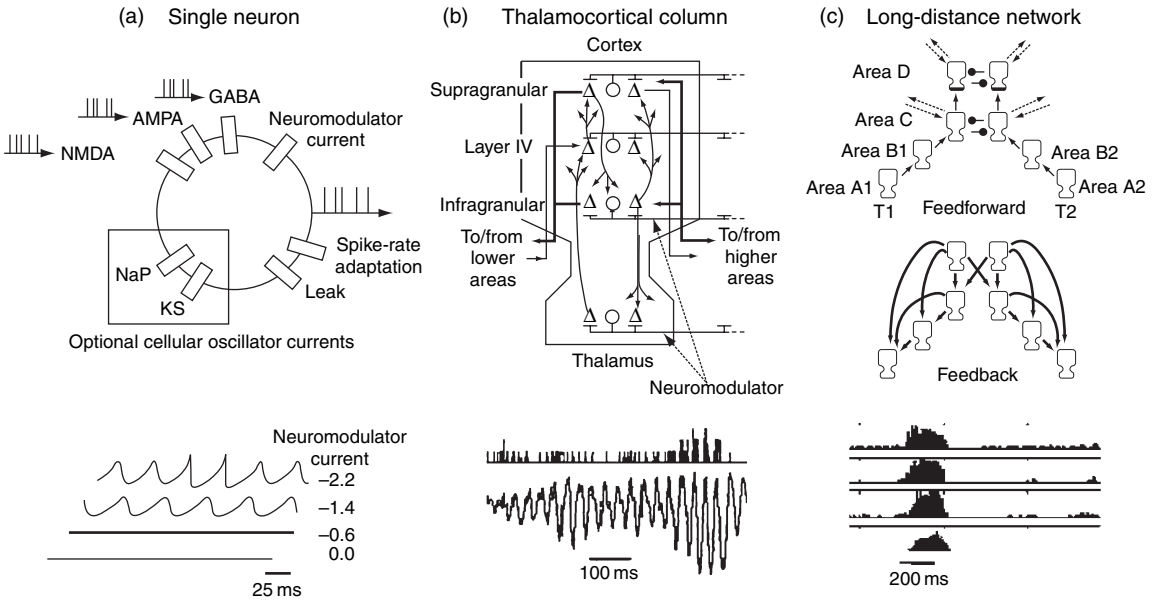

Figure 3 Detailed implementation, at the cellular and molecular levels, of the neuronal workspace model in the case of access to consciousness as in Dehaene et al. (2003b) and Dehaene and Changeux (2005). Single neurons may generate sustained oscillations of membrane potential at high enough level neuromodulator current (a) but only the thalamocortical column (b), and global network levels do generate complex waxing and waning EEG-like oscillations (b) and metastable global states of sustained firing (or 'ignition') (c). From Dehaene S, Sergent C, and Changeux JP (2003b) A neuronal network model linking subjective reports and objective physiological data during conscious perception. *Proc. Natl. Acad. Sci. USA* 100: 8520–8525, with permission from the National Academy of Sciences; and Dehaene S and Changeux JP (2005) Ongoing spontaneous activity controls access to consciousness: A neuronal model for inattentional blindness. *PLoS Biol.* 3: 910–927, with permission from the Public Library of Science.

with $\delta = 1$ for consecutive areas, 2 for areas two levels apart in the hierarchy, etc.).

1.38.3.1.4 Spontaneous activity

Although we studied stimulus-evoked activity (see later discussion), a most important goal of these stimulations was to also capture spontaneous corticothalamic activity and its modulation with states of vigilance. We studied two possible sources for spontaneous activity, both of which were meant as theoretical idealizations on a continuum of possibilities. The first case, hereafter the 'cellular oscillator model,' was a purely deterministic model in which neurons follow simple differential equations incorporating persistent sodium and slowly inactivating potassium currents whose interplay generates intrinsic gamma-band oscillations of membrane potential (Wang, 1993), comparable to those recorded experimentally (Llinas et al., 1998). We also described another simulation, hereafter called the 'random spikes' model, in which stochastic spontaneous activity arose from fast random fluctuations in membrane potential, capturing the joint effects of synaptic and postsynaptic noise on spike initiation. Both cellular sources turned out to have a similar effect on global spontaneous corticothalamic states (for details, see Dehaene and Changeux, 2005).

1.38.3.2 Minimal Models of Cognitive Architectures for Effortful Tasks

Another line of models, Type 1 simulations, attempted to capture behavioral and neuroimaging observations on higher-level 'executive' tasks that depend on prefrontal cortex (Dehaene et al., 1998), such as the Delayed-Response, Stroop, Wisconsin, or Tower of London tests (Dehaene and Changeux, 1989, 1991, 1997). We have not found it possible to design a pertinent model of such tasks while working at the level of detailed spiking neurons and columns. Thus, those models were of a more abstract nature and incorporated neural 'units' formally similar to single neurons or clusters whose average firing rate was simulated by McCulloch-Pitts units. No attempt was made to capture intracolumnar or thalamic dynamics, but the network incorporated a series of assemblies assumed to represent relevant cortical activity at several hierarchical levels.

1.38.3.2.1 Learning by reward

An interesting advantage of these coarser cognitive models is that they allowed for the simulation of longer periods of time and, therefore, of selective learning by reward, which empirically can be accompanied by drastic changes in vigilance and conscious access to task-relevant features. The network received a reward signal (R) provided after each network response ($R = +1$, correct; $R = -1$, incorrect). This reward led to two types of internal changes: classical synaptic weight changes of the Hebbian type, and a more original hypothesis of direct workspace activity modulation.

1.38.3.2.2 Synaptic weight changes

In the initial formulation of the theory (Dehaene et al., 1998) and for simplicity, only the synaptic weights between two excitatory units were assumed to be modifiable according to a reward-modulated Hebbian rule $\Delta w^{post,pre} = \varepsilon\ R\ S^{pre}\ (2\ S^{post} - 1)$, where R is the reward signal, pre is the presynaptic unit, and post is the postsynaptic unit (Dehaene and Changeux, 1989).

1.38.3.2.3 Workspace activity changes

Starting with our earliest modeling approaches (Dehaene and Changeux, 1989), we have assumed that reward entry can have either a stabilizing or destabilizing effect on prefrontal neuron activity. In Dehaene et al. (1998), we assumed that workspace neuron activity is under the influence of both vigilance and reward signals. The vigilance signal V is treated as having a modulatory influence on all workspace neurons. It is updated after each response: if $R > 0$, then $\Delta V = -0.1\ V$, otherwise $\Delta V = 0.5\ (1 - V)$. This has the effect of a slowly decreasing vigilance with sharp increases on error trials. The reward signal R influences the stability of workspace activity through a short-term depression or potentiation of synaptic weights (Dehaene and Changeux, 1989, 1991, 1997). A plausible molecular implementation of this rule has been proposed in terms of allosteric receptors (Dehaene and Changeux, 1989, 1991). It postulates that the time coincidence of a diffuse reward signal and of a postsynaptic marker of recent neuronal activity transiently shifts the allosteric equilibrium either toward, or from, a desensitized refractory conformation (Heidmann and Changeux, 1982, see also Changeux and Edelstein, 2005). Through this chemical Hebb rule, negative reward destabilizes the self-sustaining excitatory connections between currently active workspace neurons, thus initiating a change in workspace activity.

1.38.4 States of Vigilance as Spontaneous Thalamocortical Rhythms and Their Brain Imaging

The simulations of the vigilance states by Dehaene and Changeux (2005) type 2 modeling incorporate only minimal physiological mechanisms such as changes in a single current $I_{neuromodul}$, the depolarizing influence of ascending neuromodulation systems onto thalamic and cortical neurons (**Figure 3(a)**). They nevertheless suffice to generate a dynamical phase transition whose properties bear interesting similarity with actual empirical observations. We observed a robust threshold value of ascending neuromodulatory signaling beyond which structured neuronal activity emerged in the form of spontaneous thalamocortical oscillations in the gamma band (20–100 Hz, with a peak of the power spectrum around 40 Hz) (see also Bush and Sejnowski, 1996; Fuentes et al., 1996). The simulated waxing and waning synchronous bursts of oscillations bear similarity with empirical observations of transient periods of thalamocortical resonance, detected as bouts of gamma-band oscillations using electrophysiological recordings, for instance in the cat thalamus and cortex (Steriade et al., 1993; Steriade et al., 1996), or in humans using electro- and magneto-encephalography (Llinas and Ribary, 1993) (**Figure 3(b)**). They are proposed to represent the state of consciousness referred to as vigilance.

An original feature of the simulations is to characterize precisely the change in state in terms of a dynamical phase transition, referred to as a Hopf bifurcation. The Hopf bifurcation is continuous in the amplitude of spontaneous activity, which increases steadily from zero as vigilance increases. Thus it implements a true continuum of consciousness states, from high vigilance to drowsiness, and the various states of sleep anesthesia, or coma (Gajraj et al., 1999; Bonhomme et al., 2000; Sleigh et al., 2001). However, the Hopf bifurcation is also discontinuous in frequency space as the ascending neuromodulation increases. This may capture the observation that, during awakening or returning from anesthesia, there is a definite threshold for regaining of consciousness, which coincides with the threshold for emergence of high-frequency spontaneous thalamocortical oscillations.

Anatomically, the model predicts that in the awake state, spontaneous activity is present in all areas, but exhibits a higher degree of organization in higher cortical association areas, whose neurons are tightly interconnected by long distance into a global neuronal workspace and mobilize other low-level areas in a top-down manner. Thus, the model predicts that brain territories particularly rich in 'workspace neurons' with long-distance connections (i.e., prefrontal, parietal, superior temporal, and cingulate cortices) show the most intense and consistent spontaneous activity in the awake state. This prediction fits with the observation that the 'baseline' activity of the awake human brain at rest points to a network linking dorsal and ventral medial prefrontal, lateral parietotemporal, and posterior cingulate cortices (Gusnard and Raichle, 2001; Mazoyer et al., 2001; Raichle et al., 2001) which constantly fluctuates in synchrony with changes in electroencephalographic spectral content (Laufs et al., 2003) and shows the greatest drop in metabolism during anesthesia, sleep, coma, or the vegetative state (Maquet and Phillips, 1998; Fiset et al., 1999; Laureys et al., 2000; Paus, 2000; Balkin et al., 2002; Heinke and Schwarzbauer, 2002; Shulman et al., 2003). In striking agreement with the workspace model, volatile anesthetics have been recently shown to disrupt frontoparietal recurrent information transfer at gamma frequencies in the rat (Imas et al., 2005).

1.38.5 Interactions between External Stimuli and Ongoing Spontaneous Activity: Facilitation versus Competition

A most original aspect of Dehaene and Changeux's (2005) type 2 simulations on ongoing spontaneous activity concerns its interactions with external stimuli. These interactions can be facilitatory (higher spontaneous activity facilitates the detection of weak stimuli) or inhibitory (very high spontaneous activity preventing access to other external stimuli).

First, spontaneous activity may affect activation caused by external stimuli. The model predicts that ascending neuromodulatory current and the external input current combine in a smooth and largely additive fashion. The threshold for conscious access (ignition) is not fixed, but decreases as vigilance increases. At one extreme, very low levels of vigilance completely prevent the possibility of ignition, even by long and intense stimuli. Such stimuli only lead to a short pulse of activation through the thalamus and the early sensory areas of the model. Thus, we expect that early sensory signal can be processed, while higher cortical ones are attenuated, during altered states of consciousness. This prediction is consistent with empirical observations of auditory processing during sleep (Portas et al., 2000) or the vegetative state (Laureys et al., 2000), where stimuli activate the thalamus and auditory cortex, but fail to generate the distributed state of correlated prefrontal, parietal, and cingulate activity observed in awake normal subjects. Similar observations have been made with tactile or pain stimuli, suggesting that the lack of prefrontal–parietal–cingulate ignition is quite characteristic of those states (Laureys et al., 2002; Laureys et al., 2004).

Pharmacological agents such as nicotine, which can mimic and potentiate ascending cholinergic systems, might also have an influence on the perceptual threshold in visual masking or other psychophysical tests, which should be measurable both psychophysically and with brain imaging measures of ignition (e.g., prefrontal–cingulate activity in fMRI, P300 in event-related potentials). In schizophrenic patients, subliminal processing is intact, but the threshold for conscious perception of masked visual stimuli is increased, possibly relating to an impairment of top-down prefrontal–cingulate connectivity (Dehaene et al., 2003b; Del Cul et al., 2006). In such patients, we predict that nicotine might partially bring the conscious access threshold back toward its normal value.

Second, the model predicts that very high levels of spontaneous activity can prevent ignition by external stimuli (**Figure 4**). As mentioned, optical imaging of visual cortex in anesthetized animals has revealed structured states of spontaneous ongoing activity, which have the same global organization as activity patterns evoked by external stimulation (Tsodyks et al., 1999; Kenet et al., 2003). Moreover, high levels of spontaneous activity inhibit the sensory responses evoked by external stimuli, for instance, by whisker deflection in somatosensory cortex (Petersen et al., 2003). Such interactions with ongoing activity can provide an explanation for the large variability in spike trains evoked by repeated identical sensory stimuli (Arieli et al., 1996; Petersen et al., 2003).

The complete blocking of some incoming stimuli that occurs in the simulations of the model offers a plausible explanation for the psychological phenomenon of inattentional blindness (Newby and Rock, 1998). In this phenomenon, human observers engaged into an intense mental activity (such as

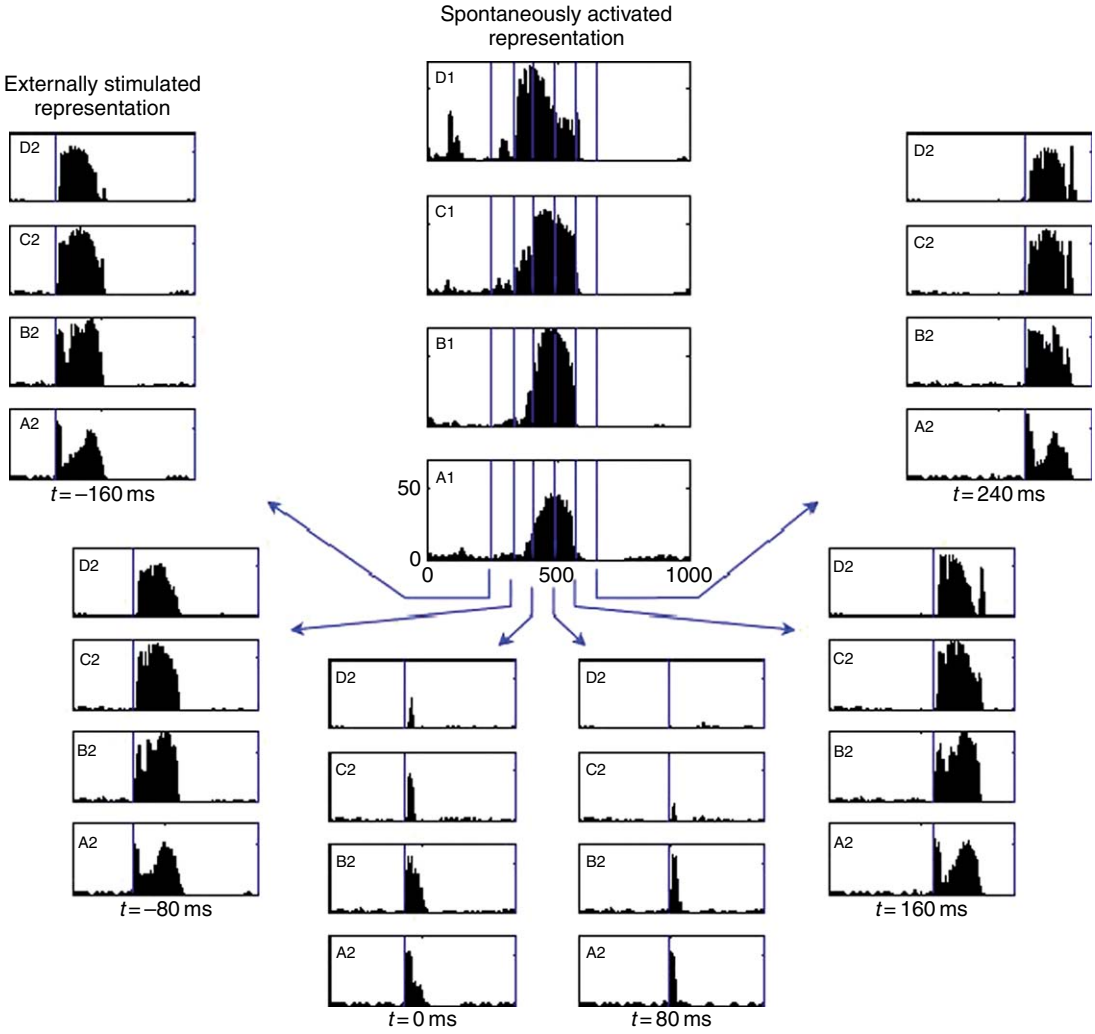

Figure 4 Competition between spontaneous workspace activity and external sensory simulation—a plausible model of the inattentional blindness state (Dehaene and Changeux (2005)). In the state of inattentional blindness, the subject fails to consciously detect external stimuli during periods of spontaneous thought. This can be reproduced by the simulations. In the boxes on the left of the figure, *before* the period of ongoing spontaneous activity, the external stimulus propagates in a bottom-up manner from the lowest (A) to the highest (B) areas of the sensory system yielding activation of the workspace (see **Figure 3(c)**). In the right boxes the same occurs *after* the period of spontaneous activity. On the other hand, when the external stimulus coincides with the period of spontaneous activity (center), its access to the workspace is inhibited. From Dehaene S and Changeux JP (2005) Ongoing spontaneous activity controls access to consciousness: A neuronal model for inattentional blindness. *PLoS Biol.* 3: 910–927; used with permission from the Public Library of Science.

detecting or counting stimuli of a certain type) become totally oblivious to other irrelevant stimuli, even when they occur within the fovea for a long duration (Simons and Chabris, 1999; Chun and Marois, 2002). Although inattentional blindness is typically studied in the laboratory by placing subjects in a predefined task, the simulations suggest that spontaneous trains of thought, unrelated to external stimuli and instructions, may also exert a temporary blocking. The model predicts that this state should be characterized by (1) an intense prefrontal–parietal–cingulate activation by the distracting thought or object prior to the presentation of the target stimulus; and (2) a proportional reduction of the target-induced activation to a brief bottom-up activation in specialized processors. fMRI studies provide direct support for those predictions (Rees et al., 1999; Weismann et al., 2005). Future research should extend those paradigms using time-resolved neuroimaging methods such as event-related potentials to

test the prediction that early bottom-up activation is preserved, but top-down recurrent reverberations are suppressed in an all-or-none manner.

1.38.6 Competition between Sensory Stimuli for Access to Consciousness: Looking for Objective Records of Subjective Perception

The model was also studied under conditions simulating a classical perceptual phenomenon referred to as the attentional blink where two sensory stimuli compete for access to reportable conscious perception (Raymond et al., 1992). In a typical experiment, participants are asked to process two successive targets, T1 and T2. When T2 is presented between 100 and 500 s after T1, the ability to report it drops, as if the participants' attention had 'blinked.' In other words, rather paradoxically, perception of a first visual stimulus may prevent the subjective perception of a second one. The paradigm is sufficiently simple and explicit to study why some patterns of brain activity have access to subjective experience and thus to establish, in a causal, mechanistic manner, a link between subjective reports and objective physiological recordings.

The minimal network proposed (Dehaene et al., 2003a; **Figure 3**) is composed of four hierarchical stages of processing where stimuli T1 and T2 evoke neuronal assemblies. At the lower level, A and B correspond to primary and secondary visual areas and C and D to higher association areas, including temporal and frontal cortex. At the lower level, the assemblies do not inhibit each other (see Arnell and Jolicoeur, 1997), but further on, T1 and T2 reach higher association areas C and D, where they compete for global access via reciprocal inhibitory interactions.

With the network placed in a regime of spontaneous thalamocortical oscillations, corresponding to a state of wakefulness (see earlier discussion), one distinguishes two principal modes of signal processing by the network. First, let us consider the simple case where T1, in the absence of competing stimuli, is consciously perceived. T1 evokes a short burst of phasic physiological activity that propagates across the A to D corticothalamic hierarchy. Reaching the highest cortical levels, the sensory input generates top-down amplification signals which, about 80 ms later, cause sustained firing in areas A and B. In a larger-scale simulation, such a long-lasting dynamic state would generate brain-scale propagation of stimulus information into the entire workspace network. It is proposed that this global broadcasting constitutes the physiological basis of conscious reportability.

The network also simulates the conditions of the 'blink' when T1 and T2 are presented in close succession. Experimentally it is known that when T2 is either presented simultaneously with T1, or long after, it is, in both cases, subjectively perceived. The network simulation indeed shows that in both conditions, sustained firing supported by joint bottom-up activation and top-down amplification takes place. Yet, under conditions of close temporal succession, a T2 stimulus presented during T1-elicited global firing elicits bottom-up activation restricted to levels A and B, but fails to propagate to higher cortical levels. As a result, the second phase of top-down amplification does not occur. The T2 stimulus is blinked from conscious perception (**Figure 5**).

The simulation predicts that a temporary drop in firing rate of pyramidal cells coding for T2 in areas C or D is associated with a loss in performance typical of the attentional blink. The model also shows a global drop of power emitted in the gamma band and of cross-correlations between distant T2-coding neurons. Thus, several indexes of firing and synchrony all point to a drop in global activity during the blink, particularly evident in the higher areas C and D.

An original property of the model is the distinction of two modes of signal processing – a nearest-neighbor bottom-up propagation of sensory stimulation across the hierarchy of areas and a long-distance top-down network that sends amplification signals back to all levels below it. In particular, it predicts a dynamic all-or-none bifurcation between the two modes associated with different subjective perception of the stimulus. Indeed, objective physiological data indicate that during this blink, T2 fails to evoke a P300 potential, but still elicits event-related potentials associated with visual and semantic processing (P1, N1, and N400) (Vogel et al., 1998).

The prediction of an all-or-none loss of conscious perception and of T2-induced higher-level brain-scale activation during the attentional blink was tested experimentally (Sergent and Dehaene, 2004; Sergent et al., 2005). We used a modified attentional blink paradigm in which human subjects merely had to report to what extent they had seen a word (T2) within a rapid letter stream that contained another target letter string (T1). To obtain a continuous measure of subjective perception, subjects were asked to move a

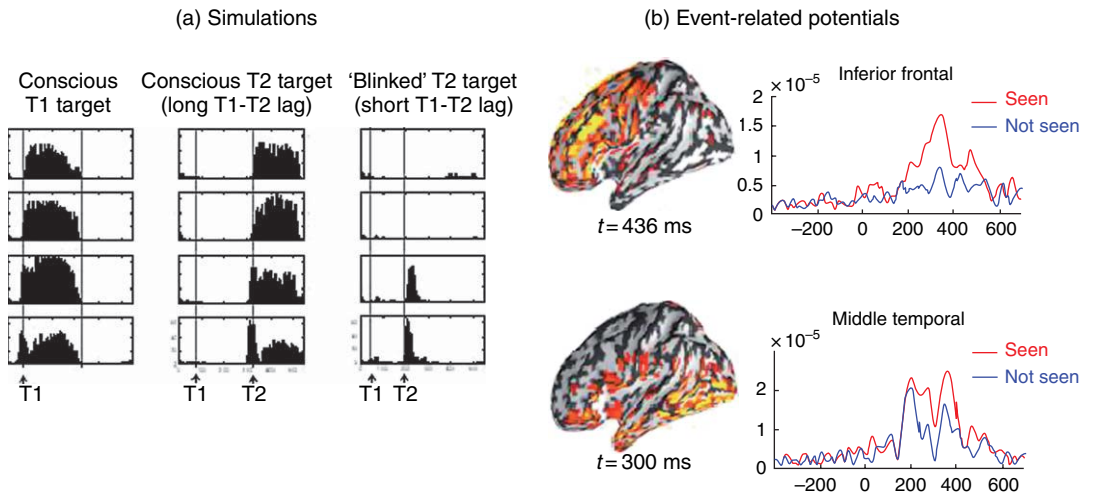

Figure 5 Comparison of the predictions of the neuronal workspace model (from Dehaene et al., 2003b) with the temporal dynamics of cortical electrical activity evoked by seen and unseen stimuli (from Sergent et al., 2005) during the attentional blink task. (a) Simulation of three trials of the attentional blink task. In each column with eight boxes (reproducing the superposed areas of **Figure 3(c)**) is shown the evolution of the computed firing rate in excitatory neurons. *Left column:* the sensory stimulus T1 accesses the workspace; *central column*: the lag between T1 and the second stimulus T2 is such that the sustained activity elicited by T1 has decayed in such a way that T2 accesses the conscious workspace; *right column*: the short lag between T2 and T1 is such that the sustained activity in T1 interferes with the access of T2 to the workspace. (b) Event-related potentials recorded during the attentional blink task at the level of the inferior frontal cortex where differences are noted between subjectively seen and not seen stimuli. Such difference is not observed in the initial bottom-up activation of the temporal cortex (200 ms) but converges later on during a global reverberation phase (300–400 ms). From Dehaene S, Sergent C, and Changeux JP (2003b) A neuronal network model linking subjective reports and objective physiological data during conscious perception. *Proc. Natl. Acad. Sci. USA* 100: 8520–8525, with permission from the National Academy of Sciences; and Sergent C, Baillet S, and Dehaene S (2005) Timing of the brain events underlying access to consciousness during the attentional blink. *Nat. Neurosci.* 8: 1391–1400, with permission from Nature Publishing Group.

cursor on a continuous scale, from 'not seen' on the left to 'maximal visibility' on the right. The results indicate that the reported subjective perception during the blink is indeed all-or-none (Sergent and Dehaene, 2004; Sergent et al., 2005) and relates to the loss of activation in a distributed, synchronous network prominently involving inferior and lateral prefrontal cortices as well as anterior cingulate (Marois et al., 2004; Gross et al., 2004; Sergent et al., 2005; Hommel et al., 2006).

The model in its simple formulation is coherent with previous proposals of a role of top-down recurrent (Lamme and Roelfsema, 2000), reentrant (Edelman, 1993), or resonant (Llinas et al., 1998) connections in the integrative processing of consciously perceived signals. It is also supported by recent experimental data. Because the blink is attributed to competition for workspace access, the proportion of T2 targets that are blinked, as a function of time, roughly traces the inverse shape of the neural activity evoked by T1 in higher-level areas C and D. In actual experiments, similarly, there is an inverse relation between the P300 waveform evoked by T1 and the size of the blink (Sergent et al., 2005). Furthermore, the fMRI activation elicited by T1 in parietal, frontal, and cingulate areas predicts the size of the blink (Marois et al., 2000). Last, the timing of the brain events during the attentional blink using letter strings was recently resolved by event-related potentials. The data show that early potentials (P1 and N1) were equally evoked by seen and not seen words, indicating that these early brain events do not fit with conscious perception. However, a rapid divergence was observed around 270 ms, with late brain events solely evoked by seen words (Sergent et al., 2005) (**Figure 5**). The data are thus fully consistent with the proposal of the model (Dehaene et al., 2003a) that top-down amplification signals and sustained firing into the workspace network constitutes the physiological basis of conscious reportability.

Although there have been no single-neuron recordings during the attentional blink, the simulated profiles of single-neuron activity to seen and blinked T2 targets can be compared to electrophysiological recordings obtained in other paradigms of conscious and unconscious processing. In perceptual areas A and B of the

model, neurons fire phasically in tight synchrony with the stimulus, then show a broader period of late amplification only in seen trials, not in blinked trials. This parallels experimental recordings in areas V1 and IT under conditions of inattention, reduced contrast, masking, or anesthesia, where late amplification occurs only for reportable stimuli (Lamme and Roelfsema, 2000; Super et al., 2001; Lamme et al., 2002). The presently available physiological data are thus consistent with the proposal of the neuronal workspace model that conscious access of reportable signals is a sudden self-amplifying bifurcation leading to a global brain-scale pattern of activity in the workspace network.

1.38.7 Preconscious States of Activity

Despite considerable progress in the empirical research on the brain imaging of conscious perception, debates have arisen about the coherence of these data. For instance, some researchers emphasize a correlation of conscious visual perception with early occipital events (Zéki, 2003), others with late parietofrontal activity (Sergent et al., 2005). Also, following Weiskrantz (1997), we insisted on the notion that subjective reports are the basic criterion that can establish whether a percept is conscious or not. Yet, the philosopher Ned Block (2005) has suggested that in reality, we may experience conscious experiences that are richer in content than what we can report. For instance, when an array of letters is flashed, viewers claim to see the whole array, although they can later report only one subsequently cued row or column. The initial processing of the array might already be considered as 'phenomenally' conscious though not 'seen' in a fully conscious manner (Lamme, 2003; Block, 2005).

We have expressed our disagreement with the phenomenal/access distinction, whose empirical testability is debatable, and have argued instead that within nonconscious processing, one must introduce a transient preconscious state of activity in which information is potentially accessible, yet not accessed (Dehaene et al., 2006). This led to the formal distinction (Dehaene et al., 2006) (**Figure 6**) within nonconscious information processing of:

(1) ***Subliminal processing*** of input signals that may occur when bottom-up activation is insufficient to trigger a large-scale reverberating state. The described simulations of a minimal thalamocortical network (Dehaene and Changeux, 2005) show that in a global network of neurons with long-range axons exhibiting nonlinear self-amplifying properties, a well-defined dynamic threshold exists beyond which activity quickly grows until a full-scale ignition is seen, while a slightly weaker activation quickly dies out.

(2) ***Preconscious processing***, a term coined to design a neural process that potentially carries enough activation for conscious access, but is temporarily buffered in a nonconscious store. Such a buffering might result

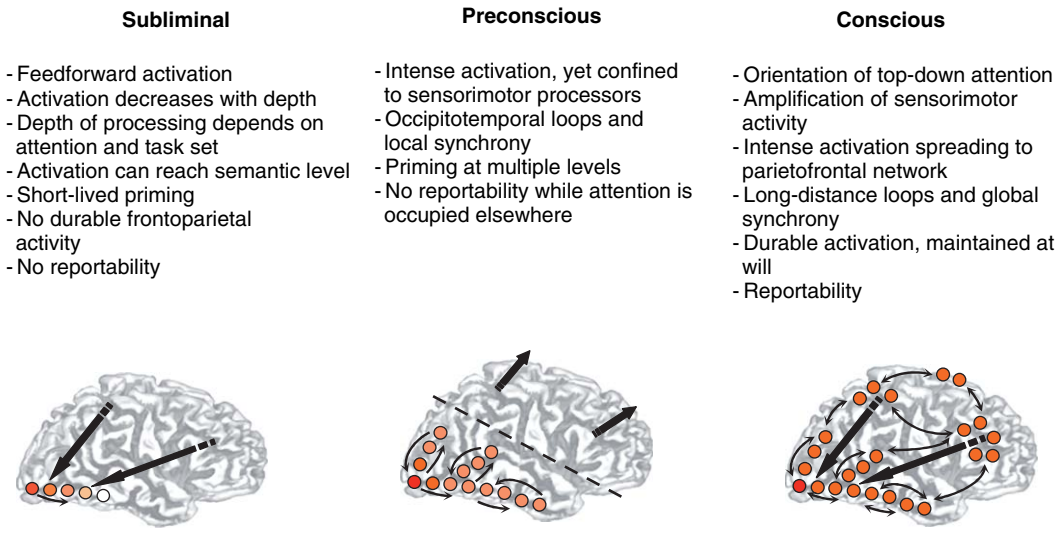

Figure 6 Schematic representation of the subliminal, preconscious, and conscious states of processing of visual stimuli. From Dehaene S, Changeux JP, Naccache L, Sackur J, and Sergent C. (2006) Conscious, preconscious, and subliminal processing: A testable taxonomy. *Trends Cogn. Sci.* 10: 204–211; used with permission from Elsevier.

from a lack of top-down attentional amplification, for example, owing to transient occupancy of the central workspace system (see preceding discussion and Dehaene and Changeux, 2005). The formal analysis of the attentional blink and inattentional blindness paradigms, indeed, has shown that even strong visual stimuli may remain temporarily preconscious. They are potentially accessible (they could quickly gain access to conscious report if they were attended), but they are not consciously accessed at the moment. At the neurocomputational level, preconscious processing is proposed to involve resonant loops within medium-range connections which maintain the representation of the stimulus temporarily active in a sensory buffer for a few hundred milliseconds.

In a fair attempt to establish objective recordings of subjectively reported conscious perception, these various conditions have to be experimentally and theoretically examined. In particular, other independent methods for decoding conscious states based, for instance, on trained pattern classifiers of fMRI or alternative physiological signals might be used to 'objectively' track signal processing in the course of conscious perception (Haynes and Rees, 2005, 2006), thus offering closer tests of the theoretical models.

1.38.8 Performance of an Effortful Deduction Task: The Stroop Task

Our modeling approach was developed along two distinct lines: *type 2* models were intended to capture some fine-grained physiological characteristics of neuronal firing trains and event-related potentials during conscious and subliminal perception. These simulations therefore necessarily incorporated considerably more physiological details of receptor types and cortical layers, but were not extended in a brain-scale architecture solving a precise task (e.g., Dehaene et al., 2003a; Dehaene and Changeux, 2005). On the other hand, the *type 1* models were intended to describe an entire task-related cognitive architecture and thus focused more on global connectivity than on fine physiological details (e.g., Dehaene et al., 1998). The Stroop task (McLeod, 1991) was selected as a simple experimental paradigm where a subject has to make a decision about the meaning of a written word under conditions where interference may occur. For instance, the subject is asked to give the color of the ink with which a color word is printed, and the meaning of the word may differ from the actual color of the printed word. Under this last condition, the subject has to make a conscious effort to give the correct response. The task was originally simulated with the standard neuronal workspace model (Dehaene et al., 1998), in which four input units were dedicated to encoding four color words, four other input units encoded the color of the ink used to print the word, and four internal units corresponded to the four naming responses. Routine color naming and word naming are implemented by direct one-to-one connections between these units and the corresponding output naming units. Workspace activation is not needed for any of these tasks. However, the effortful task (color naming with word interference) consists of providing conflicting word and color inputs and rewarding the network for turning on the naming unit appropriate to the ink color. When the naive network is switched to the effortful condition, an initial series of errors takes place as the network steadily applies the routine naming response. Yet, the delivery of negative reward leads to an increase in vigilance and to the sudden activation of variable patterns among workspace units resulting in a search phase for the next $\sim$30 trials. Workspace activation varies in a partly random manner as various response rules are explored, but the workspace activation patterns that lead to activating the incorrect response unit are negatively rewarded and tend to be eliminated in subsequent trials (**Figure 7**). Eventually, the network settles into a stable activation pattern, with a fringe of variability that slowly disappears in subsequent trials. This stable pattern, which leads to correct performance, is characterized by the differential amplification of the relevant word units relative to color units and by strong excitatory connections among active workspace units maintaining the pattern active in the intertrial interval.

Following the search phase, the network goes through a phase of effortful task execution in which workspace activation remains indispensable to correct performance. During this phase, workspace activity remains high, even on occasional trials in which the word and ink color information do not conflict. When performance is correct for a series of consecutive trials, vigilance tends to drop. However, any lapse in workspace activation is immediately sanctioned by an error. Each error is immediately followed by an intense reactivation of the workspace. Progressively, though, the task becomes routinized as the Hebbian rule applied to processor units tends to increase the color-to-name connections and to decrease the

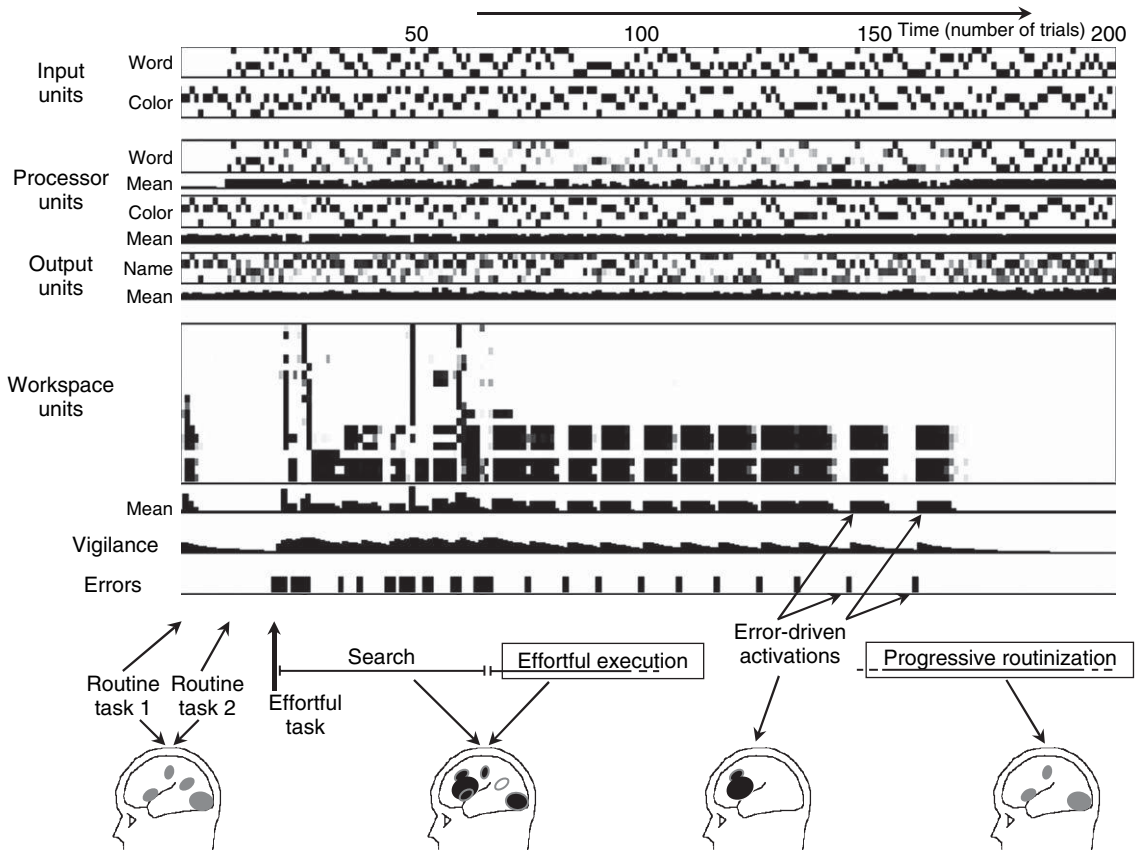

Figure 7 Simulation of the temporal dynamics of the Stroop task based on the original simulation of the neuronal workspace model of Dehaeneet al. (1998). The Stroop task was introduced without warning after routine trial no. 20. Note the selective activation of workspace units with a simultaneous amplification of color processors and a suppression of word processors. Workspace unit activation is seen in the initial phase of searching the appropriate response rule during the effortful execution of the task and following each erroneous response. Lower line: putative brain imaging correlates of workspace activation and routine are shown. From Dehaene S, Kerszberg M, and Changeux JP (1998) A neuronal model of a global workspace in effortful cognitive tasks. *Proc. Natl. Acad. Sci. USA* 95: 14529–14534; used with permission from the National Academy of Sciences.

word-to-name connections. Routinization is characterized by increasingly longer periods of correct performance in the absence of workspace activation.

The key empirical prediction of our hypothesis in the domain of brain imaging is the existence of a strong correlation between cortical areas that are found active in conscious effortful tasks and areas that possess a strong long-distance corticocortical connectivity (**Figure 7**). The global activation of neurons dispersed in multiple cortical areas is expected to be visualized as a temporary increase in the long-distance coherence of brain activity in electro- and magnetoencephalography or in studies of functional connectivity with fMRI.

The model also predicts that areas rich in workspace neurons will appear as suddenly activated when a novel, nonroutine task is introduced while being absent during routine tasks and will vary semi-randomly during the initial learning of a novel task. The level of activation should be high and stable during execution of a known but not yet routinized effortful task and should decrease during routinization, but should resume sharply following an error.

Brain-imaging experiments indicate that the workspace network which includes dorsolateral prefrontal cortex (dlPFC) and anterior cingulate (AC) is active in effortful cognitive tasks, including the Stroop test, with a graded level of activation as a function of task difficulty (Pardo et al., 1990; Cohen et al., 1997; Paus et al., 1998). With automatization, activation decreases in dlPFC and AC, but it immediately recovers if a novel, nonroutine situation occurs (Raichle, 1994). AC activates in tight synchrony with subjects' errors (Dehaene and

Cohen, 1994; Carter et al., 1998). Data consistent with the model have been recently obtained with a rather elaborate reward-based logical deduction task referred to as 'master-brain' task (Landmann et al., 2006). In the course of this trial-and-error learning process, the subjects have to infer the identity of an unknown four-key code on the basis of successive feedback signals but also through internal autoevaluation deductions. This search period is followed by a routine period during which subjects merely repeatedly execute the identified sequence. fMRI measurements reveal a sudden activation during search of the expected workspace circuits which include bilateral frontoparietal (particularly the lateral orbitofrontal and dorsolateral prefrontal cortex) and anterior cingulated cortex, striatum, and midbrain together with the cerebellum (**Figure 8**). This activation collapses during ensuing periods of routine sequence repetition. Furthermore, examination of brain activation during logical and chance discovery showed an early collapse when the correct logical sequence could be deduced without waiting to receive an actual external reward. In agreement with the simulations of the neuronal workspace model in the case of the Stroop task (Dehaene et al., 1998), the data reveal large-scale changes in interconnected distant cortical areas, which may take place tacitly according to an autoevaluation process. They add an important aspect, the differential activation of the striatum: The activation of the putamen and a part of the right caudate body indexes the sign of the reward prediction error (referred to as a ventral 'critic'), and the head of the right caudate indexes the available information that can be extracted from it (referred to as a dorsal 'actor') (see Sutton and Barto, 1981; Schultz et al., 1997; O'Doherty, 2004). This relationship between the workspace network and the underlying subcortical reward networks,

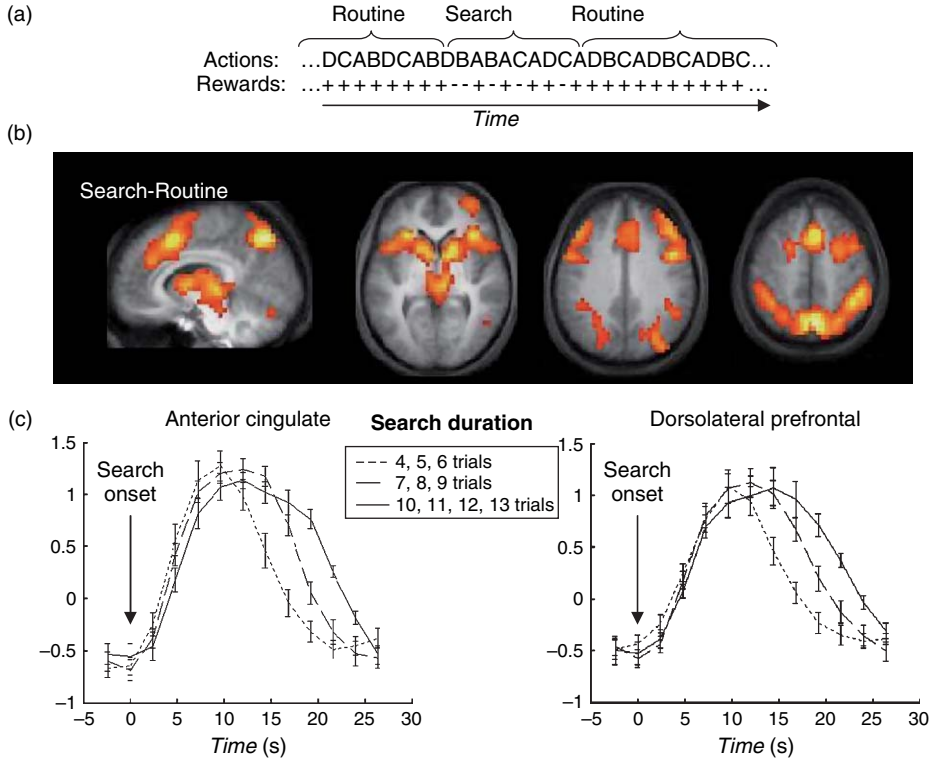

Figure 8 Brain imaging fMRI data of the dynamics of prefrontal and cingulate activity during a reward-based logical deduction task (Landmann et al., 2006). (a) Subjects were engaged in a motor trial-and-error learning task, in which they had to infer the identity of a hidden four-key press by trial-and-error (here ADBC). The design of the task allowed subjects to base their inferences not only on the feedback they received but also on internal deductions and evaluations. (b) fMRI imaging revealed, in agreement with the neuronal workspace model (**Figure 7**), a large bilateral activation of parietal, prefrontal, cingulate, and striatal networks during the search period that collapsed during ensuing routine execution. From Landmann C, Dehaene S, Pappata S, et al. (2006) Dynamics of prefrontal and cingulate activity during a reward-based logical deduction task. *Cereb. Cortex* 17: 749–759; used with permission from Oxford University Press.

which was not taken into consideration in the detailed model of access to consciousness, becomes accessible on both theoretical and experimental grounds.

1.38.9 The Evolution of Consciousness

1.38.9.1 Animal and Human Consciousness

Since the provocative statements of Thomas Huxley that "we are conscious automata," that "brutes" share consciousness with humans (1874) and that "all states of consciousness in us, as in them, are immediately caused by molecular changes of brain substance," nonhuman species and especially laboratory animals have served as experimental models for the scientific investigation of behavior but also of animal consciousness (Thorndike, 1898; Yerkes, 1916; Barresi and Moore, 1996; Jasper, 1998; Koch, 2004; Changeux, 2006). In the framework of the present discussions about neurocomputational models of consciousness, a first challenging issue is thus to what extent the neuronal workspace model may be usefully exploited to define and evaluate consciousness in animals. A second related question is whether or not functionally homologous (rather than analogous) neural structures might be at work in these nonhuman species. Answers to both questions are of importance, in particular if one wishes to use laboratory animals like the mouse as experimental models to investigate the neural bases of consciousness (see Changeux, 2006).

As early as 1921, the Italian neurologist Luigi Bianchi stated that "among the phenomenal factors of the activities of living organisms" arises a "bond of coherence" which "progresses with the development and complexity of living organisms and of their nervous system" that he referred to as consciousness. He further specified that "the dawn of higher consciousness coincides with the apparition of the frontal lobes in the evolution of the brain" and also noted their "inhibitory power" and their capacity for "intellectual syntheses." Bianchi in many respects anticipated several of the presently suggested ideas and theories about consciousness (Changeux, 1983; Shallice, 1988; Edelman, 1989; Crick, 1994; Crick and Koch, 2003; Dehaene and Changeux, 2004; Changeux and Edelstein, 2005; Naccache, 2005; and Naccache et al., 2005, among many others). Following these views, one may then argue that lower species like mice, or even birds, which have a reduced or even absent prefrontal cortex – a critical component of the neuronal workspace circuits – have little if any consciousness. Would experimental and theoretical investigations with the laboratory mouse be simply irrelevant to a scientific investigation of consciousness (see Block, 2005)?

It is of interest to reevaluate these issues in the framework of the neuronal workspace model with nonhumans as well as with humans in the course of both ontogenetic and phylogenetic evolutions. A first point to note is that looking at the developing human infants, Preyer already stated in 1894, "There is not the least reason for assuming in advance that every human being comes into the world endowed with complete consciousness of self" and "there are several grades of consciousness." Developmental studies with humans from the newborn to the adult (Zelazo, 1996; Lagercrantz et al., 2002; Zelazo, 2004; Johnson, 2005; Lagercrantz, 2005; Bartocci et al., 2006) reveal without ambiguity that, beyond its diverse definitions, consciousness cannot be viewed as an irreducible and unique global entity. A similar conclusion emerges from ethological and experimental studies with evolutionarily distant species, such as mice, monkeys, and apes (see Boakes, 1984; Trivers, 1985; Barresi and Moore, 1996; Changeux, 2002). Comparative analysis of these systems suggests a breakdown of consciousness into multiple nested hierarchical levels. Here, we tentatively propose a first classification into four levels, all the while realizing that it remains necessarily arbitrary and simplistic (see Changeux, 2006). Note that these represent landmark points on a continuum rather than sharp distinctions, because our goal is to emphasize a continuity of phylogenetic and ontogenetic stages to full-blown adult human consciousness. The proposed levels comprise:

a. A lower level of minimal consciousness for simple organisms, like rats or mice, which undergo cycles of sleep and wakefulness, possess the capacity to display spontaneous motor activity and to create representations, for instance from visual and auditory experience, to store them into long-term memory and use them for approach and avoidance behavior; these organisms exhibit what is referred to as exploratory behavior (see Thinus-Blanc et al., 1996; Granon et al., 2003); they are amenable, as humans, to trace conditioning (which in humans requires awareness) and to delay conditioning (which does not) (Han et al., 2003). These organisms do not make reference to an *explicit* sense of self and display

minimal social interactions.

In humans, the 25- to 30-week preterm fetus processes tactile and painful stimuli in the sensory cortex (see brain imaging studies by Bartocci et al., 2006) and might thus perceive pain when awake; he/she might have reached a stage of brain maturation analogous (though not identical) to that of a newborn rat/mouse (see Lagercrantz, 2005).

b. Basic consciousness, present, for instance, in vervet monkeys (possibly also in some birds), manifests itself by functional use of objects, protodeclarative pointing, and searching for hidden objects; organisms at this level may display elaborate social interactions, imitations, social referencing, and joint attention; they possess the capacity to hold several mental representations in memory simultaneously and are able to evaluate relations of others to self.

In humans, newborn infants exhibit, in addition to sensory awareness, the ability to process memorized mental representations (e.g., of a pacifier), to express emotions, and to show signs of shared feelings or empathy (Singer, 2006). Even newborns differentiate between self and nonself touch (Rochat, 2003) and imitate the tongue protrusion of an adult (Meltzoff, 1990). At a few months of age, responses to novelty are present and include a late negativity wave which has been tentatively assigned to prefrontal cortex (Dehaene-Lambertz and Dehaene, 1994; Reynolds and Richards, 2005). Prefrontal cortex is active in response to speech, but only in awake infants, not when asleep (Dehaene-Lambertz et al., 2002). Thus access of sensory information to consciousness may already be present, though capacities for internal manipulations in working memory are reduced if not absent.

c. Explicit self-consciousness develops in infants at the end of the second year, together with working and episodic memory and language; it is characterized by self-recognition in mirror tests and by the use of single arbitrary rules with knowledge of one's own behavioral potential and self–other distinction; to some extent chimpanzees might reach this level (see Boakes, 1984).

d. Reflective consciousness with theory of mind and full conscious experience, first-person ontology, and explicit report, is unique to humans and develops after 3–5 years in children.

Examination of this first preliminary classification leads to a simple and unambiguous conclusion. First, adult human consciousness develops progressively, starting from rather rudimentary dispositions in the newborn. Second, mice and rats do not go far beyond the level of minimal consciousness.

1.38.9.2 Minimal Consciousness in Mice and Rats

Careful examination of mouse and rat behavior (see Brown and Bowman, 2002; Granon et al., 2003; Han et al., 2003) in the context of the neuronal workspace and as possible models of human psychiatric disorders (see Granon and Changeux, 2006) leads to the following conclusions.

a. Multiple states of consciousness (such as wakefulness, sleep, coma, general anesthesia, epileptic seizures) and the regulation of their reversible transitions occur in the mouse, as in all mammals, including humans. The circadian sleep–waking cycle mobilizes rather universal mechanisms (Llinas and Steriade, 2006) and is controlled throughout vertebrate species by brainstem reticular formation and intralaminar nuclei of the thalamus (Bogen, 1995; Jones, 1998) with complex patterned releases of neuromodulatory substances. For instance, in the framework of the current studies on nicotinic acetylcholine receptors (nAChR) (Changeux and Edelstein 2005), gene inactivation studies demonstrate the positive contribution of the $\beta 2$ subunit of the nAChR to the phasic expression of arousal promoting mechanisms by endogenous acetylcholine (Cohen et al., 2002; Léna et al., 2004), and similar phenotypes as those noticed in the knockout mice are observed after chronic in utero exposure of the fetus to nicotine (Cohen et al., 2005). These mice thus offer a plausible animal model of sudden infant death syndrome, whose prevalence is known to increase in smoking pregnant women (Cohen et al., 2005).

The use of the neuronal workspace formalism (see Dehaene and Changeux, 2005) might, in this respect, be of some help. One may, for example, view the various graded states of consciousness (from deep anesthesia and coma to full awareness) as directly related to the spontaneous activity of recurrent thalamocortical loops and reticular thalamic nuclei (see Llinas and Paré, 1991; Steriade et al., 1993) as described in the model. Conclusively, the description of the neural mechanisms involved in the transition to wakefulness appears relevant to the case of the mouse as well as its application to models of human pathologies.

b. Delayed-response tasks, exploratory behavior, and flexible goal-directed behaviors. Since the early 1990s (Kolb, 1990), a rich body of behavioral and pharmacological observations has revealed that rats display working memory, attentional processes, and flexible goal-directed behavior which rely on the contribution of the prefrontal cortex (Kolb, 1990). For example, rats may perform an effortful, counterinstinctive, delayed-response task referred to as delayed matching-to-sample that lesions of the prefrontal cortex selectively impair, at variance with a spontaneous delayed nonmatching-to-sample task (Granon et al., 1994). Moreover, in these pioneering studies, it was already shown that cholinergic pathways (Nordberg and Winblad, 1986; Levin, 1992) and specifically their nicotinic component selectively control these cognitive processes (injection of neuronal bungarotoxin into the prelimbic area of the prefrontal cortex selectively impairs the task) (Granon et al., 1995).

In the mouse, exploratory activity is a spontaneous behavior (Thinus-Blanc et al., 1996; Poucet and Herrmann, 2001) that serves to gather and store spatial information which allows allocentric coding of space, itself necessary for flexible navigational processes. Quantitative analyses (Faure et al., 2003) with mice lacking the high-affinity nAChR further reveal that the balance between navigation and exploration shifts in favor of navigation to the detriment of more precise exploration of the environment. Additional comparative studies including several objects presentations in an open-field arena and elementary social behavior (between a test resident mouse and a social intruder) revealed that mice deleted for the nAChR $\beta 2$ subunit are more rigid and exhibited less behavioral flexibility than wild-type mice (Granon et al., 2003; Maskos et al., 2005). The prefrontal cortex is particularly reduced in size in the mouse, yet its lesions (Granon, unpublished) cause evident deficit in the aforementioned conflict-resolution situations and, moreover, create a behavioral phenotype which displays several features in common with the loss of $\beta 2$-nAChR.

These studies unambiguously demonstrate: (1) the specialization of neural circuits engaged in such executive functions which most often (though not always) mobilize the prefrontal cortex; (2) the gating of these functions by nAChRs activated through endogenously released acetylcholine; and last, (3) the intimate relationships between reward and cognition evidenced by the joint recovery of exploratory behavior and reward functions by the targeted reexpression of the $\beta 2$ subunit in the ventral tegmental area dopaminergic nucleus (Maskos et al., 2005).

In conclusion, mice under these experimental conditions do far more than to simply react to sensory information. They engage in complex extended behaviors geared toward far-removed goals and sensitive to rewards. Using the word of Denton (2005), they would display some kind of curiosity being able to orchestrate locomotor behaviors according to what might tentatively be named – at our own risks – conscious intentions. Moreover most, if not all, of all these behaviors need the integrity of the prefrontal cortex. Even if in the case of rats and mice the exact homologies with primates and humans prefrontal cortex areas are still debated (Brown and Bowman, 2005), one may – still hypothetically – propose that the flexible goal-directed behaviors examined with the mouse fall into the category of conscious processes described by the neuronal workspace model.

The model was primarily designed to account for access to consciousness and reportability (see Dehaene et al., 1998). Reporting responses have been demonstrated with some animal species, for instance, using a commentary key (Weiskrantz, 1991; Cowey and Stoerig, 1995) in the case of macaque blind-sight. Yet, a still unanswered question is whether or not reportability can be demonstrated in a species like the mouse. In any case, the invention of a reliable assay with this species is urgently needed. In conclusion, the neuronal workspace model obviously deals with important features of *minimal consciousness*. It accounts, for instance, for the active maintenance of abstract rules through top-down amplification and the flexible control of tasks that require a novel interconnection of existing processors as it typically occurs in the Stroop task (see earlier discussion) as well as with the aforementioned mice behaviors. It deals, *a fortiori*, with the active maintenance of information during a delay period (see Han et al., 2003; Koch, 2004). Even though the relevant simulations have not been carried out, the neuronal workspace architecture should adequately fit exploratory behavior and offer an appropriate mechanism for the ultimate stage of spatial processing introduced by Poucet's model (1993) where, in a workspace homologue, unified location-independent representations with one unique reference direction are being built.

1.38.9.3 Social Relationships and Consciousness

The hierarchical scale of levels of consciousness mentioned at the beginning of this section underlines the importance of social interactions to the extent that empathy was viewed as a characteristic feature of newborn consciousness. Social organisms, including humans, represent intentional relations of themselves and other agents, yet at different levels. They unambiguously distinguish their own intentional relations (or first-person information) from the qualitatively different information available about other agents' intentional relations (or third-person information). In this respect, one should remember that the analysis of the exploratory behavior leads to the distinction between allocentric and egocentric motor behavior in the mouse (Rondi-Reig et al., 2006), pointing to the still highly speculative occurrence of a self. In the mouse, such self is primarily oriented toward the outer physical world, though empathy to pain has been recently reported in the mouse (Langford et al., 2006). No evidence was found at this stage with the mouse for comparability between the actions of self and others, as is found in higher species, and no sign of imitating goal-directed activity or of understanding the viewpoints of others was observed (Barresi and Moore, 1996). In other words, the presently available evidence does not support the occurrence of authentic social relationships in the adult mouse.

The human infant at birth is already at a stage more advanced than the adult mouse; in this respect, as mentioned earlier, he or she may already distinguish between his own and others' movements, in particular by touch, and the newborn displays rudiments of imitations (Meltzoff and Gopnik, 1993; Barresi and Moore, 1996; Lagercrantz, 2005). Moreover, human neonates display emotional contagion by responding more with crying when hearing another newborn crying than when hearing white noise or their own cry (see Decety and Jackson, 2004). Thus, the mouse cannot be a good animal model to investigate intentional relations and social understanding whose highest level is reached exclusively in humans. On the other hand, it may serve as *baseline* to define the elementary neural circuits mobilized by these social relationships in higher mammals and humans.

Extension of the neuronal workspace model to these issues may help in the definition of the minimal components of neural networks able to simulate what may be referred to as social consciousness. One has first to realize that several successive hierarchical levels have to nest the basic states of consciousness of the newborn to reach the full reflective consciousness of the human adult. They include imitation, social referencing, and joint attention, but also what is referred to as the standard theory of mind (see Premack and Woodruff, 1978; Baron-Cohen et al., 2000; Frith and Frith, 2003; Gusnard, 2005). This disposition to represent other people's intentions and beliefs, commonly referred to as propositional attitudes, mobilizes circuits distinct from empathy (Singer, 2006). It develops relatively late in the child (4–5 years), long after empathy. Moreover, both empathy and mentalizing are the objects of a severe maturation before the child reaches the stage of reflective consciousness; it includes in particular the general use of symbols (linguistic or not). Interestingly, this evolution through childhood and adolescence is accompanied by a nonlinear loss of gray matter in the cerebral cortex linked to the selective stabilization (pruning) of synapses (Giedd et al., 1999a,b; Singer, 2006), which takes place during postnatal development (see Changeux, 1983, 2004).

Considerable work has to be developed to establish a useful match between an extended neuronal workspace model and reflective consciousness.

1.38.9.4 The Neuronal Workspace and Human Pathologies

On the clinical side, the neuronal workspace model offers simple interpretations of a variety of human pathologies which cannot be reviewed here. For instance, the neuronal workspace model may account for characteristic deficits caused by frontal lobe lesions in performing delayed-response tasks like the Wisconsin card sorting task (Dehaene and Changeux, 1991) or the Stroop task (see the first simulations of the model; Dehaene et al., 1998) and/or in working memory or declarative memory tasks (Squire, 1987–1988; Ungerleider, 1995; Naccache, 2005; Zeman, 2005).

Frontal lobe pathology is also associated with senescence and dementia (Parkin and Walter, 1992). Particularly relevant to the theory is the case of frontal lobe dementia. This degenerative disease is characterized by apathy, unconcern, disinhibition, distractibility, loss of social awareness, and loss of emotional empathy (Brun, 1987; Neary et al., 1988; Baker et al., 2006). Interestingly, it can be caused by either a mutation in the microtubule-associated protein tau at Chr17q21 (characterized by cytoplasmic neurofibrillary inclusions) or a null mutation in the gene of a growth factor, progranulin, at the Chr17q21

31 locus (characterized by ubiquitin–immunoreactive neuronal inclusions) (Baker et al., 2006; Mackenzie et al., 2006). It manifests itself by a selective loss of layers 2 and 3 pyramidal cells of the prefrontal cortex, the long axon neurons which were postulated as the basic anatomical components of the workspace circuits (Dehaene et al., 1998). In other words, this disease offers a striking example of a genetic dissection of the neuronal workspace in the adult human brain.

Impairments at the level of workspace neurons might also shed some light on the cognitive deficits underlying psychiatric diseases such as schizophrenia. Indeed, cognitive deficits in schizophrenia often affect a broad variety of cognitive tests, and thus may fit better within the present perspective than within the classical neuropsychological perspective, whereby an individual patient's deficits are explained by a local impairment within a modular architecture of specialized subsystems. Many neuroimaging studies suggest decreased frontal and anterior cingulate activation in schizophrenia, as well as decreased long-distance connectivity (Andreasen et al., 1997; Friston, 1998). Furthermore, a dissociation between preserved subliminal processing and impaired conscious access has been reported: the threshold for masking is systematically elevated in schizophrenia, and preserved visual, semantic, and even motor priming suggest that this deficit is due to a central integration impairment, not a basic sensory impairment (Dehaene et al., 2003; Del Cul et al., 2006). Interestingly, similar deficits of access to consciousness are also seen in patients with early multiple sclerosis (MS) and diffuse white matter damage (Reuter et al., 2007). The parallels between MS and schizophrenia, and the conceptualization of at least part of their cognitive deficits as affecting a global workspace for flexible conscious processing, offer interesting avenues for future research.

Another consequence of the workspace theory is that it leads to a plausible interpretation of drug (e.g., nicotine) addiction. Addiction may indeed be viewed as an escape from the voluntary control of drug taking behavior, for instance, as a consequence of the disconnection of a reciprocal-loop linking the neuronal workspace circuits, including prefrontal cortex, dopaminergic neurons, and striatum, thus uncovering the compulsive nonconscious aspect of drug addiction (for discussion see Gutkin et al., 2006).

Moreover, as noted earlier, the nicotinic receptor knockout mice which are compulsively navigating without pausing for exploration may offer an animal model for human attention-deficit/hyperactivity disorder behavior, for which hyperactivity symptoms are known to improve with nicotine treatment (Shytle et al., 2002; Granon and Changeux, 2006).

Last, the differential role of the ventral tegmental area in the recovery of some aspects of cognitive functions in the mouse by local reexpression of nicotinic receptors (Maskos et al., 2005) points to an analogy with the human disease called auto-activation deficit described by Laplane and Dubois (2001). Human patients display a characteristic inertia—they stay at the same place all day long without signs of spontaneous activity but may perform complex activities when stimulated. They show an empty mind for hours yet without cognitive impairment but with stereotyped activities and flattened affects. Their deficit is caused by striatopallidal lesions accompanied by frontal hypometabolism, suggesting, as in the case of the mouse model, a close link between reward and, here, the content of consciousness.

These are a few examples of human pathologies in which the Neuronal Workspace model offers simple and productive interpretations.

2.01 Introduction and Overview

H. L. Roediger III, Washington University in St. Louis, St. Louis, MO, USA

2.01.1 The Cognitive Psychology of Memory: Introduction

The main problem in the scientific study of memory is that it proceeds on many different fronts. Neurochemical and neurobiological approaches propel some researchers; systems neuroscientists examine changes in larger pathways in the nervous system; animal behaviorists examine learning and memory as reflected in behavior of (mostly) infrahuman animals, such as birds finding caches of seed; cognitive psychologists study human memory through behavioral means using measures such as recall and recognition; computer scientists endorse computational approaches to memory that sometimes pay little attention to behavioral or neuroscience constraints; and, of course, the study of memory has been the topic of discourse by philosophers for over 2000 years. This four-volume series covers a huge selection of topics that are central to the scientific study of memory. In a different edited volume, Roediger et al. (2007) considered 16 critical concepts in the science of memory from the various viewpoints described above.

2.01.2 Cognitive Approaches to Memory

Practitioners of what is today called cognitive psychology have a long tradition of the experimental study of various aspects of memory. Experimental psychology is often dated from the founding of Wilhelm Wundt's laboratory in Leipzig in 1879. Coincidentally, that same year marks the year that Hermann Ebbinghaus (1850–1909) began his painstaking research that led to his great book, *Über das Gedächtnis (On Memory)* in 1885 (Ebbinghaus, 1885). Ebbinghaus conducted meticulous experiments that asked many fundamental questions about learning and memory, and virtually all his results have stood the test of time in that they have been widely replicated. His work dates the start of the cognitive/behavioral study of learning and memory in humans, although of course centuries of speculation and theorizing (particularly by the British empiricist philosophers) preceded and informed his first experimental efforts. Bower (2000) provides a brief historical overview of this approach to studying learning and memory.

Cognitive psychologists approach the problem of memory through careful experimentation to examine theories that vary in their levels of specification. Some theories (say, transfer-appropriate processing) are broad and seek to capture a wide range of performance across many situations, whereas other approaches (such as mathematical models of performance in specific tasks) are more formal and often attempt to capture memory performance only in tightly structured paradigms.

Traditionally, up until perhaps 30 years ago, cognitive psychologists paid little attention to neuroscience discoveries, and likewise, neuroscientists paid little attention to the experimental work of the cognitive psychologists. Although this division of labor is honored to some degree in the separate volumes of this work, the interests of scientists are clearly broader today. Unlike the case 30 years ago, cognitive psychologists today follow advances in neuroscience with great interest, and many of the concepts and tasks used by neuroscientists were originally developed by psychologists (either those studying animal learning and memory or those applying cognitive methods to these topics in humans). Although this volume is largely devoted to the cognitive/behavioral study of memory, many chapters lean heavily on neuroscience findings. The authors were given leeway to cover their particular topic from

the vantage they deemed most appropriate, bringing in the types of evidence they considered most relevant. Some chapters rely heavily on neuroscience evidence, whereas others refer to purely behavioral experimentation. I see this as perfectly appropriate for the various topics covered in this volume.

2.01.3 Organization of the Volume

One time-honored procedure in the study of cognitive processes is sorting (e.g., Mandler, 1967). An experimenter can give a subject a set of concepts and ask him or her to sort them into groups. The hope is to discover something about how the subject's mind organizes experiences into concepts or categories. The titles of chapters for this volume were originally listed alphabetically, but then the editors of each volume were asked to organize them in some meaningful way, which corresponds reasonably well to a sorting task. I took several trials to reach criterion on this task and can still quibble with myself on various decisions. Luckily, the editors were not asked to create sections of the volume and to label our categories. Here I provide some rationale for the ordering of the chapters and, at the same time, outline the contents of the volume.

The volume begins with a chapter on attention and memory by Neil Mulligan (*See* Chapter 2.02). After all, events in the world that are not attended will not be encoded well and cannot be remembered later, so this seemed a logical starting point. Nelson Cowan's chapter on sensory memory (*See* Chapter 2.03) follows this one. Sensory memory (iconic storage, echoic storage, and similar processes in other modalities) lies at the borderline between perceiving and remembering. No one has ever proposed a good solution to the question of where perceiving ends and remembering begins, and ideas about sensory storage bridge this gap. Susan Gathercole's chapter on working memory comes next (*See* Chapter 2.04). The topic of how people hold information in mind while manipulating it in reasoning and solving problems represents a huge topic in cognitive psychology over the past 40 years. The next chapter is on serial learning by Alice Healy and William Bonk (*See* Chapter 2.05). Most research on serial learning uses paradigms requiring short-term recall (such as digit span and similar procedures), so placing it after the working memory chapter seems reasonable. However, the chapter also covers long-term processes in serial organization.

Robert Greene provides a chapter on the fundamental topic of repetition and spacing effects (*See* Chapter 2.06). Perhaps the first principle of learning and memory is that repeated experiences are (almost) always better remembered than single experiences; further, having two experiences distributed in time (up to some limit that differs for various tasks and retention intervals) leads to greater performance. Another fundamental principle, dating at least to George Miller's (1956) pioneering work on recoding in memory, is that events are not remembered as they are presented in the outside world (events do not somehow leap into the brain as veridical copies of experience), but, rather, events are coded (or recoded) as they are filtered through an individual's personal experiences (or apperceptive mass, to bring back a useful term from early in psychology). Events are remembered as they are coded and not as they necessarily 'are' in the environment. Reed Hunt's chapter on coding processes brings out this important point and shows how recoding can improve retention in some cases but in other cases can lead to errors (*See* Chapter 2.07). Mental imagery is one type of code that has received great attention in the literature, and Cesare Cornoldi, Rossana DeBeni, and Irene Mammarella review this literature in the next chapter (*See* Chapter 2.08).

An event that differs dramatically from many other events that are themselves similar is usually well remembered, which constitutes a distinctiveness effect. For example, a picture of a horse embedded in the middle of a 99-word list of other concrete nouns is much better remembered than if the word 'horse' is presented in a uniform list of 100 words (with 'horse' embedded in the analogous position in the list). This outcome occurs even if the mode of recall is verbal (i.e., people must recall the word 'horse' both when it is presented as a picture and as a word). Distinctiveness effects are ubiquitous in memory research, and Stephen Schmidt provides a review of what is known about this topic in his chapter 'A Theoretical and Empirical Review of the Concept of Distinctiveness in Memory Research' (*See* Chapter 2.09). The next chapter, 'Mnemonic Devices: Underlying Processes and Practical Applications,' by James Worthen and Reed Hunt, brings together the chapters on recoding, imagery, and distinctiveness by reviewing techniques for memory improvement that have been developed over the years (*See* Chapter 2.10). Some of these techniques date back to the ancient Greeks, but modern research has helped to uncover the reasons for their effectiveness. Many of these techniques depend on

imagery, and some (such as the method of loci) rely on humans' ability to remember routes and spatial layouts well, especially ones experienced repeatedly. Timothy McNamara, Julia Sluzenski, and Bjorn Rump review the interesting topic of human spatial memory and navigation (*See* Chapter 2.11).

The next chapters in the volume have to do with memory losses and errors. Forgetting refers to the loss of information over time, and James Nairne and Josefa Pandeirada review the topic in their chapter by that name (*See* Chapter 2.12). A complementary topic is on inhibitory processes, a chapter by Karl-Heinz Bauml (*See* Chapter 2.13). Inhibitory processes are concerned with another set of phenomena that have to do with forgetting. The basic idea is that forgetting may result from an active process of memories being inhibited and therefore forgotten, at least temporarily. Forgetting is often considered an error of omission – information does not come to mind when we try to retrieve it – but errors of commission are of great interest, too. False memories arise when we retrieve information differently from the way it was experienced or, in the most dramatic cases, when we retrieve confident memories of events that never happened at all. Elizabeth Marsh, Andrea Eslick, and Lisa Fazio review this topic in their chapter titled 'False Memories' (*See* Chapter 2.14). Eric Eich, Elke Geraerts, Jonathan Schooler, and Joseph Forgas provide a chapter on mood and emotion in memory, titled 'Memory in and About Affect' (*See* Chapter 2.15). When people are in different moods when they experience events and then try to retrieve them later, they often remember more poorly than if the moods are the same between encoding and retrieval (the phenomenon of mood-congruent memory). However, when people experience greater emotional states during encoding (e.g., strong fear), they often remember events well.

The next few chapters have to do with retrieval of information from memory, as well as associated states of consciousness and processes during this process. Suparna Rajaram and Sarah Barber provide an overview of retrieval processes in memory (*See* Chapter 2.16). John Gardiner writes on the distinction between remembering and knowing, which are responses representing two states of conscious awareness during retrieval (*See* Chapter 2.17). Asher Koriat, Morris Goldsmith, and Vered Halamish discuss control processes in voluntary remembering, dealing with issues such as the criterion people use when deciding that recovered information should be reported as a memory and the factors affecting memory reports (*See* Chapter 2.18). Stephen Lindsay writes on the related topic of source monitoring, or the issue of how people recollect the source of information they report as a memory – did I read the fact in the newspaper, did a friend tell me, or was it learned from television (*See* Chapter 2.19)? Janet Metcalfe and John Dunlosky write on the issue of metamemory, or what people know about their own memories and the strategic processes used in regulating encoding and retrieval of information (*See* Chapter 2.20). Alan S. Brown has provided two chapters on puzzling phenomena of memory retrieval, the experience of déjà vu (when a person has the strange sensation that an event or scene has been experienced previously), and the tip-of-the-tongue phenomenon (the annoying experience when a desired bit of information can almost, but not quite, be retrieved) (*See* Chapters 2.21, 2.22).

Colleen Parks and Andrew Yonelinas provide the chapter 'Theories of Recognition Memory' (*See* Chapter 2.23), with particular emphasis on whether a single-factor or two-factor theory best accounts for the data. William Hockley writes about the related topic of memory search in various types of memory tests, including short-term recognition (S. Sternberg's (1966) item recognition test), long-term recognition, free recall, and other tasks (*See* Chapter 2.24). Both the chapter on recognition and the chapter on memory search involve considerations of mathematical modeling, and the next chapter by Jeroen Raaijmakers explicitly considers mathematical models of human memory (*See* Chapter 2.25). His chapter is followed by a related one by Michael Kahana, Marc Howard, and Sean Polyn on associative retrieval processes in episodic memory (*See* Chapter 2.26). Karl Szpunar and Kathleen McDermott provide an overview on the concept of episodic memory as it has developed since Tulving's seminal chapter in 1972 (Tulving, 1972) (*See* Chapter 2.27). They discuss how neural processes involved in episodic memory may also subserve a person's envisioning the future as well as recollecting the past.

The next series of chapters involves memory of a different kind from episodic memory. David Balota and Jennifer Coane's chapter on semantic memory concerns representation of well-learned information such as words and their meanings (*See* Chapter 2.28). Brian Ross, Eric Taylor, Erica Middleton, and Timothy Nokes survey the related field of how humans learn concepts and categories in 'Concept and Category Learning in Humans' (*See* Chapter 2.29). Gideon Deák and Anna Holt describe research on the critical issue of language learning and report how theories have advanced over the years (*See*

Chapter 2.30). Peter Frensch and Hilde Haider discuss research on the venerable topic of transfer and expertise (*See* Chapter 2.31), a topic that really runs throughout the book in many ways.

Pierre Perruchet reviews the evidence concerning implicit learning, which uses transfer designs as a major tool for understanding (*See* Chapter 2.32). Dale Stevens, Gagan Wig, and Daniel Schacter then review recent evidence on the related topic of implicit memory and priming (*See* Chapter 2.33). Timothy Lee and Richard Schmidt provide an overview on the topic of motor learning and memory, which is related to implicit learning in some ways (*See* Chapter 2.34). Much recent work has shown that procedural and motor skills (as well as some other forms of learning) consolidate while people sleep. Jessica Payne, Jeffrey Ellenbogen, Matthew Walker, and Robert Stickgold review this exciting frontier in memory research in 'The Role of Sleep in Memory Consolidation' (*See* Chapter 2.35).

The next group of chapters is concerned with development of memory across the lifespan, as well as individual differences among people in memory ability. Carolyn Rovee-Collier and Kimberly Cuevas review evidence about infant memory (*See* Chapter 2.36), and then Peter Ornstein, Catherine Haden, and Priscilla SanSouci consider the development of skilled remembering in children (*See* Chapter 2.37). Elena Grigorenko discusses developmental disorders of learning (*See* Chapter 2.38), and Michelle Dawson, Laurent Mottron, and Morton Gernsbacher describe learning in autism (*See* Chapter 2.39). Michael Kane and Tina Miyake write about individual differences in episodic memory among adults (*See* Chapter 2.40), and Moshe Naveh-Benjamin and Susan Old discuss aging and memory (*See* Chapter 2.41). Finally, Anders Ericsson describes research on superior memory of mnemonists and experts in various domains (*See* Chapter 2.42).

The next few chapters of the book focus on more applied aspects of learning and memory research. Mark McDaniel and Aimee Callendar discuss work on cognition, memory, and education, focusing on applying principles from learning and memory research to educational practice (*See* Chapter 2.43). Jeffrey Neuschatz and Brian Cutler discuss the important issue of eyewitness identification (*See* Chapter 2.44). Since the advent of DNA evidence, over 200 people convicted of crimes – often on the basis of eyewitness evidence - have been released from prison, exonerated by DNA evidence. This state of affairs has caused a searching examination of the typical methods used by police to conduct eyewitness identifications. Gilles Einstein, Mark McDaniel, Richard Marsh, and Robert West discuss another popular topic in recent research – how people remember to do things in the future, such as taking an antibiotic pill four times a day when fighting an infection. Their chapter, 'Prospective Memory: Processes, Lifespan Changes, and Neuroscience,' discusses this interesting line of research (*See* Chapter 2.45).

The last three chapters of the volume examine memory from a broader perspective. Most chapters previously described are based on laboratory tasks concerned with learning and memory. Martin Conway and Helen Williams write on the nature of autobiographical memory, which is concerned with how people recollect the events of their lives (*See* Chapter 2.46). Michael Ross, Craig Blatz, and Emily Schryer discuss social memory processes, which includes the issue of how people influence one another as they remember (as well as other topics) (*See* Chapter 2.47). Finally, James Wertsch discusses the emerging topic of collective memory (*See* Chapter 2.48), which is a representation of the past that is shared by members of a group. The group might be people in a nation recollecting an important historical event, such as how people in the United States remember the Revolutionary War. Different groups may see the past in different ways, as Wertsch brings out in his chapter. The empirical study of collective memory is an emerging topic but one that is sure to be more important in the future.

2.01.4 Conclusion

The 47 substantive chapters in this volume represent a marvelous, state-of-the art digest by leading scholars as they summarize what is known about many of the critical topics in the cognitive psychology of learning and memory. The entries range from topics that have a long history (e.g., transfer) to those that have emerged only recently (prospective memory, collective memory). Editing the volume has caused me to learn much, and I believe every reader of this volume will share this experience.

2.02 Attention and Memory

N. W. Mulligan, University of North Carolina, Chapel Hill, NC, USA

> Very great is the dependence of retention and reproduction upon the intensity of the *attention* and *interest* which were attached to the mental states the first time they were present. [italics in original] (Ebbinghaus, 1885: 3)

> Whatever future conclusions we may reach as to this, we cannot deny that *an object once attended to will remain in the memory,* whilst one inattentively allowed to pass will leave no traces behind. [italics in original] (James, 1890: 427)

2.02.1 Introduction

This chapter provides a brief overview of the relationship between attention and memory. The above quotations, although specifically written about the relationship between attention and long-term memory, provide a traditional viewpoint articulating the intimate connection between these constructs. Indeed, as Norman (1969) notes, a researcher would have little difficulty finding similar speculations in the earliest surviving writings in philosophy of mind. Ancient practical manuals on memory and rhetoric begin with the fundamental assumption that successful memory starts with attention (Yates, 1966). Modern researchers in cognitive psychology are likewise interested in attention and memory, but typically for theoretical reasons rather than the practical demands of the rhetorician's 'art of memory.' We shall see that, despite disputes about the details, these quotations remain quite apt regarding many aspects of the relationship between attention and memory.

At the outset, it should be noted that there is a tremendous amount of research under the general heading of 'attention and memory,' enough to require a book-length review even in the early days of the 'cognitive revolution' (Norman, 1969), and even more so in later eras (Cowan, 1995). Consequently, this short review is necessarily selective and incomplete. My goal is simply to describe some of the most important trends and results and to point the interested reader in the direction of additional resources. To begin, we briefly discuss the varieties of memory and the varieties of attention before proceeding to discuss the relationship between the two.

2.02.1.1 Varieties of Memory

Psychologists have long found it useful to differentiate among forms or aspects of memory. The most basic distinction is based on duration, the difference between immediate, fleeting retention of recently presented material and longer-lasting, more permanent aspects of memory. This distinction was captured early on in James's distinction between primary and secondary memory and was similarly

delineated in the modal model of Atkinson and Shiffrin (1968), with its distinction between the short-term and long-term stores. Contemporary psychology continues to distinguish between shorter-term and longer-term memory, as well as among different forms of long-term memory, based on neuropsychological, neuroscientific, and behavioral evidence (e.g., Schacter et al., 2000).

Working memory is the current term for short-term or primary memory, although this conception is more complicated than the unitary short-term store envisaged in the modal model. Working memory is the system responsible for the short-term storage and manipulation of mental representations and contains three primary components, the phonological loop, the visuospatial sketchpad, and the central executive (Baddeley, 1986). The phonological loop is the mechanism responsible for the storage and rehearsal of phonological/verbal information. In a similar way, the visuospatial sketchpad provides temporary maintenance of visual and spatial patterns. The central executive coordinates the operation of these two subsidiary components and mediates the manipulation and transformation of information in these subsystems. The central executive is often associated with limited-capacity attentional resources (Engle, 2002), as discussed later. Finally, a recent version of the working memory model (Baddeley, 2002) proposes an additional component, the episodic buffer, responsible for binding together information represented in different forms or codes (**Figure 1**).

As short-term memory has been fractionated into multiple components, recent theorizing also distinguishes among multiple forms of long-term memory. These distinctions are based on several dimensions, key among them differences in phenomenology and differences in informational (or representational) content. First, it is common to differentiate among varieties of long-term memory based on phenomenology at retrieval, that is, whether the retrieval produces conscious recollection or not. This is critical to the distinction between explicit memory, which refers to conscious, intentional recollection of the past, and implicit memory, which refers to unconscious or unintentional influences of the past. Numerous differences (or dissociations) between explicit and implicit memory lend credence to the importance of this distinction (e.g., *See* Chapter 2.33; Mulligan, 2003b). The distinction between recollection and familiarity made in dual-process models of memory similarly relies on differences in the phenomenology of retrieval (Yonelinas, 2002).

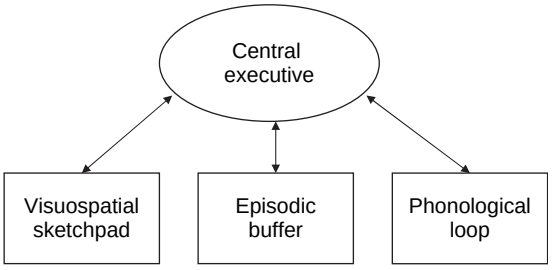

Figure 1 The working memory model. Adapted from Baddeley AD (2002) Is working memory still working? *Eur. Psychol.* 7: 85–97, with permission.

Distinctions based on informational content are important to the multiple systems view of long-term memory (e.g., Schacter et al., 2000), a view that overlaps with distinctions based on phenomenology. First, and most important for our present purposes, is episodic memory, long-term memory for personally experienced events. This form of memory records autobiographical experiences that occurred at a specific time in a specific place. As noted by Tulving (2002), this form of memory permits 'mental time travel,' allowing a person to reexperience an event from the first-person perspective. Episodic memory overlaps with the concept of explicit memory because it supports the conscious and intentional recollection of the past. Semantic memory refers to the organized body of general knowledge about the world. This form of memory includes concepts, categories, vocabulary, and so on. This form of memory is distinguished from episodic memory by its depersonalized nature. Retrieving information from semantic memory is tantamount to retrieving facts rather than reexperiencing prior episodes.

The perceptual representation system (PRS) is

> a collection of domain-specific modules that operate on perceptual information about the form and structure of words and objects. (Schacter et al., 2000: 635–636)

This system represents long-term knowledge of perceptual objects in the modality in which they are processed. Finally, procedural memory is the system that represents skilled behaviors, including perceptual and motor skills, as well as more abstract cognitive skills. This system is marked by slow, incremental strengthening of representations through repeated practice. Procedural memory encompasses the learning of motor skills, such as riding a bike or

swinging a golf club, as well as cognitive skills, such as learning to read.

Conscious recollection (explicit memory) is associated with the episodic system. Implicit memory is more various, forms of which appear to be mediated by each of the other nonepisodic systems. For example, perceptual priming (one manifestation of implicit memory) is attributed to the PRS, whereas conceptual priming is attributed to the operation of the semantic system. Finally, the expression of procedural skills is also associated with implicit memory.

2.02.1.2 Varieties of Attention

Just as memory is multifaceted, so too is attention. To begin, let us examine James' classic definition of attention:

> It is the taking possession by the mind, in clear and vivid form, of one out of what seems several simultaneously possible objects or trains of thought. Focalization, concentration of consciousness are of its essence. It implies withdrawal from some things in order to deal effectively with others. (James, 1890: 403)

From such a description, researchers have typically teased out several aspects or dimensions of attention. First, attention is used for selection among the multitude of stimuli that impinge on our senses at any given moment. Perception would lack coherence if we attempted extensive analysis of every stimulus in the perceptual field. Second, attention implies a limited ability to process information. This is often characterized as a limited pool of attentional resources. Third, attention pertains to control in several ways: control of the flow of information, control of ongoing behavioral responses, and control of prepotent responses (e.g., inhibition).

The dominant distinction in recent research is between peripheral (or modality-specific) aspects of attention (such as visual attention) and central (or modality-independent) aspects of attention. For example, Johnston et al. (1995) propose a distinction between input and central attention, which distinguishes two limited-capacity mechanisms: one responsible for selective aspects of attention, and the other involved in higher-level mental functions (decision making, response selection, etc.). The distinction between selective and central attention corresponds quite closely to similar distinctions made in the literature on attention systems (Wickens, 1984; Duncan et al., 1997; Duncan, 1999), such as the distinction between perceptual and decisional attention (Ashby et al., 1998; Maddox, 2002), the distinction between perceptual and executive attention (Pashler, 1998; Engle, 2002), and the distinction raised in the neuroscience literature between the posterior and the anterior attention systems (Posner and Peterson, 1990; see also Freiwald and Kanwisher, 2004; Humphreys and Samson, 2004). Finally, the concept of central attention is often associated with the central executive component of Baddeley's (1986) model of working memory (e.g., Engle, 2002).

Studies of selective attention and central attention have typically used different experimental paradigms. In the typical experiment on selective attention, multiple stimuli are presented in the same modality, and the participant's attention is either directed at a critical stimulus or directed away from the critical stimulus by requiring the participant to respond to other (distracter) stimuli. Studies of central aspects of attention typically use divided-attention (or dual-task) paradigms. In these experiments, the participant is presented with two streams of stimuli in different modalities (e.g., visual and audition) and required to divide attention across the two sets. This is usually done by requiring the participant to respond to both streams of stimuli and by instructing the participant that both types of responses are important (i.e., encouraging the participant to divide attention equally over both tasks).

2.02.2 Attention, Memory, and the Beginnings of the 'Cognitive Revolution'

2.02.2.1 Cherry's Dichotic Listening Studies

Many of the landmark studies of the studies of the modern era of cognitive psychology focused on attention and memory. Specifically, studies of dichotic listening sought to analyze the role of selective attention in perception and memory. The initial study was that of Cherry (1953), who pioneered the experimental paradigm that would have such profound effect on later empirical and theoretical work. Cherry and the other early researchers were taken by the 'cocktail party problem,' which serves as a natural example of selective attention. At a cocktail party, there may be numerous conversations occurring all around the listener, any one of which could, in principle, be comprehended if attention were so directed.

A person in a conversation must attend to one speaker (and filter out all of the competing messages) to successfully take part in the conversation. How does this occur, and what is the fate of the unattended message(s)? To study this problem, Cherry developed an experimental analogue that would set the agenda for much of the early research on attention and memory. In this experimental technique, participants attended to one of two simultaneously presented messages. The messages were presented over different tracks of a stereo headset so that one message was presented to one ear, and a different message was presented to the other ear. The attended message was human speech, and the ignored message might consist of other human speech (in English or in another language), reversed speech, music, a steady tone, and so on. To ensure that subjects were attending to the correct message, the message was repeated by the subject as it was heard – a task called shadowing. The message that was not shadowed can be characterized as ignored or irrelevant rather than unattended. Although the goal of the dichotic listening task is to render the irrelevant message unattended, this may not always happen. It is possible that subjects might shift their attention on occasion to the nonshadowed message, undermining the goal of the experimental technique. This possibility makes a more neutral term (ignored or irrelevant) a better designation for the nonshadowed input.

Cherry found that subjects were successful in the shadowing task when the two messages differed in terms of their physical properties. The typical physical difference between the messages was spatial location, with one message presented to one ear and the competing message presented to the other. The messages could also be successfully segregated (and one successfully shadowed) when both messages were presented on the same track, provided the messages differed on another physical dimension, such as a male versus a female voice. However, if the two messages were physically similar (e.g., same location, or input ear, and same or similar voices), then the shadowing task became extremely difficult even if the messages differed in other ways, such as the topic or meaning of the messages. Cherry concluded that selection could only operate on the physical characteristics of the message and not on their content.

Most important for the present purposes was the memorial fate of the ignored message. Consistent with his conclusions about selection, Cherry (1953) found that only the physical properties of the ignored message were later remembered. After the shadowing task was over, subjects were asked what they remembered of the ignored message. Typically, subjects could remember whether it was human speech as opposed to a tone or music. Furthermore, they could recall whether it was a male or female voice. However, the subjects showed very little memory for the content of the unattended speech. That is, they showed little memory for words or phrases in the unattended message. Moray (1959) showed that, even when the same word was presented repeatedly – as many as 35 times – in the ignored ear, there was no memory for the stimulus. Furthermore, subjects were not entirely certain that the language was English. Reversed speech and speech in other languages were rarely recognized as non-English. Cherry's broad conclusion was that the unattended material is analyzed at the level of gross perceptual characteristics, but that selective attention is required for the analysis of and long-term memory of detailed aspects of the message such as the language spoken, the identity of individual words, and semantic content.

2.02.2.2 The Filter Model and the Debate between Early and Late Selection Theories

From research on dichotic listening, Broadbent (1958) developed an early, highly influential information processing account of attention, perception, and memory (**Figure 2**). In this model, Broadbent depicted cognition as a series of discrete, serial information-processing stages. Processing begins with sensory systems, which can process large amounts of raw sensory information in parallel. Other research (e.g., split-span studies) indicated that sensory information may be preserved for a short time prior to selection. Thus, Broadbent argued that the initial sensory processing of the perceptual characteristics of inputs was deposited into a short-term memory buffer. This is the point at which attention operates in Broadbent's model, acting as a selective filter. The filter blocks out unwanted inputs based on selection criteria that reflect the goals of the cognitive system. For example, given that the subject's goal is to succeed at the shadowing task, selection is based on the physical location of the to-be-attended message. The selection criteria operate on one of the perceptual characteristics of inputs in the memory buffer. The attended material gains access to a limited-capacity perceptual system (the P system in **Figure 2**), which allows analysis for content, conscious awareness, and ultimately, encoding into long-term memory.

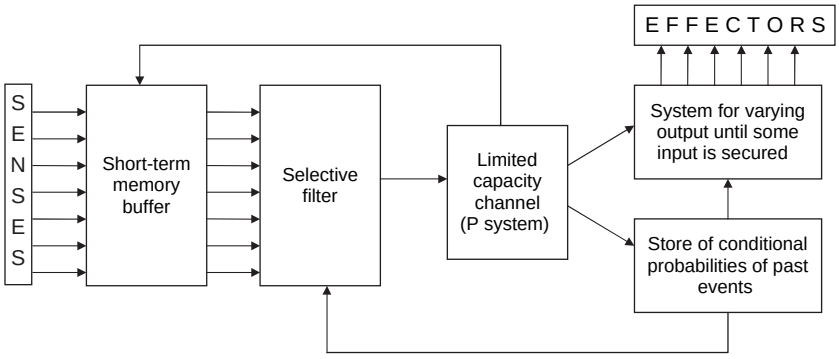

Figure 2 The filter model. Adapted from Broadbent DE (1958) *Perception and Communication.* London: Pergamon Press, with permission.

It should be noted that Broadbent's model has many similarities to the Atkinson and Shiffrin (1968) modal model. The memory buffer in Broadbent's model corresponds to the sensory register of Atkinson and Shiffrin, in that both store raw sensory information prior to selective attention and refined perceptual analysis. The limited-capacity perceptual system of Broadbent is analogous to the short-term store of Atkinson and Shiffrin in terms of its limited capacity, its equation with the contents of awareness, and its role as a conduit to long-term storage.

Broadbent's model proposed that the selective filter operates on the basis of physical characteristics of the message and prior to the analysis of meaning. Consequently, this model is referred to as an early-selection model of attention. Subsequent research on the filter theory raised questions about early selection and gave rise to important competitor models. For example, Moray (1959) found that participants often noticed their own name when it was presented in the ignored channel. According to the filter model, detailed content such as the identity of a word or name should be unavailable from an unattended message. A converging result came from Treisman's (1960) study, in which one story was presented to the attended ear (and shadowed by the subject) and a second story was presented to the ignored ear. Partway through the study, the first story switched tracks and replaced the story in the ignored ear (the first story itself being replaced in the attended track with a new, third, story). According to the filter theory, if the subject is not attending to the irrelevant ear, then they should not process any of its content, and thus should have no awareness that the first story continued in the irrelevant channel. However, subjects typically continued to shadow the first story even after it switched ears. Neither of these results comports with Broadbent's original filter model.

Treisman (1964) handled these new findings by modifying Broadbent's theory. Treisman argued that selective attention does not operate as an all-or-none filter but, rather, operates like a gain control, attenuating unattended inputs. Such attenuated stimuli still might be recognized (i.e., their content fully analyzed) if the stimulus is very important (such as one's own name) or has been primed by attended semantic context. This attenuation view preserves the early placement of the selective filter (now an attenuator) as operating prior to semantic analysis and the processes required for encoding into long-term memory.

An alternate approach was adopted by late selection models (e.g., Deutsch and Deutsch, 1963; Norman, 1968). These models proposed that stimuli routinely undergo substantial analysis (up to identification processing), whether attended or not. The selective mechanism in these models operates after perceptual and content analysis but before response selection. Under this view, semantic analysis helps determine which stimulus is most relevant for current goals and should guide behavioral response.

A number of subsequent results were taken as supportive of late selection. For example, Lackner and Garret (1972) found that the interpretation of ambiguous sentences in the attended ear was biased by words presented in the ignored channel. The results of Corteen and associates (Corteen and Wood, 1972; Corteen and Dunn, 1974) were similarly interpreted as supporting late selection and memory access without attention. Participants in these studies initially underwent a learning phase in which a set of words was paired with electric shock. In a subsequent phase of the experiment, participants showed a heightened galvanic skin response (GSR) to the

shock-paired words even when these words were presented to the ignored channel in a dichotic listening task.

Results such as these imply semantic analysis of unattended information (and late selection) but have been controversial because of the possibility of covert shifts of attention. It is possible in dichotic listening tasks (and in other selective attention tasks) that a subject's attention might wander to the nominally unattended ear. The critical question is whether results such as the above represent semantic analysis of unattended information or momentary shifts of attention to the ignored ear. As framed by Lachter et al. (2004), the issue is whether there is leakage (penetration of the selective filter by semantic content) or slippage (covert, perhaps unintentional, shifts of attention). In a review of the literature, Holender (1986) concluded that results that appear to support late selection in auditory selective attention are actually the result of such attentional slippage. A more recent review comes to the same conclusion for studies of both auditory and visual selective attention (Lachter et al., 2004). Furthermore, Lachter et al. (2004: 884–885) argue that the potential for slippage was underestimated in early research because estimates of the time necessary for attentional shifts were quite high (estimated to be 500 ms or longer in Broadbent (1958)). More modern estimates are as low as 150 ms for voluntary (endogenous) shifts of attention and 50 ms for involuntary (exogenous) shifts. If attention can be so rapidly shifted from one stimulus (or channel) to another, it raises the possibility that rapid shifts of attention might go unnoticed by the experimenter.

This issue has been raised regarding a number of studies. Following up on the results of Corteen and Dunn (1974), Dawson and Schell (1982) presented shock-associated words in the ignored channel of a dichotic listening task. Trials were separated based on evidence for attentional shifts to the ignored channel (based on on-line performance such as shadowing errors). The heightened GSR effect was much greater on trials exhibiting evidence of attention shifts than on trials exhibiting no such evidence. In a similar vein, Wood et al. (1997) varied the difficulty of the primary shadowing task (by increasing the rate of speech to be shadowed) under the assumption that, as the shadowing task becomes more demanding, covert attentional shifts to the ignored channel would be less likely. Evidence for semantic processing and long-term memory of the ignored channel was only found for easier shadowing tasks; no such evidence was found for the more demanding shadowing task, consistent with the idea that covert shifts of attention may give the appearance of semantic processing and long-term memory for unattended materials (for thorough review of these issues, see Holender, 1986; Lachter et al., 2004).

Finally, working memory resources, to be discussed in more detail next, may play a critical role in selective attention. For example, Conway et al. (2001) investigated the cocktail-party effect of Moray (1959), with participants of high and low working memory capacity. Prior research indicates that low working memory capacity is associated with distractibility. Conway et al. (2001) reasoned that more distractible subjects are more likely to allow their attention to shift to the irrelevant channel. This study found that the low-capacity subjects were much more likely to notice their name in the irrelevant channel. This result is consistent with the previous research suggesting that attention shifts may be responsible for the appearance of semantic processing of the ignored channel. In addition, this result indicates a close connection between working memory and selective attention. Similarly, deFockert et al. (2001) found that increasing a working memory load made subjects more susceptible to distraction in a visual selective-attention task. Several researchers have now suggested that selective attention processes are controlled by working memory resources (e.g., Engle, 2002; Lavie et al., 2004). That is, working memory capacity may dictate the extent to which we can successfully focus on one input in the face of distraction (as in dichotic listening). From a historical perspective, this is an interesting inversion. Psychology has traditionally described attention as controlling access to memory structures, but this view implies that a memory structure (working memory) controls the function of an attentional process (selective attention).

2.02.3 Working Memory and Attention

The concept of immediate or short-term memory has long been defined in terms associated with attention. For example, in the modal model of Atkinson and Shiffrin (1968), the presence of information in the short-term store rendered it available to consciousness and allowed the information to guide and control ongoing behavior. Attention is likewise associated with conscious awareness and control of behavior. The short-term store is defined as having a sharply limited capacity, as is attention when

discussed in terms of processing resources. The same points could be made about the limited-capacity perceptual system in Broadbent's filter model. Of course, short-term memory is currently conceptualized in terms of the working-memory model (Baddeley, 1986), which contains specialized subsystems. However, the subsystems are similarly characterized as limited-capacity processing resources, although in the case of the phonological loop and visuospatial sketchpad, the resources are applied for specialized purposes.

In the modal model, the digit span task was the standard measure of the capacity of short-term memory, which along with numerous other assessments of capacity, yielded the famous estimate of 7 ± 2 (Miller, 1956). In the contemporary working memory model, digit span (along with other simple span tasks) is interpreted as a measure of the phonological loop. Analogous measures assess the capacity for storing visual and spatial information in the visuospatial sketchpad. For example, in one visual span task (Logie, 1996), a subject is presented with a matrix of blocks for a brief time. Some of the blocks are filled in, and others are unfilled. After a brief delay, the matrix is represented with one block changing from filled to unfilled (or vice versa). The participant's task is to identify the changed block. This task is relatively easy if the matrix consists of few blocks but becomes increasingly difficult as the size of the matrix increases. The matrix size at which the subject can no longer reliably identify the changed block is taken as the upper bound of the storage capacity of the visuospatial sketchpad.

The phonological loop and sketchpad are subject to dual-task interference, another of the ways in which the subsystems of working memory can be characterized as capacity-limited resources. In the case of these subsystems, the limitations are most clearly exhibited for distracter tasks requiring the same working memory resource. For example, if subjects simultaneously carry out a digit span task and a verbal distracter task (both tasks that draw on the phonological loop), the measure of capacity (i.e., digit span) is dramatically reduced relative to baseline. Alternatively, if digit span is carried out along with a distracter task requiring visual or spatial imagery (which should draw on the sketchpad and not the phonological loop), minimal reduction of digit span occurs. Visual span exhibits the opposite pattern of interference. A secondary task requiring visual or spatial imagery greatly reduces visual span, whereas a verbal secondary task produces much less of an effect. This pattern of selective interference provides part of the rationale for positing the two distinct storage systems (Logie, 1996). Furthermore, this demonstrates that the two subsystems are limited-capacity resources for specialized purposes or information types.

Although the phonological loop and visuospatial sketchpad can be related to the construct of attention via limited capacity, it is the central executive component of working memory that is most typically associated with attention. In contrast to the specialized subsystems, the central executive is a general, amodal processing resource that monitors and controls the actions of the working memory subsystems. Increasingly, the central executive is seen as playing the more general role of an attentional controller, prompting Baddeley (1993) to wonder whether working memory, particularly the central executive component, might be better labeled 'working attention.'

To assess the relationship between the central executive (and the entirety of working memory) and attentional control, it is useful to have a general measure of working memory capacity. These assessments do not solely measure the central executive, because the executive is assumed to regulate and control the other processes in the system rather than provide active storage of information itself. Measures of working memory are called complex span tasks because they seek to assess the joint processing and storage capacities of the whole system, in contrast with simple span tasks (like digit span) that predominantly measure passive storage of a single subsystem (such as the phonological loop). One example is the reading span task (Daneman and Carpenter, 1980) in which subjects read a series of sentences and simultaneously try to maintain the last word from each sentence. At the end of a set of sentences, the participant recalls the final words. The number of words recalled serves as the measure of working-memory span. This task requires both processing (for comprehension) and storage. A similar task is the operation span task (Engle, 2002), every trial of which consists of an equation and a word (e.g., "$4/2 - 3 = 6$? (yes or no) DOG"). The participant's task is to verify whether the equation is correct and remember the word for subsequent recall. At the end of a small set of trials (e.g., 2–7), the words are recalled (again serving as the measure of working memory span).

Working memory capacity, as measured in these tasks, correlates with a number of higher cognitive skills, such as language comprehension, reading ability, reasoning, and general intelligence (see Engle

and Kane (2004), for a review). Importantly for the present purposes, working memory capacity also relates to the control of attention. As noted earlier, individuals with higher working memory spans are less distractible in dichotic listening tasks and exhibit greater control over inhibitory processes (e.g., Conway et al., 2001). Experimental manipulations of working memory capacity produce similar effects in selection and inhibition paradigms (deFockert et al., 2001; Engle and Kane, 2004; Lavie et al., 2004).

2.02.4 Attention and Episodic Memory

The preceding section focused on the relationship between attention and working memory. Returning to the quotations that began this chapter, we now turn to research on attention and long-term memory, beginning with episodic memory. The vast majority of research on long-term memory has focused on episodic (or explicit) memory, conscious recollection of the past on direct tests of memory such as recognition, free recall, and cued recall. Furthermore, most of this research on memory and attention examines the role of attention during encoding. The bulk of this research provides little challenge to the intuitive sense that attention is critical for long-term memory; that is, memory for a stimulus is negatively affected by manipulations of selective or divided attention. Rather, research in this domain typically examines whether some aspects of stimulus encoding might be less reliant on attention than others and whether any elements of episodic encoding can be thought of as being free of attentional influence. In addition, there has been recent interest in determining whether retrieval from episodic memory requires attention to the same degree as encoding.

2.02.4.1 Attention and Encoding

The deleterious effects of reduced attention during encoding have been amply documented from the earliest days of psychological research (Smith, 1895). This holds for manipulations of selective attention as well as dual-task manipulations meant to divide central attentional resources. Beginning with selective attention, the research on dichotic listening makes clear that memory for the content of material presented in the unattended channel is greatly diminished on explicit memory tests such as recognition and recall (Broadbent, 1971). Furthermore, it is often the case that there is no measurable episodic memory at all for ignored material. For example, Eich (1984) found that recognition memory was at chance for words presented in the ignored channel of a dichotic listening study. Of course, it is also clear from this early research that at least some rudimentary perceptual information about the unattended message persists. Even in studies with tight controls for covert attentional switching, subjects recall whether the ignored channel was human speech, a male or female voice, a tone, and so on, implying that some encoding of perceptual information occurs without selection (Lachter et al., 2004). On the other hand, it should also be noted that, even if perceptual information about ignored stimuli is encoded to some degree, the encoding of this information is enhanced by focused attention (Cowan, 1995).

Research on visual selective attention reveals similar results. For example, Wolford and Morrison (1980) developed a visual analogue to dichotic listening in which the study trials consisted of a word flanked by two digits (e.g., 3 DOG 5). In one condition, participants attended to the digits, judging if they were of the same parity (both odd or both even) or of different parity. Although the word was focally presented, it was not the object of attention. In another condition, participants attended to the word. Several blocks of trials were presented to fully accustom the participants to the encoding task. Later, participants were given a recognition test for the words. Not surprisingly, recognition memory was greater when participants attended to the words as opposed to the digits. In addition, when tested on words from the final study blocks (after practicing the parity judgment task over many trials), participants in the parity-judgment condition exhibited no recognition memory for the words. This is quite similar to dichotic listening results that imply that selective attention is critical for later long-term memory and may be absent in an unattended condition (Merikle and Reingold, 1991).

It is clear that selective attention to a stimulus enhances (and may be necessary for) long-term episodic memory for the stimulus. Substantial research has also been conducted to examine the role of central attentional resources in memory encoding, typically by using a dual-task paradigm (i.e., a divided-attention manipulation), in which encoding is carried out under full or divided attention conditions. For example, in the full attention condition, the participant might read a series of study words and

attempt to memorize them for a later test. In the divided-attention condition, the participant attempts to read and memorize the study words while simultaneously carrying out a secondary task. The secondary tasks take on a number of forms but are all designed to compete for central attentional resources. For example, in the three-odd task, the participant hears a series of digits and signals whenever he/she detects a sequence of three odd numbers in a row. Alternatively, one might divide attention with a short-term memory load, in which the participant keeps in mind a set of digits or letters while reading and trying to memorize a set of study materials (the participant recalls the memory load at the end of the study trial to ensure that the material was kept in mind).

It is abundantly clear that dividing attention with tasks such as these degrades later memory on explicit tests, such as recognition or free and cued recall (e.g., Craik et al., 1996; Mulligan, 1998). It should be noted, however, that even quite demanding secondary tasks are unlikely to eliminate explicit memory (Mulligan, 1997, 1998). In addition, the effects of divided attention on encoding are graded: As the secondary task becomes more and more difficult, later memory for the study materials is reduced accordingly (e.g., Mulligan, 1997).

Much of the research in this area focuses on whether there are certain aspects of episodic memory that are more or less dependent on central attention. For example, Castel and Craik (2003) examined whether memory for item versus associative information has differential reliance on attention. Item memory refers to the recognition or recall of individual stimuli as having been present in some particular episode (e.g., the study phase of a memory experiment). Associative memory refers to memory for a newly formed association between stimuli. This goes beyond memory for which stimuli were present in a given context but requires remembering which stimuli were associated with one another. Castel and Craik argued that the formation of new associations requires binding processes that are carried out in prefrontal cortex and are highly dependent on central attention (e.g., Moscovitch, 2000). Consequently, these authors predicted that dividing attention during encoding should disrupt associative memory more than item memory. To test this prediction, participants were presented with pairs of study words under either full or divided attention (attention was divided with the three-odd task). Item memory was assessed by a recognition test for the second word of each pair. That is, participants merely had to remember whether the test word was presented during the study phase. Associative memory was assessed with a paired recognition test, using several types of test pairs. Some of the test pairs were identical to pairs on the study list (intact pairs), some test pairs consisted of two old words from different study pairs (rearranged pairs), and other test pairs contained one or two new words. On this test, participants try to recognize intact pairs from the study list, a discrimination requiring memory for a particular association formed during the encoding phase. Divided attention reduced accuracy in both of the item and associative tests, but as predicted, the deficit was substantially greater for associative recognition. Similar results are found on tests of context and order memory, tests that likewise require episodic binding of previously unrelated information (e.g., Troyer et al., 1999; Troyer and Craik, 2000).

Dual-process models of episodic memory, which propose two independent memory processes, recollection and familiarity (Jacoby, 1991; Yonelinas, 2002), are similar to the distinction between item and associative information. Recollection refers to consciously remembering both the specific test item and the context in which it occurred, whereas familiarity is an undifferentiated feeling that a stimulus was previously encountered. Recollection is assumed to entail a recall-like search process that is consciously controlled and intentional. Familiarity, however, is assumed to be unconscious and unintentional, reflecting processing fluency. Recollection is reliant on binding processes during encoding that associate items and their spatiotemporal context. This suggests that recollection should be quite sensitive to divided attention during encoding. Alternatively, familiarity is assumed to have much less reliance on associative processing, and consequently less reliance on attention. Several lines of research support these notions. First, different types of episodic tests show differential sensitivity to divided attention at encoding, with free recall being the most affected and recognition memory the least (e.g., Craik et al., 1996). Given that free recall is assumed to be heavily reliant on recollective search processes and recognition is more heavily influenced by familiarity, it makes sense that recall is more affected by divided attention than recognition. Second, methods used to tease apart recollection and familiarity within recognition memory (such as the process-dissociation and remember/know procedures) generally indicate that dividing attention during encoding has robust effects on later recollection but little effect on familiarity (see Yonelinas (2002) for a review).

2.02.4.2 Attention and Retrieval

Because the traditional view states that attention is critical for the *creation* of memory traces (e.g., James, 1890; Cherry, 1953; Broadbent, 1958; Norman, 1969), it is not surprising that the vast majority of the research on attention and episodic memory has focused on encoding. Interest in the role of attention in memory retrieval is a more recent development. In an early study on the topic, Baddeley et al. (1984) examined the effects of divided attention on both episodic encoding and retrieval using free-recall, cued-recall, and recognition memory tests. As one would expect, dividing attention during encoding decreased performance on all the memory tests. However, when attention was divided during retrieval there was little decrease in memory accuracy, leading Baddeley et al. to conclude that retrieval processes are relatively automatic.

Craik et al. (1996) likewise varied attention during encoding and during retrieval but came to somewhat different conclusions. Craik et al. used a secondary task that permitted two complementary assessments of the role of attention in memory retrieval. First, as in Baddeley et al. (1984), accuracy in the memory task was compared under the full and divided attention conditions. Second, performance on the secondary task in the divided-attention condition was compared with performance in this task when performed alone (in a baseline condition, in which the secondary task was the sole task). The first comparison indicates whether the secondary task has an effect on memory retrieval. The second comparison indicates whether memory retrieval has an effect on the secondary task. Such secondary task costs are a traditional way to measure whether a process (like memory retrieval) requires attention. The results of the first comparison were consistent with Baddeley et al. (1984): dividing attention during retrieval produced little decline in memory accuracy (of course, divided attention during encoding produced the typical reduction in memory performance, **Figure 3**). However, the second comparison indicated that performance in the secondary task was disrupted when paired with memory retrieval. This contradicts the proposal that retrieval processes are automatic. Rather, Craik et al. argued, retrieval processes make use of attentional resources (as evidenced by the secondary task costs) but proceed in an obligatory (or 'protected') manner (Naveh-Benjamin et al., 2000). Under this view, retrieval takes precedence over other ongoing activities, protecting retrieval accuracy from the deleterious effects of a secondary task.

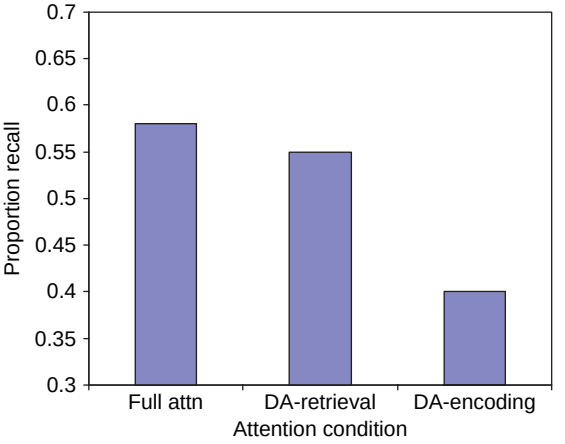

Figure 3 Craik et al. (1996) found that dividing attention during encoding produced a substantial decrease in recall, whereas dividing attention during retrieval produced minimal effect. Full attn = full attention at both encoding and retrieval; DA-encoding = divided attention during encoding, full attention during retrieval; DA-retrieval = full attention during encoding, divided attention during retrieval.

Although Baddeley et al. (1984), Craik et al. (1996), and several other studies (see Craik (2001) for a review) found no effect of divided attention at retrieval on memory accuracy, such effects sometime emerge. Some studies report significant effects on free and cued recall without finding a comparable effect on recognition accuracy (e.g., Park et al., 1989; Anderson et al., 1998). In other studies, a significant decrement to recognition accuracy is reported (Fernandes and Moscovitch, 2000; Hicks and Marsh, 2000; Lozito and Mulligan, 2006). It is important to ascertain why such effects might be found.

Fernandes and Moscovitch (2000, 2003) have argued that memory retrieval is more likely to be disrupted when the secondary task and the memory task use the same type of materials. For example, Fernandes and Moscovitch (2000) used either a number-based or word-based secondary task as participants carried out a recall or recognition test for studied words. The number-based task did not disrupt test accuracy (consistent with Craik et al., 1996), whereas the word-based task significantly reduced memory accuracy. Although the results indicate a divided attention deficit in recognition, Fernandes and Moscovitch argued that decrements obtained were not caused by competition for central attentional resources but were, rather, a result of competition for word-specific representational

systems. Fernandes and Moscovitch labeled this a material-specific interference effect.

Hicks and Marsh (2000), in contrast, posited that competition for central resources can also lead to a divided attention effect under certain conditions. They based this claim on the dual-process model described above, arguing that search-based recollection processes should be disrupted by a secondary task, whereas familiarity processes should be less susceptible. Consequently, encoding conditions that produce higher levels of recollection should exhibit divided-attention effects. Hicks and Marsh had participants either read or generate words during encoding under the standard assumption that generation enhances later recollection. During the recognition test, memory accuracy was reduced by divided attention in the generate condition but not in the read condition. Lozito and Mulligan (in press) also found significant divided-attention effects on both conceptual and perceptual recognition tests, converging on a similar conclusion: Memory retrieval that is recollective in nature is susceptible to divided-attention effects during retrieval. In light of the results of Fernandes and Moscovitch (2000), it is critical to note that the secondary tasks of Hicks and Marsh and of Lozito and Mulligan used numbers, whereas the memory test used words, implying that the divided-attention effect is general (i.e., implicating central attention), rather than material specific.

2.02.5 Attention and Other Forms of Long-Term Memory

2.02.5.1 Attention and Implicit Memory

At the outset of this chapter we differentiated between explicit (episodic, recollective, intentional, conscious) memory and implicit (unconscious, unintentional, nonepisodic) memory. Explicit memory is typically measured with traditional memory tests, such as recognition and free and cued recall, in which participants are directed to think back about a prior event and report on it. Implicit memory tests simply require participants to perform a task (e.g., completing word fragments, generating category examples) without reference to any prior experience. Memory for prior events is inferred from the increased ability to complete, generate, identify, or otherwise process recently presented stimuli. The enhanced processing is called priming.

The principles that govern implicit and explicit memory appear to differ in a number of ways, as evidenced by striking population and functional dissociations (*See* Chapter 2.33; Roediger and McDermott, 1993; Mulligan, 2003b). Coupled with neuroimaging evidence (e.g., Schacter and Badgaiyan, 2001), these dissociations indicate separable components of memory underlying implicit and explicit memory phenomena. Given the centrality of attention in theories of memory encoding and the rather uniform effects of divided attention on episodic memory, it is important to evaluate the role of attention in implicit memory.

With regard to manipulations of selective attention, the results are quite clear: Directing attention away from a stimulus diminishes the amount of priming detected (e.g., Eich, 1984; Bentin et al., 1998; Crabb and Dark, 1999; Mulligan and Hornstein, 2000). This implies that selective attention is necessary for robust levels of priming. A separate question is whether implicit memory can arise in the absence of attention. This question is a matter of some debate. A study by Eich (1984) indicated this possibility. In this dichotic listening experiment, subjects shadowed a prose passage presented to one ear while word pairs were presented in the other ear. Each word pair consisted of a homophone and a word biasing its less common meaning (e.g., taxi-FARE). Subjects showed no explicit recognition for these words. In an implicit test condition, subjects were given a spelling test for aurally presented words. This test contained the homophones presented during the shadowing task as well as a control set of homophones. The subjects were more likely to choose the uncommon spelling for homophones from the ignored channel than for the control homophones, demonstrating above-chance priming for the word pairs presented in the irrelevant channel. This has been taken as evidence of implicit memory for unattended stimuli. It should be noted that, when the word pairs were presented to the shadowed ear, even greater levels of priming resulted. So Eich's results demonstrate reduced priming for the ignored versus attended channel, coupled with above-chance priming for the material presented in the ignored ear. Merikle and Reingold (1991) showed a similar pattern of results for visual selective attention.

Although the results of Eich (1984) were impressive and indicate that implicit memory has less reliance on selective attention than does explicit memory, there is reason to wonder whether these results represent implicit memory for unattended material. Wood et al. (1997) suggested that the presentation rate of the material in Eich's (1984) study was too slow to preclude rapid, covert switches of

attention. As noted in the earlier discussion of dichotic listening, there is always the concern of attentional slippage. Wood et al. investigated this issue by varying the speed with which the attended materials was presented. At the slower rate used by Eich, Wood et al. found the same results: chance-level recognition coupled with above-chance priming on the spelling task. However, at the faster rate (a rate at which subjects could still successfully shadow), priming in the spelling task was not above chance. Wood et al. argued that a faster rate in the attended channel renders the shadowing task more attention demanding and diminishes the likelihood of covert (and undetected) switches of attention to the putatively unattended channel. Consequently, even though the unattended materials were presented at the same slow rate as in the Eich study, no priming was found. This argues against the notion that implicit memory is found for unattended stimuli. Similarly, Berry et al. (2006) recently failed to replicate Merikle and Reingold's results with visual selective attention, strengthening the concern about implicit memory in the absence of attention.

A related line of research has used dual-task paradigms to examine the role of central attention resources in implicit memory. As with selection attention studies, initial studies implied important differences in the role of attention in implicit and explicit memory, with later studies modifying this conclusion. Consider an experiment by Parkin and Russo (1990), in which participants named pictures of everyday objects during the study phase. In the full-attention condition, this was the sole task. In the divided-attention condition, participants named the pictures and carried out a tone-monitoring task, in which a series of tones were categorized as high, medium, or low. Participants were later given an explicit test, in which they recalled the names of the pictures, or an implicit test, in which they identified fragmented pictures. Priming in this task is indicated by identification of studied (or old) pictures at lower levels of clarification than the new pictures. As would be expected, recall was greatly diminished by divided attention. However, the amount of priming on the picture-fragment task was essentially the same for the full- and divided-attention conditions. Several other studies produced similar results (see Jacoby et al., 1989; Parkin et al., 1990; Russo and Parkin, 1993; Mulligan and Hartman, 1996; Schmitter-Edgecombe, 1996a,b), giving rise to the claim that implicit memory has little reliance on attention and largely reflects automatic encoding processes (e.g., Jacoby et al., 1989, 1993; Parkin et al., 1990; Parkin and Russo, 1990; Bentin et al., 1995; Isingrini et al., 1995; Aloisi et al., 2004).

The notion that implicit memory reflects automatic encoding processes has not withstood subsequent research, however (see Mulligan and Brown (2003) for a review). First, this initial research focused on perceptually based priming tasks (such as perceptual identification and word and picture fragment completions), in which degraded or partial perceptual cues guide memory retrieval. Implicit memory may also be assessed with conceptually based tests in which memory retrieval is guided by conceptual cues, such as category names or associates. Mulligan and Hartman (1996; Mulligan, 1997, 1998) demonstrated that conceptual priming is quite sensitive to division of attention during encoding. Second, even perceptually based implicit tests have proven susceptible to divided-attention manipulation under some conditions. For example, Mulligan (2003a) found that a divided-attention task requiring frequent response selection affected perceptual priming, whereas a divided-attention task requiring less frequent response selection left priming unaffected.

To summarize the results, it is now clear that implicit memory is generally affected by a variety of selective- and divided-attention manipulations, indicating that implicit memory relies on both selective attention and central attentional resources. In addition, the effects of these attention manipulations are generally larger on explicit than implicit memory. At present, the results indicate that implicit and explicit memory differ quantitatively rather than qualitatively in terms of their reliance on attention. Both forms of memory rely on attention (in both the selective and central-resources senses), but explicit memory appears to rely on attention more heavily (see Mulligan, 2003a, for speculation as to why).

2.02.5.2 Attention and Procedural Learning

Procedural learning encompasses the acquisition of perceptual, motor, and cognitive skills and is another form of nonconscious memory. Skill acquisition is characterized by gradual improvements in performance over many sessions of practice. To isolate processes of procedural learning and make it amenable to experimental analysis, researchers have typically turned to a small set of laboratory tasks. The most prominent example is the serial reaction time (SRT) test. In this test, participants identify the location of a target as it moves among a fixed set of

(usually four to seven) locations by pressing the key that corresponds to each new location. Embedded in the sequence of locations is a repeating pattern. Reaction times gradually decrease over hundreds or thousands of trials. Procedural learning is assessed in a transfer block in which the pattern is no longer present. An increase in reaction times indicates that something about the repeating pattern had been learned. Another commonly used task is the artificial grammar (AG) learning task developed by Reber (1967). In this task, participants are presented with strings of elements (e.g., letters) that were produced by a complex set of rules – the underlying grammar – that dictates the order in which the elements may occur. After exposure to the learning set, a new set of strings is presented, some of which are consistent with the grammar (i.e., these are strings generated by the grammar), and others that violate the grammar. The participant's task is to categorize the test strings as grammatical or nongrammatical. Above-chance accuracy on this test in the absence of verbalizable knowledge of the grammatical rules is usually taken as evidence of implicit learning of (at least some aspects of) the underlying grammar (see Dienes and Berry, 1997, for a review).

The bulk of the research on attention and procedural learning has examined the role of central attentional resources, using dual-task paradigms. In an early study, Nissen and Bullemer (1987) reported that dividing attention during learning eliminated procedural learning in the SRT task. The dual task used in that study was a tone counting task, in which participants heard high and low tones and kept a running count of the number of low tones. However, there is evidence that the tone-counting task may disrupt procedural learning by interfering with the timing or organization of responses in the SRT task rather than through its demands on central attention (e.g., Stadler, 1995). An arguably less problematic secondary task, the symbol counting task, produces similar effects, disrupting procedural learning relative to a full-attention condition (e.g., Shanks and Channon, 2002; Shanks et al., 2005). Research using the AG task produces similar results. Procedural learning in this task is reduced by a concurrent decision task (Dienes et al., 1991). The learning of complex motor skills has a similar reliance on attention (Wulf and Prinz, 2001). Thus, the acquisition of procedural skills appears to rely on central attentional mechanisms. However, the expression of highly learned skills may not. For example, Helman and Berry (2003) found that dividing attention during the final test in an AG task produced no effect on the expression of procedural information that was initially acquired in a full attention condition. Eversheim and Bock (2001) present a single study of procedural learning, which reveals the typical pattern of results across early acquisition trials and later expression of a practiced skill. These authors used a tracking task in which the visual feedback had been reversed. Over the early trials of the tracking task, performing a secondary task greatly diminished the rate of improvement. However, after extensive practice with the task, a dual-task condition produced little decrement in performance. That is, the acquisition of this new perceptual-motor skill was harmed by distraction, whereas the expression of the attained skill was little disrupted by divided attention.

Although the majority of the relevant studies examined central-attentional resources, a few have examined the relationship between selective attention and procedural learning. Perhaps not surprisingly, most have concluded that procedural learning requires selective attention to the stimuli of the learning task (e.g., Jiang and Chun, 2001; Turk-Browne et al., 2005; see also Wulf and Prinz, 2001).

2.02.6 Concluding Comments

This chapter began with quotations from James and Ebbinghaus articulating the traditional view that attention is critically important for memory. Modern researchers differentiate among multiple forms of both memory and attention, which has allowed a more fine-grained analysis of this relationship. We have seen the ways in which attention is intertwined with the concept of working memory, so much so that aspects of working memory (i.e., the central executive) are sometimes equated with central attention. It is also apparent that attention is critical for acquisition in long-term memory. This is especially clear with regard to episodic memory, although reliance on attention might be greater for certain aspects of episodic encoding (e.g., associative information) than for others (e.g., item information). Furthermore, recent research highlights the importance of attention during encoding for nonepisodic forms of memory, such as implicit and procedural memory phenomena. It is only in the case of long-term memory retrieval that the role of attention is debated. Retrieval from episodic memory appears to be attention demanding, albeit less so than memory encoding. In contrast, retrieval in procedural memory, especially of

well-learned skills, is much less dependent on attention. Finally, there is little research on the role of attention in implicit memory, an area in need of systematic research.

2.03 Sensory Memory

N. Cowan, University of Missouri, Columbia, MO, USA

2.03.1 Introduction

Sensory memory refers to the short-lived memory for sensory details of events. This can include how things looked, sounded, felt, smelled, and tasted. To some extent, this type of information must persist in long-term memory. It allows us to recognize a familiar voice over the telephone or to recognize the taste of a favorite food. However, the human information processing system seems to be designed in such a way that the richness of sensory memories is quickly lost, leaving behind more categorized memories. For example, when one hears or reads a sentence, the gist is strongly saved but the exact manner in which the material was presented is more quickly lost; verbatim wording is readily accessible only for the most recent phrase, and it is incomplete even for that phrase (Sachs, 1967; Jarvella, 1970). Physical features of stimuli do leave long-term memory traces that influence later behavior (Kolers, 1974; Cowan, 1984; Weldon et al., 1995), but these may lack the fine-grained subtlety of short-lived sensory memories. Sensory memory is typically distinguished from mental imagery, which can include sensory-like qualities but is typically less detailed. For example, one may form an image of a U.S. penny (one-cent coin), but it is distinguished from a sensory memory in its vagueness, such as not really knowing which way Lincoln's head faces.

It has long been recognized that at least some sorts of sensory memory operate in a manner that is different from other forms of memory. In classic research on attention, subjects were asked to repeat a message presented to one ear and ignore a conflicting message presented to the other ear concurrently. Although they could recall little of the message presented to the ear to be ignored, when the task ended the last few words of that message often could be recalled (Broadbent, 1958). This suggested that the information in the unattended message was held temporarily in a form that soon would be lost if it were not attended. A natural way to understand that phenomenon is that the temporary storage consists of sensory information and a longer-lasting record can be saved only if that sensory information is attended before it fades away, which allows the formation of memory for the words that were spoken.

Sperling (1960) carried out a classic study that dramatically illustrated the difference between

sensory and abstract forms of memory for a recent event. Subjects saw a briefly presented array with three rows of characters and then received a tone indicating whether the top, middle, or bottom row should be recalled (a partial-report cue). If the tone was presented soon enough, almost all characters in the designated row could be recalled, provided that there were four or fewer characters in the row. As the delay between the array and the tone cue was increased, performance diminished, quickly at first and then more slowly, curving down to a steady level (asymptote) within 1 s. By that point, the cue came too late to be of use, and subjects could remember only as many characters as one would expect if the limit were about four characters retained from the entire display. This pattern of results could be accounted for on the basis of two types of memory: a sensory memory that held the entire display like a snapshot for a very short time, even though the number of characters was far too large to be attended at once, and a more abstract memory that could hold only about four items. The partial-report cue could influence which part of the sensory memory was transferred to an abstract form and then reported, but the cue had to be presented before the sensory memory faded.

One can see from this finding that an understanding of sensory memory is critical for an understanding of performance on memory tests. Even if one is trying to assess the availability of abstract forms of memory, the contribution of sensory memory must be either eliminated or taken into account. Beyond that, sensory memory is an important aspect of our conscious experience of the outside world, as we will see.

One thing that makes sensory memory controversial is that the boundaries between it and other types of memory are debatable. By some accounts, there is a distinction between sensory storage that comes before perception and postperceptual storage (Massaro and Loftus, 1996). It does appear that there are two phases of temporary memory for stimulus qualities: a brief phase that seems like a continuation of the stimulus for about a quarter second, and a second phase that seems like a vivid recollection for some seconds (Massaro, 1975a; Cowan, 1984, 1988, 1995). However, one could argue that the process of perception begins quite rapidly in the brain, and that the first phase of memory for sensation is already part of perception. When this brief memory begins to fade away, it is not the same thing as a picture becoming hazy or indistinct, as if viewed through a fog. Instead, it is as if different features of each object can be lost separately. In Sperling's (1960) type of procedure, for example, the errors that crop up as the partial-report cue is delayed (or omitted) appear to be primarily location errors, in which a character is reported at the wrong location rather than forgotten completely (Townsend, 1973; Mewhort et al., 1981; Irwin and Yeomans, 1986). Consistent with this, a great deal of neurological research suggests that different features of an object, such as its identity versus its location, are perceived using different neural subsystems (in vision: Haxby et al., 1991; in hearing: Alain et al., 2001; in touch: Pons et al., 1992), and that perception of an object therefore requires a subsequent integration of these features. Sensory memory could include a constellation of features that have not necessarily been integrated. The full integration of these features into objects could require attention (Treisman and Gelade, 1980), which could result in a nonsensory type of memory.

It also may be that the brief sort of sensory memory is not truly a memory as such but, rather, a side effect of perceptual processing. The difference is that the neural effect of a stimulus giving rise to sensation begins before the stimulus ends and, for very brief stimuli, may not even reach a peak until some time after the stimulus has ended. The duration of this sensory memory appears longer for less intense stimuli. Such findings suggest that the sensory persistence of the stimulus may reflect conscious access to neural processes involved in perception (cf. Weichselgartner and Sperling, 1985; Dixon and Di Lollo, 1994; Massaro and Loftus, 1996; Loftus and Irwin, 1998).

Given such debates, it is important to back up and examine the distinctions regarding sensory memory that often are taken as its defining characteristics.

2.03.2 Defining Characteristics of Sensory Memory

2.03.2.1 Memory for Stimuli As Opposed to Ideas

Consider how the perception of a newborn infant must differ from that of an adult: it differs in many ways, but one important difference is as follows. The infant has a range of sensory experiences, but there is not yet any way to attach significance or meaning to most of those experiences. An adult does have meanings, or ideas, to attach to experiences. For example, if an American adult

sees a red octagon, it may remind him or her of a traffic stop sign. Yet it seems reasonable to believe that there is perception and memory of the shape and color that can be separated from its meaning. That may not be exactly true, inasmuch as it is difficult for people to remember or perhaps even to perceive objects without some influence of their knowledge that apples are red, grass is green, and so on (Bartleson, 1960; Ratner and McCarthy, 1990). After identification of a stimulus and its meaning has taken place, there may be neural feedback to the parts of the brain that perceive sensations. Nevertheless, to a first approximation, we can think of sensory memory as the memory for the knowledge-free, sensation-based characteristics of stimuli that resemble what a newborn would perceive. If it turns out to be impossible to think of sensory memory in this way, the postulation of a distinction between sensory and nonsensory forms of memory may have to be weakened.

2.03.2.2 Memory for Information More Fine-Grained Than a Familiar Category

A critical step in perception is categorization: gaining the knowledge that a particular stimulus is an example of items in a certain category, whether or not one knows a verbal label for that category. For example, one can perceive two successive piano notes as coming from different tone categories even if one does not know or remember the names of those categories. Sensory memory is typically viewed as coming before that step of categorization. As a result, it can include fine details that distinguish items within a category, such as differences in tone frequency too small to change the identity of the note, except to make it slightly out of tune (Keller et al., 1995), differences between two slightly different pronunciations of the same vowel (Pisoni, 1973), or differences between two slightly different shades of the same color (Massaro, 1975a). In each case, if slightly different stimuli are presented in close succession (ideally within about 250 ms of each other), the sensory memory of the first stimulus can be compared to the second stimulus with good acuity. This characteristic could be important, as when one is trying to learn exactly how to imitate a word spoken in an unfamiliar language or, in infants, learning language in the first place.

2.03.2.3 Memory Even for Unattended Stimuli

As mentioned in the introduction, the concept of sensory memory arose to explain how people can briefly retain more information than they can process. The concept of a short-lived sensory memory for unattended information was present in the selective listening procedure (Broadbent, 1958) and the partial-report procedure using visual arrays (Sperling, 1960). Darwin et al. (1972) brought these two lines of research together by constructing an auditory analogue of Sperling's procedure. In this analogue, an array of three simultaneous spoken characters presented to left, center, and right spatial locations was followed by a second such array and then a test for the information presented at one location. Similar findings were obtained using arrays of tones (Treisman and Rostron, 1972; Rostron, 1974).

In the auditory studies, it was not possible to present 12 or more simultaneous stimuli as Sperling (1960) did in the visual modality. Consequently, it is possible that subjects were able to carry out a perceptual analysis of the sounds. Nevertheless, other evidence suggests that the perceptual analysis is incomplete and that the items need not have received full attention to have been remembered in the procedure of Darwin et al. (1972). Cowan et al. (1990) carried out a procedure in which nine syllables (*bee, bih, beh, dee, dih, deh, gee, gih, geh*) were presented at random intervals through headphones while the subject ignored them and silently read a novel. When a light signal occasionally appeared, the subject was to stop reading and identify the last spoken syllable, which occurred 1, 5, or 10 s ago. Generally, performance was good at a 1-s retention interval and decreased dramatically across the longer intervals. However, in an experiment in which subjects had to monitor the speech stream while reading (pushing a button if *dih* was presented), there was no forgetting across retention intervals, even though the monitoring task was performed correctly on only 60% of the trials. In another experiment, the reading was whispered by the subject and recorded so that diversions in attention away from the reading could be observed (as 1-s pauses in reading). It was found that consonant perception was much better on trials in which there were diversions of attention while the target syllable was presented. The sensory form of memory may only be adequate for vowel perception, and memory for consonants may be nonsensory in nature and may require attention to be formed. Vowels are more or less steady-state sounds, whereas

stop consonants involve rapid acoustic changes that may be too complex to be maintained in a long form of sensory memory.

In sum, it seems apt to say that sensory memory is a special type of memory that may not require attention to be formed. It cannot hold all aspects of the environment; perhaps it comprises a snapshot of information or slice of time and is unable to hold much information that changes over time. Nevertheless, it is sufficient to save information about far more than one can attentively process at once and thereby serves as a sort of multichannel bulletin board helping the perceiver to shift attention from one sensory channel to another as the incoming information warrants.

2.03.3 Why Study Sensory Memory?

Cognitive psychologists and other students of human behavior have not been consistently enthralled by the concept of sensory memory. The majority of them are interested in learning how meaningful information is processed, and for that enterprise, the fate of sensory information seems to be of secondary interest. Taking this paucity of interest further, Haber (1983) asserted that sensory memory is a byproduct of processing that is not really of any use in ecologically relevant circumstances, with rare exceptions such as when one wants to read on a dark, rainy night by the light produced by flashes of lightning. However, there are several key reasons why sensory memory is of interest. Some important phenomena in the modern world make use of visual sensory memory; without its smearing of the effects of sensation, we would not perceive motion pictures as moving but, rather, as a rapid succession of still frames. It seems likely, as well, that there are analogous phenomena in the natural world. As one spots a deer running across the forest, the continual disappearance of parts of the animal behind trees and reappearance of those parts is reconstructed by one's perceptual system to form a continuous event, the deer running. Sensory memory may be critical in allowing this smooth percept to be formed. In audition, the case is straightforward, inasmuch as sounds inherently change over time. Some mental device must capture segments of the sounds in order to interpret them. For example, as we already have noted, language learning may depend on sensory memory for how words are pronounced. Some less obvious reasons to be interested in sensory memory are as follows.

2.03.3.1 Understanding Qualia and Consciousness

Philosophers speak of qualia, the essential mental states corresponding to experiences. These may be considered the building blocks of conscious experience. The equivalent notion within psychology is the study of subjective experience that can be traced back to the introspectionist method of Wilhelm Wundt, who founded the first laboratory of experimental psychology in 1879. Experimental methods related to introspection make use of similarities in the verbal descriptions of an event across individuals. Descriptions of fleeting events get at the smallest temporal unit of consciousness, or psychological moment, during which all events appear simultaneous even if they are not (e.g., Stroud, 1955; Lichtenstein, 1961; Allport, 1968; Eriksen and Collins, 1968; Creel et al., 1970; Robinson and Pollack, 1971). In the typical experiment to examine this concept, multiple visual displays (such as two sets of dots) are presented rapidly, and when they are presented in close enough temporal proximity, they are perceived as a single image that includes all of the presented items (e.g., all of the dots together). The presentation time within which there is perceived simultaneity depends on stimulus factors but is typically in the range of 100 to 200 ms. One account of the psychological moment states that the sensory memory of the first presentation still must be sufficiently active when the second presentation arrives, so that it becomes impossible to tell the difference between sensory memory and sensation, allowing them to be fused into an apparently simultaneous percept. On that basis one can explain, for example, why a loud noise and a closely following quieter noise can be perceptually fused into a single noise if the gap between them is no more than 100 ms or so (Plomp, 1964). The second noise must be mistaken for part of the decaying sensory trace of the first noise, and the chances of that happening increase as the gap between them gets shorter and the second noise gets quieter.

There were two competing hypotheses of the psychological moment, and only one of them is consistent with a sensory memory account. According to a continuous-moment hypothesis, the psychological moment is a sliding window of time. This is compatible with the notion that the sensory memory of each stimulus can be combined with immediately successive stimuli. In contrast, according to a discrete-moment hypothesis, there are successive windows defined by internal neural events (e.g., oscillation in

the firing of neurons so as to collect incoming sensory signals). Two brief events occurring, say, 80 ms apart would fall in either the same psychological moment or in different moments, depending on when they happened to occur relative to the boundary between successive moments.

Allport (1968) carried out an experiment to decide between these hypotheses that seems especially elegant and decisive. On every trial, 12 horizontal lines were presented in rapid succession, over and over, progressing from a line high on the oscilloscope screen to lines lower and lower on the screen. Only one line was presented at a given time, but because of perceived simultaneity, multiple lines were visible at once. The rate of succession was adjusted for each subject until exactly 11 of the 12 lines were visible at once. At this rate, one could observe what was termed shadow movement as the remaining line that could not be seen changed over time. Now, according to a continuous-moment hypothesis, the shadow should move from top to bottom. While the 12th, lowest line is presented, the sensory afterimage of the 1st, highest line is the oldest and fades. While this line 1 is again presented, the sensory afterimage of line 2 becomes the oldest and fades; while line 2 is again presented, the sensory afterimage of line 3 becomes the oldest and fades; and so on. In contrast, according to a discrete moment hypothesis, the shadow should move from bottom to top. If lines 1–11 fit within one discrete perceptual moment, line 12 is not visible. Then line 12, along with the next presentation of lines 1–10, will all fit into the next moment, and line 11 will not be visible; then lines 11–12 along with the next presentation of lines 1–9 will all fit into the next moment, and line 10 will not be visible; and so on. The results consistently showed downward shadow movement, supporting a continuous psychological moment and a sensory memory explanation.

2.03.3.2 Understanding Group Differences in Information Processing

If the psychological moment is determined by sensory memory, then group differences in sensory memory have important implications for how the groups perceive the world. It determines which events will be grouped together within the duration of sensory memory and which will be separated, beyond that duration (e.g., Dixon and DiLollo, 1994; Loftus and Irwin, 1998).

A study by Cowan et al. (1982) suggested that 8- to 9-week-old infants have a longer first phase of sensory memory than adults do. The procedure that was used was one of auditory backward recognition masking (Massaro, 1975b). In that type of procedure in adults, two brief sounds are presented in rapid succession, and the subject is to identify the first sound in a multiple-choice test. Performance improves as the time between the onsets of the first and second sounds (the stimulus onset asynchrony or SOA) increases to about 250 ms. Even if the choices are so close that performance is substantially below 100%, performance levels off to an asymptotic level at about that SOA. The explanation (in concert with other, convergent procedures that we discuss later) is that information must be extracted over time from sensory memory into a more abstract form of memory until the second sound masks or overwrites the sensory memory of the first sound, interrupting the process of extracting information. By an SOA of 250 ms, the auditory sensory memory fades, so delays of the second, masking stimulus beyond that point would not help. For infant study, an *ah-ah* vowel pair was presented repeatedly, but with different SOAs among the pairs. Sometimes, an *eh-ah* pair was presented instead, but the access to this different pair was restricted to pairs with a particular SOA. The dependent measure of sound discrimination was how long and how vigorously infants were willing to suck on a pacifier that yielded not food but access to pairs that changed from *ah-ah* to *eh-ah,* rather than being stuck with a monotonous repetition of *ah-ah.* (For other infants, the assignment of the two vowels was reversed.) Higher sucking rates for this condition than for a condition in which there was no acoustic benefit of sucking yielded evidence of sound discrimination when the changes occurred within pairs with a 400-ms SOA, but not when the changes occurred within pairs with the 250-ms SOA that is sufficient for optimal performance in adult studies.

Various methods also have been used to show that the duration of sensory memory may differ from the norm in children with mental retardation (Campbell, and Meyer, 1981) or reading disability (Sipe and Engle, 1986) and in patients who have had unilateral temporal lobectomy (Efron et al., 1985). It is not known whether sensory memory abnormality contributes to cognitive disabilities in these groups.

2.03.3.3 Eliminating Contamination from Nonsensory Aspects of Cognition

Even if one is interested in abstract forms of memory, it is necessary to examine sensory memory in order

to control its contribution in various test procedures. A good example is the procedure of Luck and Vogel (1997) to examine working memory. An array of simple, schematic objects is presented and then followed by a second array identical to the first or differing in the identity of one of the objects. In such procedures, people can remember about four items (cf. Sperling, 1960). If the interest is on that working memory limit, then one needs to be sure that sensory memory has faded away before the test. One could use a partial-report cue to determine when it has faded, as Sperling did. Another method is to mask the array with another, interfering array after various intervals and to determine how much information already has been transferred from sensory memory to working memory. Woodman and Vogel (2005) did that and suggested that sensory memory for items in an array was transferred to working memory at a rate of about 50 ms per item in the array.

A similar point could be made with respect to understanding attention. Imagine an experiment in which different word lists are presented simultaneously to the left and right ears. Suppose one has evidence suggesting that an individual can attend to both channels of speech at once. Such evidence may be misleading. If the speech is presented too slowly, there is the possibility of instead (1) attending to the word presented to one ear, and then (2) switching attention to the other ear in time to perceive the sensory memory of the word presented to that ear. If this is the case, speeding up the presentation may eliminate evidence that both channels are being perceived. For an example of this see Wood et al. (1997). In attention research, as in working memory research, the effect of sensory memory must be taken into account.

2.03.4 Techniques to Examine Sensory Memory

Of necessity, we already have discussed a number of techniques used to examine sensory memory. Now it should be helpful to take a brief inventory of these methods. In taking this inventory it is important to keep in mind that different methods disagree. Still, it may be proposed that different outcomes theoretically might result from a common sensory memory. For example, a subjective impression of the duration of a stimulus might result from the duration for which the sensory neural response exceeds a certain intensity, whereas a measure of information about the stimulus might result from an integration of the neural response intensity over time (cf. Cowan, 1987; Loftus and Irwin, 1998).

2.03.4.1 Sensory Persistence Procedures

In the most straightforward types of investigation, stimuli extended over time are perceived as being simultaneous, as in the investigations of the psychological moment described above. Johann Andreas Segner, a German physicist and mathematician living in the 1700s, attached a glowing coal to a cartwheel, rotating the wheel at various speeds. He found that a complete circle was perceived if the wheel was rotated at a rate of at least 100 ms per rotation. This implies that the sensory memory of the glowing coal fell below some minimal level of brightness by about 100 ms.

Efron (1970a,b,c) carried out quite a nice set of experiments to refine the sensory persistence procedure. An indicator (e.g., a click) stimulus was presented along with a target stimulus (e.g., a light flash), and the study estimated when the indicator sounded as if it occurred at the same time as the offset of the target (or, in a control condition, the onset of the target). The result was that the onset of the target was only very slightly overestimated, whereas the offset was overestimated by up to about 200 ms. The nature of the overestimation depended heavily on the duration of the target, such that the target appeared to have a minimal perceived duration of about 200 ms. Very similar results were obtained when the target was visual and when it was auditory. The duration of a perception appears to be the duration of the perceptual response, and if the target stimulus is brief, it reflects the duration of the target plus its perceptual afterimage or sensory memory.

2.03.4.2 Partial-Report Procedures

We already have described the procedures like that of Sperling (1960) and Darwin et al. (1972), in which an array of items is followed by a partial-report cue that allows part of the sensory memory representation to be transferred to a more abstract, categorized, reportable state, working memory. One enigma worthy of consideration is that, whereas persistence procedures have produced similar results for vision and audition, partial-report procedures seem to produce much shorter periods of cue utility for vision (under 1 s) than for audition (about 4 s). We return to this enigma when discussing theories of forgetting from sensory memory.

2.03.4.3 Selective-Attention Procedures

We have touched upon procedures in which an auditory stimulus is ignored at the time of its presentation and only subsequently receives the benefit of attention applied to the sensory memory (Broadbent, 1958; Cowan et al., 1990; there are various other examples such as Treisman, 1964; Norman, 1969; Glucksberg and Cowen, 1970).

It is possible also to examine memory for unattended material in the visual modality. Various techniques can be used to get the subject to contract or expand the focus of visual attention (Eriksen and St. James, 1986; LaBerge and Brown, 1989), and one can then examine memory for information inside or outside of the attentional focus. One difficulty is that there is poorer perceptual analysis of information in the periphery of the visual field, regardless of whether that part of the field is the focus of attention. Usually, the center of the visual field of gaze is also the focus of attention, so attention and visual acuity are confounded. (That is not the case in audition, for which there is no change in the effectors accompanying attention.) Luckily, it is possible to direct a subject's attention to an area outside of the center of gaze (e.g., Brefczynski and DeYoe, 1999). For this reason, it is theoretically possible to determine the effects of attention on visual perception and examine memory for centrally presented but unattended stimuli. It does seem clear that visual attention affects perception, but more research is needed to reveal the details of unattended sensory images in the center of gaze.

2.03.4.4 Backward-Masking Procedures

We already have touched upon the technique of backward masking, in which a brief target stimulus is followed by a mask and impedes recognition of the target. Notably, little masking occurs if the mask precedes the target (Massaro, 1973). This confirms that the critical aspect of backward masking is overwriting of the target's sensory memory by the mask, not the mere proximity of target and mask. It is also noteworthy that the period of backward masking obtained in the auditory modality is quite similar to the visual modality (Turvey, 1973). That appears to be true also in persistence procedures, but not in partial-report or selective-attention procedures, a point to which we return shortly.

One benefit of the masking procedure is that it can be used to show that the neural locus of sensory memory is not entirely peripheral. Turvey (1973) showed that substantial backward masking occurs even when the target was presented to one ear and the mask was presented to the other ear. (For convergent evidence of a central locus of the visual afterimage using a persistence technique, see Haber and Standing, 1969, 1970.) Kallman and Morris (1984) showed something similar in audition, though the opposite conclusion is often cited (Hawkins and Presson, 1977). Cowan (1995, Section 2.5) cited physiological studies supporting the notion that auditory sensory memory has a central locus.

2.03.5 Theories of Forgetting From Sensory Memory

2.03.5.1 Modality-Specific Rates of Decay

It is interesting to see how a scientific field responds to inconsistency. Although the methods described above have been present for quite some time, most theoretical mentions of sensory memory in textbooks seem to go along with the conclusion that auditory memory outlasts visual memory. That could account for the findings of partial-report and selective-attention procedures, but not the findings of persistence and backward-masking procedures. An alternative view is described in the sections that follow.

2.03.5.2 Two Phases of Sensory Memory with Different Rates of Decay

The study of Sperling (1960) was truly seminal in the field. When Darwin et al. (1972) found that sensory memory appeared to be useful for a much longer period in audition (about 4 s) than Sperling found in vision (less than 1 s), it led to the belief that auditory memory lasts longer than visual memory. However, Massaro (1976) offered a different interpretation. Whereas Sperling's experiments used a large number of simultaneous characters (e.g., 12), the smaller number of simultaneous characters used by Darwin et al. (1972) allowed perceptual analysis. According to this view, the sensory memory observed by Sperling was preperceptual, whereas that was not true of the memory observed in the auditory studies. Consistent with Massaro's view, Cowan (1984, 1988, 1995) summarized evidence from various procedures that there are two phases of sensory memory in both the visual and auditory modalities (as well as in other modalities): a short, literal phase lasting about 250 ms and a longer, second phase lasting several seconds. The second phase was said to comprise temporarily

activated sensory features in long-term memory and was said to be both functionally similar to temporarily activated semantic features in long-term memory and much more processed than the first phase.

A couple of studies, one in vision and one in audition, provide striking evidence that there are two types of sensory memory. Phillips (1974) presented two spatial patterns of black and white squares that differed in at most the fill of one square. At short interpattern delays, performance was excellent but was harmed if there was a displacement of the screen location from the first pattern to the second. It was as if the subject actually could see the superimposition of the patterns. In contrast, at longer delays, performance was poorer, and displacement of the screen location did not matter. This suggests that the longer representation was more abstract than the shorter representation.

Kallman and Massaro (1979) carried out a backward-masking procedure in which a standard tone had to be compared to a subsequent comparison tone. Either the standard or the comparison tone was followed by a masking tone. At issue in this experiment was the effect of the similarity between the mask and the tone it masked. When the mask followed the standard tone, it could result in either interference with extraction of information from the sensory trace, which could be termed Masking Type 1, or overwriting of information about the tone even after it has been extracted from the sensory trace, which could be termed Masking Type 2. As the interval between the standard tone and the mask increased, Masking Type 1 presumably disappeared, whereas Masking Type 2 remained. On other trials, it was the comparison tone that was masked, and therefore, only Masking Type 1 was possible; a judgment could be made as soon as information was extracted from that comparison tone. Given that similarity effects were obtained only for Masking Type 2, it was possible to distinguish two phases of auditory memory with different properties. These were termed preperceptual auditory storage and synthesized auditory memory, respectively. These terms correspond to the short and long auditory stores of Cowan (1984).

2.03.5.3 No-Decay Theories

Last, it must be mentioned that some investigators have proposed that there are no decaying memories, including no decaying sensory memory. These investigators view the decline in performance with increasing retention intervals as a matter of a loss of temporal distinctiveness of the items at the end of the list (Neath and Crowder, 1990; Crowder, 1993; Nairne, 2002). That type of theory, combined with the notion that there is better temporal distinctiveness in the auditory modality (e.g., Glenberg and Swanson, 1986), could help to explain why there is an advantage for items at the end of a verbal list presented in the auditory as opposed to the visual modality (cf. Penney, 1989; Marks and Crowder, 1997; Beaman and Morton, 2000; Cowan et al., 2004). However, it is not an easy matter to distinguish between decay and distinctiveness accounts.

Cowan et al. (1997) considered that there might be a distinctiveness explanation for performance in two-tone comparison procedures, in which performance decreases as a function of the time between the standard and comparison tones. As that time increases, it may become larger than the time between trials, so that the tones are not neatly grouped in episodic memory into the trials to which they belong. To overcome this problem Cowan et al. manipulated the time between trials as well as the time between the standard and comparison tones within a trial. Examining trials with the ratio between these two times held constant, and performance decreased only slightly as the time between the standard and comparison tone increased, until it exceeded 6 s. Between 6 and 12 s, the drop was a bit more severe. However, Cowan et al. (2001) reexamined the evidence, taking into account distinctiveness caused by intervals before the penultimate trial, and found no strong evidence of decay (although the data were preliminary in this regard).

A remaining possibility is that, in these procedures, sensory memory information that is attended can be rehearsed (Keller et al., 1995). A study that argues against the effects of time on nonsensory short-term memory (Lewandowsky et al., 2004) takes into account verbal rehearsal, but not the possibility of an attention-based, possibly nonverbal type of rehearsal (cf. Barrouillet et al., 2004). It remains to be seen whether sensory information that is unattended at the time that it is presented, and thus cannot be rehearsed, is lost over time in a way that can be explained by temporal distinctiveness or in a way that cannot be so explained.

2.03.6 Comments on the Future of Research on Sensory Memory

Sensory memory is one of the oldest topics in experimental psychology. Currently, there is only a small to moderate amount of ongoing research on the topic,

but that does not imply that the great problems in the field have been solved, or that the field has become trivial or uninteresting. Sensory memory is an intrinsically fascinating set of neural mechanisms that must be strongly associated with basic conscious experience. As brain researchers investigate how humans know what is real and what is only imaginary, their research no doubt will lead them back to the persistent mysteries within the topic of sensory memory.

2.04 Working Memory

S. E. Gathercole, University of York, York, UK

2.04.1 Introduction

A common feature of our everyday mental life is the need to hold information in mind for brief periods of time. We frequently have to remember a new telephone or vehicle registration number, to write down the spelling of an unusual name that has been dictated to us, or to follow spoken instructions to find our destination in an unfamiliar environment. At other times, we need to engage in mental activities that require both temporary storage and demanding cognitive processing. Mental arithmetic provides a good example of this: successfully multiplying two numbers such as 43 and 27 in our heads involves storing not only the numbers but the products of the intermediate calculations, accessing and applying the stored rules of multiplication and addition, and integrating the various pieces of information to arrive at the correct solution. Our conscious experience of the calculation attempt is of a kind of mental juggling, in which we try to keep all elements of the task – the numbers we are trying to remember as well as the calculations – going at the same time. Often, the juggling attempt will fail, either because the capacity of working memory is exceeded, or because we become distracted and our attention is diverted away from the task in hand.

Working memory – which is the term widely used by psychologists to refer to the set of cognitive processes involved in the temporary storage and manipulation of information – supports all of these activities and many more. A useful informal way of conceptualizing working memory is as a mental jotting pad that we can use to record useful material for brief periods of time, as the need arises in the course of our everyday cognitive activities. Although it a valuable and highly flexible resource, working memory has several limitations: its storage capacity is limited, and it is a fragile system whose contents are easily disrupted. Once lost from working memory, material cannot be recovered.

The basic features of working memory are described in this chapter. Leading theoretical accounts of the cognitive processes involved in working memory are described, and key findings and experimental phenomena are outlined. As it is now also known that

working memory is important not only for the temporary retention of information, but also for the acquisition of more permanent knowledge, theories of how different aspects of working memory mediate learning are also considered in this chapter.

2.04.2 The Working Memory Model

One influential theoretical account of working memory has framed much of the research and thinking in this field for several decades. In 1974, Baddeley and Hitch advanced a model of working memory that has been substantially refined and extended over the intervening period. The influence of the working memory model extends far beyond the detailed structure of its cognitive processes, which are considered in the following sections. The radical claim made by Baddeley and Hitch was that working memory is a flexible multicomponent system that satisfies a wide range of everyday cognitive needs for temporary mental storage – in other words, it does important work for the user. The distinction between short-term memory and working memory is a key element in the philosophy of this approach. The term working memory refers to the whole set of cognitive processes that comprise the model, which as we will see includes higher-level attentional and executive processes as well as storage systems specialized for particular information domains. Activities that tap a broad range of the functions of working memory, including both storage and higher-level control functions, are often described as working memory tasks. The term short-term memory, on the other hand, is largely reserved for memory tasks that principally require the temporary storage of information only. In this respect, short-term memory tasks tap only a subset of working memory processes. Detailed examples of each of these classes of memory task are provided in later sections.

A further key element of the Baddeley and Hitch (1974) approach is its use of dual-task methodology to investigate the modular structure of the working memory system. These researchers have developed a set of laboratory techniques for occupying particular components of the working memory system, which can then be used to investigate the extent to which particular activities engage one or another component. By the logic of dual-task methodology, any two activities that are unimpaired when conducted in combination do not tap common limited capacity systems. In contrast, performance decrements when two tasks are combined indicate that they share a reliance on the same component. This empirical approach has proved invaluable in fractionating working memory into its constituent parts, leading to the most recent version of the working memory model, advanced by Baddeley in 2000 (Baddeley, 2000) (**Figure 1**).

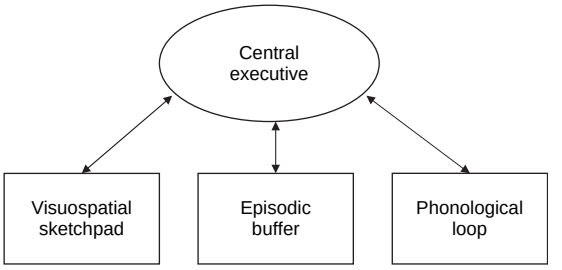

Figure 1 The Baddeley (2000) working memory model.

This model consists of four components. Two of these components, the phonological loop and the visuospatial sketchpad, are slave systems that are specialized for the temporary storage of material in particular domains (verbal and visuospatial, respectively). The central executive is a higher-level regulatory system, and the episodic buffer integrates and binds representations from different parts of the system. The nature of each of these components and associated empirical evidence are described in the following sections. Note also that components of working memory are directly linked with longer-term memory systems in various informational domains. The nature of the interface between working memory and the acquisition of knowledge is considered in later sections of the chapter.

2.04.2.1 The Phonological Loop

Originally termed the articulatory loop by Baddeley and Hitch (1974), the phonological loop is a slave system dedicated to the temporary storage of material in terms of its constituent sounds, or phonemes. The two-component model of the phonological loop advanced by Baddeley in 1986 is shown in **Figure 2**. Representations in the phonological short-term store are subject to rapid time-based decay. Auditory speech information gains obligatory access to the phonological store.

Subvocal rehearsal reactivates serially the contents of the short-term store, in a process that corresponds closely to overt articulation (speaking), but which does

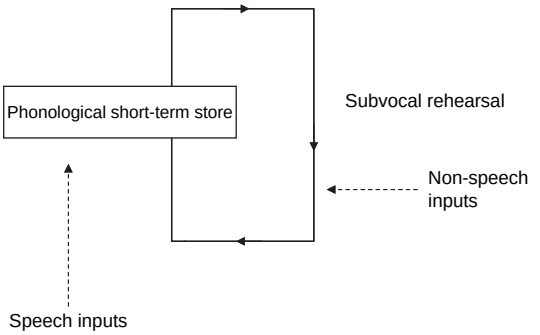

Figure 2 The phonological loop model, based on Baddeley (1986).

not necessarily involve the movement of the speech apparatus or the generation of speech sounds. Representations in the phonological store that are rehearsed before they have time to decay can be maintained in the phonological loop indefinitely, provided that rehearsal continues. Rehearsal consists of the high-level activation of speech-motor planning processes (Bishop and Robson, 1989; Caplan et al., 1992) and is a time-limited process in which lengthier items take longer to activate than short items. Material that is not presented in the form of spoken language but which is nonetheless associated with verbal labels, such as printed words or pictures of familiar objects, can enter the phonological store via rehearsal, which generates the corresponding phonological representations from stored lexical knowledge.

2.04.2.1.1 Empirical phenomena

This fractionated structure to the phonological loop is consistent with a wide range of experimental phenomena from the serial recall paradigm, in which lists of items are presented serially for immediate recall in the original input sequence. Evidence that verbal material is held in a phonological code is provided by the fact that irrespective of whether the memory lists are presented in auditory form or in the form of print, recall is poorer for sequences in which the items share a high degree of phonological similarity (e.g., C, G, B, V, T) than for those which have little overlap in phonological structure (e.g., X, H, K, W, Q). This effect of phonological similarity, first reported by Conrad (1964) and replicated many times subsequently, indicates that serial recall is mediated by phonological representations. Degradation of these representations, possibly due to decay, will thus cause confusion between representations of items with highly similar phonological structures.

The obligatory access of auditory speech information to the phonological loop is demonstrated by the irrelevant speech effect. Serial recall of visually presented verbal items is impaired if spoken items are presented during list presentation, even though participants are told to ignore these stimuli. Moreover, the recall advantage to phonologically distinct over phonologically similar sequences is eliminated under such conditions of irrelevant speech (Colle and Welsh, 1976; Suprenant et al., 1999). This finding indicates that irrelevant speech operates on the same process that gives rise to the phonological similarity effect, so that the unwanted stimuli generate representations in the phonological store that disrupt those of the list items to be recalled.

Evidence for the existence of a distinct subvocal rehearsal process that operates on the contents of the phonological store is provided by other empirical phenomena. An important finding first reported by Baddeley et al. (1975) is that serial recall accuracy is impaired when memory lists contain lengthy items (e.g., aluminum, hippopotamus, tuberculosis) than otherwise matched short items (e.g., zinc, stoat, mumps). Detailed analyses have established that a linear function related recall accuracy to the rate at which participants can articulate the memory sequence: items that are be spoken more rapidly are recalled more accurately, to a commensurate degree. This phenomenon, known as the word length effect, is present for visually and auditorily presented verbal material and is suggested to reflect the serial rehearsal process, which requires more time to re-activate lengthy than short items. As a consequence, representations in the phonological store of lengthy items are more likely to have decayed between successive rehearsals, leading to decay and loss of information.

Support for this interpretation is provided by findings that the word length effect disappears if participants engage in articulatory suppression by saying something irrelevant such as “hiya, hiya, hiya” during presentation of the memory list, for both visually and auditorily presented lists (Baddeley et al., 1975, 1984). These results can be simply explained. Having to engage in irrelevant articulation during a memory task prevents effective rehearsal of the memory items themselves – it simply is not possible to say one thing and to rehearse subvocally something else. As rehearsal is prevented in this condition, there can be no further impairment of recall with lengthy as opposed to short memory items, as this effect is also tied to the rehearsal process.

It should be noted that because visually presented material requires rehearsal to access the phonological store, preventing rehearsal via articulatory suppression should also eliminate the phonological similarity effect with visual presentation, as the material will not reach the store for the similarity-based interference to occur. This prediction has been supported by findings from many studies (Murray, 1968; Peterson and Johnson, 1971).

The claim that the word length effect arises only from subvocal rehearsal has not gone uncontested. Lengthier items are slower not only to rehearse but also to recall, and there is convincing evidence that the increased delay in recalling longer items is one cause of lower performance, probably due to the increased opportunity for time-based decay of the phonological representations. Cowan et al. (1992) employed mixed lists composed of both short and long words to investigate the effects of recall delay. They found a linear relation between the amount of time elapsing from the beginning of the recall attempt and the accuracy of recall, with recall declining as the delay increased (see also, Cowan et al., 1994). One possibility is that the word length effect is multiply determined, and that the slower rate of rehearsal for long than short items is just one of several mechanisms causing lower levels of recall accuracy for lists composed of lengthy stimuli.

Debate concerning the detailed processes underpinning experimental phenomena such as the effects of word length and irrelevant speech (e.g., Neath et al., 2003; Jones et al., 2006) continues, and will in time result in a fuller understanding of the precise mechanisms of serial recall. More generally, though, the broad distinction between the short-term store and rehearsal subcomponents of the phonological loop has received substantial support from several different empirical traditions. It is entirely consistent with evidence of developmental fractionation of the subcomponents of the phonological loop during the childhood years (see Gathercole and Hitch, 1993; Palmer, 2000, for reviews). The phonological store appears to be in place by the preschool period: by roughly 4 years of age, children show adult-like sensitivity to the phonological similarity of the lists items for auditorily presented material (Hitch and Halliday, 1983; Hulme and Tordoff, 1989). The subvocal rehearsal strategy, in contrast, emerges at a later time, typically after 7 years of age. Flavell et al. (1967) observed many years ago that very young children do not show the overt signs of rehearsal, such as lip movements and overt repetition, that characterize older children. Children below 7 years of age are also not disrupted by recalling memory sequences composed of lengthy rather than short items (Hitch and Halliday, 1983), although word length effects do emerge in children as young as 5 years of age if they are trained in the use of rehearsal strategies (Johnson et al., 1987). Also, there is also no consistent association between the articulatory rate and memory span in 5-year-old children, although strong links are found in adults (Gathercole et al., 1994a). Together, these findings indicate that although the phonological store is present at a very early point in children, the use of subvocal rehearsal as a means of maintaining the rapidly decaying representations in the store emerges only during the middle childhood years.

The phonological store and rehearsal process also appear to be served by distinct neuroanatomical regions of the left hemisphere of the brain. Evidence from patients with acquired brain damage resulting in impairments of verbal short-term memory indicates that short-term phonological storage is associated with the inferior parietal lobule of the left hemisphere, whereas rehearsal is mediated by Broca's area, in the left premotor frontal region (see Vallar and Papagno, 2003; Muller and Knight, 2006, for reviews). Findings from neuroimaging studies using methods such as positron emission tomography and functional magnetic resonance imaging to identify the areas of the brain activated by verbal short-term memory tasks in typical adult participants have further reinforced the neuroanatomical distinction between the phonological store and rehearsal (see Henson, 2005, for review).

2.04.2.1.2 A computational model of the phonological loop

Despite its simplicity, the Baddeley (1986) model of the phonological loop is capable of explaining much of the evidence outlined in the preceding section and several other experimental phenomena. It does, however, have one notable shortcoming as a model of serial recall. Although this paradigm requires the accurate retention of both the items in the memory list and their precise sequence, the model focuses exclusively on the representation of item information and therefore fails to account for how the serial order of list items is retained in the phonological loop. As a consequence, it cannot accommodate many detailed aspects of serial recall behaviour. One important characteristic of serial recall is the serial position function, the asymmetric bow-shaped curve that arises from high levels of accuracy of recalling initial

list items (the primacy effect), relatively poor recall of mid-list items, and a moderate increase in accuracy for items at the end of the sequence (the recency effect). Another key finding is that the most common category of errors in serial recall is order errors, in which items from the original position migrate to nearby but incorrect positions in the output sequence (Bjork and Healy, 1974; Henson et al., 1996). The Baddeley (1986) model of the phonological loop provides no explanation of either of these features of verbal short-term memory.

Burgess and Hitch (1992) addressed this problem by developing and implementing a connectionist network model that incorporated a mechanism for retaining the serial order of items in addition to temporary phonological representations and an analog of rehearsal that corresponds to the phonological loop. The structure of the model is shown in **Figure 3**. It consists of four separate layers of nodes that represent input phonemes, words, output phonemes, and a context signal. Serial order is encoded by associating the activated item representation with a slowly evolving context signal containing a subset of active nodes that change progressively during presentation of the list, and can be conceptualized as a moving window representing time such that successive context states are more similar to one another than temporally distant states. Presentation of an item causes temporary activation of input phoneme nodes, word nodes, and output phoneme nodes via existing interconnections. When one item node succeeds in becoming the most active, a temporary association is formed between the winning item node and currently active context nodes. The item node is then suppressed, allowing the same process to be repeated for the next item in the sequence. In this model, rehearsal consists of feedback from the output phonemes (activated following selection of the winning item node) to the input phonemes.

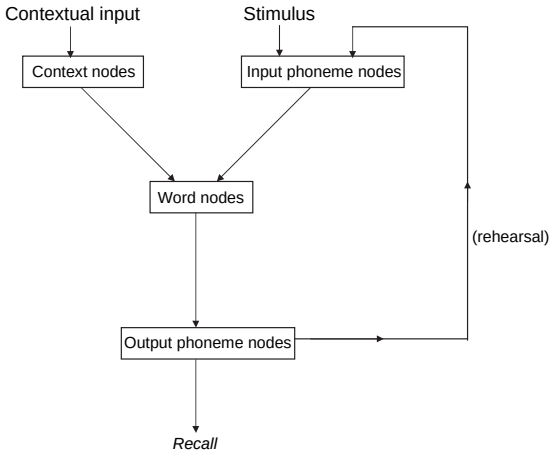

Figure 3 Simplified architecture of the Burgess and Hitch (1992) network model of the phonological loop.

At recall, the original context signal is repeated and evolves over successive items in the same way as at input. For each signal, item nodes receive activation based on their initial pairing with context in the original sequence, and the winning item is selected and activates consistent output phonemes. Noise is added to this final selection process to induce errors. Where serial order errors do occur – that is, incorrect item nodes are selected – they tend to migrate to target-adjacent positions as a consequence of the high degree of overlap in the context nodes active in successive context states.

In addition to generating the classic experimental phenomena associated with the phonological loop such as the phonological similarity, word length, and articulatory suppression effects, this model simulates many of the features of serial order behavior that the phonological loop model on which it was based could not address. Consider first the serial position function. Primacy effects arise largely from the greater number of rehearsals received by early list items, and recall of both initial and final items is enhanced by the reduced degree of order uncertainty at these terminal list positions. A preponderance of order errors is also readily generated because context signals, like item representations, degrade with time. Thus on some occasions, the retrieved item representation will have been associated with an adjacent context signal, yielding recall of a list item at an incorrect output position. When items do migrate in simulations of the model, they show the bell-shaped migration function in which the distances traveled in the sequence are usually small rather than large, which has also been established in the behavioral data.

2.04.2.1.3 The phonological loop and language

Although the cognitive processes underpinning the phonological loop are well understood, one puzzle for many years was exactly why this system exists. It may have turned out to be useful for remembering telephone numbers, but why do we have the system in the first place? A number of possibilities were considered. One plausible hypothesis was that the phonological loop acts as a buffer for planned speech.

The presence of a phonological output buffer that stores the retrieved phonological specifications of intended lexical items and enables the smooth and rapid production of speech has long been recognized as a logical necessity by speech production theorists (e.g., Bock, 1982; Romani, 1992). There is, however, little evidence that the phonological store fulfills this function (see Gathercole and Baddeley, 1993 for review). It has consistently been found that adult neuropsychological patients with very severe deficits of verbal short-term memory leading to memory spans of only one or two items can nonetheless produce spontaneous speech normally: utterance length rates of hesitations and self-corrections are comparable to those of control adults (Shallice and Butterworth, 1977).

A second hypothesis was that the phonological loop provides an input buffer to incoming language that is consulted in the course of normal comprehension processes (Clark and Clark, 1977). Once again, findings from adult short-term memory patients provided the opportunity to test this hypothesis. The prediction was clear: if short-term memory plays a significant role in comprehension, the very low memory span of short-term memory patients should lead to substantial impairments in processing the meaning of language. Findings from many research groups and many different patients provided little support for this prediction. Despite severe deficits in phonological loop functioning, short-term memory patients typically had few difficulties in processing sentences for meaning, except under conditions in which lengthy, unusual, and ambiguous syntactic structures were used, or the sentences were essentially memory lists (see Vallar and Shallice, 1990; Caplan and Waters, 1990; Gathercole and Baddeley, 1993; for reviews). It therefore appears that although under most circumstances the language processor operates online without recourse to stored representations in the phonological loop, these representations may be consulted in an off-line mode to enable backtracking and possible re-analysis of spoken language under some conditions (McCarthy and Warrington, 1987).

There is, however, one area of language functioning in which the phonological loop appears to play a central role, and that is in learning the sound structure of new words. Evidence from many sources converges on this view. Studies of typically developing children have consistently found close and selective associations between measures of verbal short-term memory and knowledge of both native and foreign language vocabulary (e.g., Gathercole and Baddeley, 1989; Service, 1992; Cheung, 1996; Masoura and Gathercole, 1999). The accuracy of nonword repetition – in which a child hears a spoken nonword such as woogalamic and attempts to repeat it immediately – is particularly highly correlated with vocabulary knowledge, although so too are more conventional measures of verbal short-term memory such as digit span (Gathercole et al., 1994b). A similar link is found between verbal memory skills and the rate of learning nonwords in paired-associate learning paradigms, in which participants learn to associate unfamiliar phonological forms with either novel objects (Gathercole and Baddeley, 1990a, used toy monsters with names such as Pimas), unrelated words (such as fairy-kipser), or semantic attributes (e.g., bleximus is a noisy, dancing fish). Both of the latter examples are from a study reported by Gathercole et al. (1997), in which the phonological memory skills of the participating 5-year-old children were in contrast found to be independent of the ability to learn word–word pairs.

Further evidence that the phonological loop is involved in the long-term learning of phonological structures in particular has been provided by the study of individuals with developmental or acquired deficits in language learning. Specific language impairment (SLI) is a condition in which children fail to develop language at a normal rate despite normal intellectual function. Word learning represents a particular problem for affected children. It has consistently been found that children with SLI have substantial impairments of nonword repetition and of other measures of verbal short-term memory (e.g., Gathercole and Baddeley, 1990b; Bishop et al., 1996; Archibald and Gathercole, 2006). A corresponding neuropsychological patient, PV, had a severe deficit of the phonological loop, and was found to be completely unable to learn word–nonword pairings such as rose–svieti, but performed within the typical range on a word–word learning task (Baddeley et al., 1988). Experimental studies of paired-associate learning with normal adult participants have shown that word–nonword learning is disrupted by variables known to interfere with phonological loop functioning, such as phonological similarity and articulatory suppression (Papagno et al., 1991; Papagno and Vallar, 1992). In contrast, learning of word–word pairs is not influenced by these variables.

On this basis, it has been proposed that the primary function of the phonological loop is to support

learning of the sound structures of new words in the course of vocabulary acquisition (Baddeley et al., 1998b). It is suggested that initial encounters with the phonological forms of novel words are represented in the phonological short-term store, and that these representations form the basis for the gradual process of abstracting a stable specification of the sound structure across repeated presentations (Brown and Hulme, 1996). Conditions that compromise the quality of the temporary phonological representation in the phonological loop will reduce the efficiency of the process of abstraction and result in slow rates of learning. In a recent review of this theory and associated evidence, Gathercole (2006) has suggested use of the phonological loop to learn new words is a primitive learning mechanism that dominates at the early stages of learning a language and remains available as a strategy throughout life. However, once a substantial lexicon is established in a language, word learners increasing rely on lexically mediated learning of new words, thereby building on the phonological structures that they have already acquired.

2.04.2.1.4 Summary

The phonological loop model advanced by Baddeley (1986), consisting of a short-term store and a subvocal rehearsal process, is the most influential current account of verbal short-term memory. Convergent evidence for the model is provided from a range of research traditions including experimental cognitive psychology, developmental psychology, neuropsychology, and neuroimaging. A similar diverse range of findings indicate that the phonological loop plays a key role in vocabulary acquisition (Baddeley et al., 1998; Gathercole, 2006).

The successful implementation of the model in the form of a connectionist network by Burgess and Hitch (1992) is an important development that has stimulated competing computational models of serial recall with distinct architectures. The network model has also been further developed to simulate learning of novel sequences by the phonological loop (Burgess and Hitch, 1999). The availability of detailed models of short-term memory and the reciprocal stimulation of empirical findings and computational simulations is a sign of advanced theoretical development that is in large part due to the guiding influence of the phonological loop concept on this field over many years.

2.04.2.2 The Visuospatial Sketchpad

2.04.2.2.1 Theory and empirical phenomena

The second slave system of the working memory model is the visuospatial sketchpad, specialized in the storage and manipulation of information that can be represented in terms of either visual or spatial characteristics. Short-term memory for visuospatial material is associated with increased activity in the right hemisphere regions of the inferior prefrontal cortex, anterior occipital cortex, and posterior parietal cortex, and acquired damage to these regions of the brain leads to selective deficits in remembering these domains of material (see Gathercole, 1999, for review).

Several tasks have been designed to tap the visuospatial sketchpad. These include recognizing the pattern of filled squares in a two-dimensional grid (Phillips and Christie, 1977; Wilson et al., 1987), remembering the order in which a set of blocks are tapped (often known as the Corsi blocks task), using a grid to generate a mental image corresponding to a set of spatial instructions (Brooks, 1967), and recalling the path drawn through a maze (Pickering et al., 2001).

Like its sister slave system the phonological loop, the sketchpad has now been fractionated into two distinct but interrelated components: A visual store or cache that preserves the visual features of perceived or internally generated objects and a spatial or sequential component that may serve a recycling function analogous to subvocal rehearsal (Logie, 1995). The strongest evidence for the separation of the sketchpad into these two components is provided by studies of neuropsychological patients with acquired brain lesions resulting in selective impairments of visual storage but preserved spatial short-term memory (Hanley et al., 1991) and converse deficits in spatial but not visual short-term memory (Della Sala et al., 1999; Della Sala and Logie, 2003).

Dual task studies have played an important role in illuminating the functional organization of the visuospatial sketchpad. One popular method for tapping the capacity for the generation and temporary storage of spatial material is the Brooks (1967) task, in which the participant is presented with a 4×4 empty grid in which one particular cell was designated as the starting square. The experimenter then gives a series of verbal instructions which participants are encouraged to remember by mentally filling in the grid, as shown in **Figure 4**. Following the

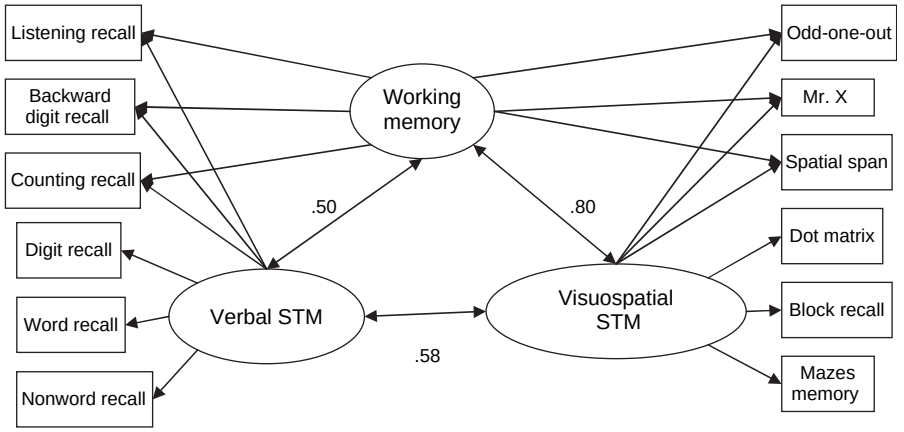

Figure 4 Measurement model of working memory, based on data from children aged 4–11 years. STM, short-term memory. From Alloway TP, Gathercole SE, and Pickering SJ (2006) Verbal and visuo-spatial short-term and working memory in children: Are they separable? *Child Dev.* 77: 1698–1716; used with permission from Blackwell Publishing.

instructions, participants recall the sequence by filling in the grid with the numbers. This condition facilitates the use of spatial imagery and hence the visuospatial sketchpad. In a control condition which does not encourage the use of such spatial imagery, the spatial terms up, down, left, right were replaced by the nonspatial adjectives good, bad, slow, and fast to yield nonsensical sentences. Presumably, recall in this condition was supported by the phonological loop rather than the sketchpad.

Evidence that participants use mental imagery to mediate performance in the spatial but not the nonsense condition is provided by the superior levels of recall accuracy in the former condition (Brooks, 1967). In a systematic study of the effects of concurrent activities on memory performance in the two cases, Baddeley and Lieberman (1980) reported further evidence that distinct components of working memory are employed in the two conditions. Performing a concurrent task – tracking an overhead swinging pendulum – disrupted recall in the spatial but not the nonsense condition. Thus, spatial recall appears to be selectively impaired by the encoding of unrelated spatial content, consistent with the employment of a spatial code to mediate recall performance.

Subsequent investigations indicate that eye movements may play a key role in the maintenance of spatial images in the sketchpad. Postle et al. (2006) reported a series of experiments showing that voluntary eye movements impair memory for spatial locations but not for nonspatial features of visual objects, providing further support for a distinction between visual and spatial components of the sketchpad. Other studies have shown that the engagement of other movement systems such as hands (finger tapping), legs (foot tapping), and arms exerts similar disruptive influences on memory for spatial sequences such as Corsi block recall (e.g., Smyth and Scholey, 1988). It therefore appears that the maintenance of spatial representations in the sketchpad is supported by a central motor plan that is not specific to any particular effector system, by which is recruited the planning and execution of movements in the full range of motor systems.

There is some evidence that the visual storage component of the spatial sketchpad is selectively disrupted by the concurrent perception of irrelevant visual features. In a series of studies reported by Quinn and McDonnell (1996), memory for detailed visual characteristics was selectively impaired by visual noise that corresponded to a randomly flickering display of pixels similar to an untuned television screen that participants were required to view but asked to disregard. This finding is important, as it is directly analogous to the irrelevant speech effect in verbal serial recall (Colle and Welsh, 1976), which has been interpreted as reflecting obligatory access to the short-term store component of the phonological loop for auditory speech material.

One interpretational problem raised by many studies of visuospatial short-term memory is the extent to which these and other similar tasks reflect a genuinely distinct component of working memory, or alternatively draw on the more general resources of the central executive. The central executive, which is described in more detail in the following section, is a

limited-capacity domain-general system capable of supporting a wide range of cognitive activities. Several different lines of evidence indicate that the central executive plays a major role in many visuospatial short-term memory tasks. Performance on visual storage tasks has been found to be strongly disrupted by concurrent activities that lack an overt visuospatial component but which are known to tax the central executive, such as mental arithmetic (Phillips and Christie, 1977; Wilson et al., 1987). Also, studies of individual differences have consistently shown that measures of visuospatial short-term memory are much more closely associated with performance on central executive tasks than are phonological loop measures, in both typically developing children (Gathercole et al., 2004a, 2006a; Alloway et al., 2006) and in a clinical study of adults with bipolar mood disorder (Thompson et al., 2006).

2.04.2.2.2 Summary

Although current understanding of the detailed cognitive processes involved in visuospatial short-term memory is less well advanced than that of the phonological loop, two basic facts have now been established. First, the sketchpad functions independently of the phonological loop – it is associated with activity in the right rather than the left hemisphere of the brain and is selectively disrupted by concurrent activities that do not influence the phonological loop. Second, the processes involved in manipulating and storing visual features and spatial patterns appear to be distinct from one another, again showing neuropsychological and experimental dissociations. It is rather less clear to what extent the visuospatial sketchpad represents a distinct component of working memory that is dissociable from the central executive.

2.04.2.3 The Central Executive

At the heart of the working memory model is the central executive, responsible for the control of the working memory system and its integration with other parts of the cognitive system. The central executive is limited in capacity, and is closely linked with the control of attention and also with the regulation of the flow of information within working memory, and the retrieval of material from more permanent long-term memory systems into working memory. Neuroimaging studies indicate that the frontal lobes of both hemispheres of the brain, and particularly of the prefrontal cortex, are activated by activities known to tax the central executive (See Collette and Van der Linden, 2002; Owen et al., 2005, for reviews).

2.04.2.3.1 The supervisory attentional system

In 1986, Baddeley suggested that central executive may correspond in part at least to the model of the supervisory attentional system (SAS) advanced by Shallice (1982) to explore the control of attention in action. The SAS has two principal components. The contention scheduling system consists of a set of schemas, which are organized structures of behavioral routines that can be activated by either internally or externally generated cues. When a schema reaches a particular level of activation, it is triggered and the appropriate action or set of actions is initiated. Thus, we have schemas that govern all our skilled behaviors: walking and talking, breathing and jumping, opening doors and using a telephone. Schemas can be hierarchically organized. Skilled car drivers, for example, will have a driving schema that is composed of linked subschemas such as steering and braking schemas. Many of our actions are governed by the automatic activation of these schemas in response to environmental cues. So, once we are behind the wheel of a moving car, the sight of a red brake light in the car in front will probably be sufficient to trigger the automatic activation of the braking subschema. Activation levels of all incompatible schemas (such as the accelerating schema, in this case) are inhibited when a schema is triggered.

The second component, the SAS, controls behavior via a very different process. The SAS can directly activate or inhibit schemas, thereby overriding their routine triggering by the contention scheduling system. The intervention of the SAS corresponds to volitional control and prevents us from being endless slaves to environmental cues – it allows us to choose to change the course of our actions at will. However, because the SAS is a limited capacity system, there are finite limits on the amount of attentional control we can apply to our actions.

Baddeley's (1986) suggestion was that the central executive corresponds to the limited-capacity SAS. He also proposed that two types of behavioral disturbance associated with damage to the frontal lobes arise from malfunctioning of the central executive, and coined the term dysexecutive syndrome to describe this disorder. These neuropsychological patients are typically characterized by one of two

possible types of behavior. Perseveration is a form of behavioral rigidity in which the individual continually repeats the same action or response. An example would be greeting a newcomer by saying "Hello" and then continuing to make the same response many times to the same individual, increasingly inappropriately. Distractibility consists of unfocused behavior in which the individual fails to engage in meaningful responses but may, for example, continuously walk around a room manipulating objects. Baddeley suggested that such individuals have an impairment in central executive resources that reduces their capacity for volitional control of behavior via the SAS, which is instead dominated by the contention scheduling system. Perseveration results when a schema becomes highly activated and cannot be effectively inhibited by the SAS to allow the triggering of other appropriate behaviors, and distractibility results from the background triggering of behavior by environmental cues with no overriding focus by the SAS.

This conceptualization of the central executive has proved useful in guiding the development of laboratory tasks that engage the central executive. One such task is random generation (Baddeley, 1986). In a typical task, the participant is required to generate in a random manner exemplars from a familiar category, such as digits or letters, paced by a metronome. The importance of generating random sequences rather than stereotyped ones such as 1, 2, 3 or a, b, c is emphasized. In 1998, Baddeley et al. (1998a) conducted a series of experiments to investigate the hypothesis that the central executive is needed to intervene to override the activation of stereotyped response sequences in this task. There were several key findings consistent with this view. First, the degree of randomness of the sequences generated by the participants diminished (i.e., the responses became more stereotyped) when the generation rate was increased. This result indicates that the randomness of the responses was constrained by a limited capacity process. Second, the degree of randomness of the generated sequences was not impaired when the task was combined with other activities requiring stereotyped responses such as counting, but was substantially disrupted by nonstereotyped concurrent activities such as maintaining a digit load or generating exemplars of semantic categories. Applying the logic of dual-task methodology, it appears that both tasks tap a common limited-capacity mechanism, the central executive.

2.04.2.3.2 Complex memory span

The central executive also plays a key role in complex memory span tasks, which require both processing and storage. The first reported complex span task, reading span, was developed by Daneman and Carpenter in 1980. In this task, participants must read aloud each of a sequence of printed sentences, and at the end of the sequence they must recall the final word of each sentence in the same order as the sentences were presented. The number of sentences read on each trial is then increased until the point at which the participant can no longer reliably recall the sequence of final words. Findings from this task were impressive – complex memory span scores were highly correlated with the performance of the participating college students on their scholastic aptitude tests completed on entry to college. Importantly, the correlations with scholastic aptitude were considerably higher than those found with storage-only measures of verbal short-term memory.

A range of other complex span paradigms have been subsequently developed, all sharing the common feature of requiring both memory storage while participants are engaged in significant concurrent processing activity. A listening span version of the reading span test in which the sentences were heard rather than read by participants was employed by Daneman and Carpenter (1983), and was found to be correspondingly associated with academic abilities. Complex span tasks suitable for use by young children have also been developed. One popular task is counting span, in which the child has to count the number of elements in a series of visual displays, and at the end of the sequence to recall the totals of each array, in the order of presentation (Case et al., 1982). The odd-one-out task (Russell et al., 1996; Alloway et al., 2006) is a complex memory span task that requires visuospatial rather than verbal storage and processing (see also, Shah and Miyake, 1996). Participants view a series of displays each containing three unfamiliar objects, two identical and one different. The task is to point to the location of the odd one out, and then at the end of the sequence to recall the sequence of spatial locations of the different items. In other complex span tasks, the material to be stored is distinct from the contents of the processing activity. An example of one such task is operation span (Turner and Engle, 1989), in which participants attempt to recall digits whose presentation is interpolated with a sequence of simple additions that must be completed.

Despite the large degree of variation in both the processing and storage demands of the different

complex memory span tasks, a highly consistent pattern of findings has emerged. Performance on such tasks is strongly related to higher-level cognitive activities such as reasoning and reading comprehension (e.g., Kyllonen and Christal, 1990; Engle et al., 1992), and also to key areas of academic achievement during childhood such as reading and mathematics (e.g., Swanson et al., 1996; Hitch et al., 2001; Jarvis and Gathercole, 2003; Gathercole et al., 2004b, 2006a; Geary et al., 2004; Swanson and Beebe-Frankenberger, 2004). In the majority of these studies, associations with learning were much higher for complex memory span measures than measures such as digit span of verbal short-term memory. Corresponding closer links with measures of intellectual functioning in adulthood such as reading comprehension, scholastic aptitude, and fluid intelligence have also been consistently found in adult populations (for reviews, see Daneman and Merikle, 1996; Engle et al., 1999b).

In order to understand why complex span measures of working memory performance are so strongly associated with learning abilities and other measures of high-level cognition, it is necessary first to consider what cognitive processes these measures tap. It has been suggested that the processing portions of these tasks are supported by the domain-general resources of the central executive, whereas the storage requirements are met by the respective domain-specific slave system (Baddeley and Logie, 1999). By this view, both the central executive and the phonological loop contribute to performance on verbal complex span tasks such as reading span, listening span, and counting span, whereas performance on visuospatial complex span tasks is mediated by the central executive and the visuospatial sketchpad.

There is now substantial evidence to support this proposal. A common processing efficiency factor has been found to underlie both verbal and visuospatial complex memory tasks (Bayliss et al., 2003). Two recent studies have investigated the latent factor structure underlying individuals' performance on both simple (storage-only) and complex span measures in both the verbal and visuospatial domains, in children (Alloway et al., 2006) and in adults (Kane et al., 2004). In both cases, the best-fitting model is a structure consisting of distinct verbal and visuospatial short-term storage components (corresponding to the phonological loop and visuospatial sketchpad, respectively), plus a domain-general factor corresponding to the central executive. A summary of the factor structure of the model from Alloway et al. (2006) is shown in **Figure 4**. It can be seen that the complex span tasks load both on the domain-general factor and the respective domain-specific storage system. These data provide an impressive degree of support for the basic structure of the working memory model.

So why is it the case that slow rates of academic learning therefore characterize children who perform poorly on complex memory measures of working memory (e.g., Pickering and Gathercole, 2004; Gathercole et al., 2006a)? We have suggested that the reason is that working memory acts as a bottleneck for learning (Gathercole, 2004; Gathercole et al., 2006b). The acquisition of knowledge and skill in complex domains such as reading and mathematics requires the gradual accumulation of knowledge over multiple learning episodes, many of which will take place in the structured learning environment of the classroom. Learning is thus an incremental process that builds upon the knowledge structures and understanding that have already been acquired: any factor that disturbs this acquisition process will have deleterious consequences for the rate of learning, as the necessary foundations for progress will not be in place. It is proposed that working memory capacity is one of the factors that constrains learning success in potential learning episodes. Many classroom activities require the child to keep information in mind while engaging in another cognitive activity that might be very demanding for that individual. Mental arithmetic is an example of such a demanding working memory activity for adults. In children, whose working memory capacity is considerably smaller and who do not have the same bedrock of stored knowledge and expertise to support cognitive processing, working memory challenges of a comparable magnitude are present in much simpler activities, such as writing sentences, adding up totals of objects displayed on cards, or detecting rhyming words in a poem read by the teacher. Children with poor working memory capacities will face severe difficulties in meeting the demands of these situations and, as a result of their working memory overload, will fail in part or all of the learning activity. Such situations represent missed learning opportunities and if they occur frequently, will result in a slow rate of learning.

2.04.2.4 The Episodic Buffer

The episodic buffer is the most recent addition to the working memory model, and was first outlined in a seminal paper by Baddeley in 2000 (Baddeley, 2000).

In this article, Baddeley argued the need for a separate buffer capable of representing and integrating inputs from all subcomponents of working memory and from long-term memory systems in a multidimensional code.

One justification for the episodic buffer is that it solves the binding problem, which refers to the fact that although the separate elements of multimodal experiences such as seeing an object moving and hearing a sound are experienced via separate channels leading to representations in modality-specific codes, our perception is of the event as a coherent unitary whole. At some point, the representations must therefore converge and be chunked together and experienced consciously as a single object or event; Baddeley's suggestion was that the episodic buffer may fulfill this function.

Other evidence also points to a close interface between the subcomponents of working memory and other parts of the cognitive system. It has long been known that meaningful sentences are much better remembered than jumbled sequences of words, with memory spans as high as 16 words compared with the six or seven limit for unrelated words (Baddeley et al., 1987). This indicates that representations in the phonological loop are integrated at some point with conceptual representations arising from the language processing system. Importantly, patients with acquired impairments of verbal short-term memory show reduced memory span for sentences as well as for word lists, but still show the relative advantage of meaningful over the meaningless material. Patient PV, for example, had a sentence span of five and a word span of one (Vallar and Baddeley, 1984). As PV's long-term memory was entirely normal, the reduction in her sentence span must arise from the point of interaction between verbal short-term memory (or the phonological loop). Baddeley (2000) proposed that the episodic buffer may provide the appropriate medium for linking the phonological loop representations with those from long-term memory, and that the central executive may control the allocation of information from different sources into the buffer.

The characteristics of the episodic buffer have been explored in a subsequent experimental programme by Baddeley and collaborators. One line of investigation has looked into whether the episodic buffer plays a role in the binding of different visual features of objects into chunks by comparing memory for arrays of colors or shapes with memory for bound combinations of these features (Allen et al., 2006). In a series of experiments, recognition memory for visually presented objects was tested by presenting an array of objects followed by a probe; the participants' task was to judge whether the probe was present in the original display or not. Across conditions, recognition memory was tested either for shape by presenting a display of different unfilled shapes, for color with a display of squares of different colors, or for both color and shape by presenting objects composed of unique shape/color combinations. In line with previous findings from this paradigm (Wheeler and Treisman, 2002), recognition performance was found to be as accurate in the feature combination as the single feature conditions. Thus, feature binding appears to be a relatively efficient process.

Allen et al. (2006) investigated whether this binding process depends on central executive resources, as might be predicted from the working memory model shown in **Figure 1**, in which information is fed into the episodic buffer from the central executive. To test this possibility, participants also performed demanding concurrent tasks that would be expected to require executive resources – counting backwards and retaining a near-span digit load – while viewing the object arrays. The results were clear: although recognition memory was generally less accurate under dual task conditions, memory for bound features was not selectively disrupted. The only condition that did lead to a greater impairment of recognition for feature combinations than single features was one that involved sequential rather than simultaneous presentation of objects.

On the basis of these findings, Allen et al. concluded that binding the features of simple visual features takes place in the visuospatial sketchpad and does not require executive support. However, it was suggested that storage of such automatically bound information is fragile and may fall apart when further feature combinations need to be encoded and stored in visuospatial memory.

The possible role of the attentional resources of the central executive in integrating linguistic information with representations in the phonological loop in the episodic buffer was investigated by Jefferies et al. (2004). The main focus of this study was the substantial advantage found in the immediate recall of prose compared with unrelated words, which Baddeley (2000) had suggested may be mediated by the integration of linguistic and phonological information in the episodic buffer. Jefferies et al.

conducted a series of experiments in which the relative difficulty of different kinds of lists was equated for individual participants. Thus, an example of an unrelated word list that corresponds to 50% above span for an average participant with a word span of six was the nine items essay, marmalade, is, lots, clowns, wine, spaces, often, a. In the sentence condition of a corresponding level of difficulty, an average participant with a sentence span of 13 would receive the following sequence of unrelated sentences for immediate recall: Railway stations are noisy places. Guns can cause serious injuries. Water is boiled in kettles. Pink roses are pretty flowers. In a further story condition, the sentences were thematically related, as in the following example: A teenage girl loved buying clothes. She went shopping with her mom. They traveled into town by bus.

The possible engagement of attentional processes associated with the central executive was investigated by comparing the impact of a continuous reaction time (CRT) task completed during the presentation of the memory sequence on performance in the different conditions. Following Craik et al. (1996), the CRT task involved pressing one of four keys corresponding to the spatial location of a visual target that appeared on a computer screen; as soon as the key was pressed, the next stimulus was presented. This task is known to place significant demands on controlled attentional processing. If the central executive does play a crucial role in loading phonological and linguistic information into the episodic buffer where it can be integrated into a multidimensional code underpinning sentence span, a selective decrement in the recall of sentences relative to unrelated words would be expected in the concurrent CRT conditions.

Jefferies et al. (2004) found that recall of unrelated words was more or less unaffected by the concurrent task, as was the recall of thematically organized material in the story condition. These findings indicate that the use of the phonological loop places few demands on attentional resources, and also that the activation of preexisting representations relating to the semantic and syntactic content of the stories occurs relatively automatically. In contrast, CRT did markedly impair performance in the condition involving the recall of unrelated sentences. It therefore appears that substantial attentional support from the central executive is required for the retention of unrelated chunks of linguistic information, possibly within the episodic buffer.

Although the study of the episodic buffer is still in its infancy, the concept is being refined in light of new evidence and is proving useful in guiding research on memory for relatively complex forms of material. The simple idea that the central executive is required to feed information through to the episodic buffer for the purposes of feature binding has not received strong support from the research completed so far: there is little evidence for central executive involvement in either the binding of simple visual features (Allen et al., 2006) or in the recall of coherent prose, although attentional support does appear to be crucial for the temporary retention of chunks of unrelated linguistic information (Jefferies et al., 2004). Ongoing and future research designed to delineate the precise conditions under which the central executive and episodic buffer interact seems certain to provide further fruitful insights into the role played by working memory in the storage and manipulation of complex and structured information.

2.04.2.5 Other Models of Working Memory

The multicomponent model of working memory initially advanced by Baddeley and Hitch (1974) is the most enduring and influential theoretical framework in the field. Its success rests with the breadth of scope of the model – incorporating verbal and visuospatial short-term memory, as well as attentional processes – and also with the capacity of the model to evolve in light of incoming evidence. Although the original tripartite structure of the 1974 model has been largely preserved, each component has been elaborated and differentiated over the intervening years, largely but not exclusively by using the dual task methodology to identify distinct subcomponents of the system. The model has also proved successful in accommodating evidence from a wide range of empirical traditions including cognitive development, neuropsychology, and neuroscience in addition to experimental psychology. It is, however, by no means the only model of working memory, and there are currently several other conceptualizations that are proving to be highly effective in guiding research and thinking in the area. Some of the significant alternative theoretical accounts of working are outlined in the following.

2.04.2.5.1 Attentional based models

One influential theoretical account of working memory of this type is Cowan's (1995, 2001) embedded process model, summarized in **Figure 5**. According to this model, long-term memory can be partitioned

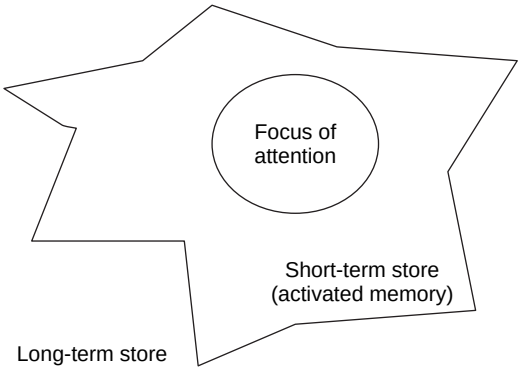

Figure 5 Cowan's (1995) embedded process model of working memory.

in three ways: the larger portion that has relatively low activation at any particular point in time, a subset that is currently activated as a consequence of ongoing cognitive activities and perceptual experience, and a smaller subset of the activated portion that is the focus of attention and conscious awareness. The focus of attention is controlled primarily by the voluntary processes of the executive system that are limited in capacity in chunks. Recent work indicates that typically between three and five chunks of information can be maintained in the focus of attention (Cowan, 2001; see also Chen and Cowan, 2005; Cowan et al., 2005). In contrast, long-term memory activation is time-limited and decays rapidly without further stimulation.

Cowan et al. (2005) have put forward an interpretation of complex memory span performance and its links with scholastic aptitude measures that is markedly divergent from the explanation based on the working memory model considered in the section titled 'The central executive.' By this account, the crucial feature of complex span tasks is that the processing activity prevents the usual deployment of control strategies such as rehearsal and grouping, and thus exposes more directly the scope of the focus of attention, as indexed by the number of chunks that can be maintained simultaneously. Learning ability will be constrained by having a relatively poor scope of attention, laid bare by complex memory span tasks.

An attentional-based account of working memory function has been also advanced by Engle and associates (e.g., Engle et al., 1999b). In some respects, Engle's model shares a similar architecture with the Baddeley and Hitch (1974) framework, combining domain-specific storage of verbal and visuospatial material with controlled attention. The detailed functioning of the components is, however, quite different. Short-term memory consists of traces that have exceeded an activation threshold and represent pointers to specific regions of long-term memory. They therefore do not represent temporary representations in a specialized temporary store, as in the phonological loop. Controlled attention is a domain-general resource that can achieve activation through controlled retrieval, maintain activation, and block interference through the inhibition of distractors.

Unsworth and Engle (2006) have recently put forward a new explanation of why complex memory span tasks correlate more highly with measures of higher-order cognitive function than simple memory span, based upon the distinction between primary and secondary memory. According to this account, memory items that have been recently encountered are held in primary memory, and may also be transferred into the more durable secondary memory system (Waugh and Norman, 1965). The processing activity in complex span tasks displaces items from primary memory, so that recall performance is supported principally by residual activation in secondary memory. Unsworth and Engle suggest that it is the ability to retrieve items from secondary memory that is crucial to more cognitive activities such as reasoning. Note that this interpretation is somewhat similar to that advanced by Cowan et al. (2005); in both cases, the claim is that learning is served most directly by the quality of activation of long-term memory, and not by the capacity of the controlled attention process that generates conscious experience.

2.04.2.5.2 The resource-sharing model

A contrasting theoretical perspective on working memory was provided by Daneman and Carpenter (1980, 1983; Just and Carpenter, 1992). These researchers conceived working memory as an undifferentiated resource that could be flexibly deployed either to support temporary storage or processing activity. By this account, individuals with relatively low span scores on complex memory span tasks were relatively unskilled at the processing element of the activity (reading, in the case of reading span), thereby reducing the amount of resource available for storage of the memory items. This idea that working memory is a single flexible system fueled by a limited capacity resource that can be flexibly allocated to support processing and storage was applied by Case et al. (1982) to explain developmental increases in working memory performance across the childhood years.

They proposed that the total working memory resource remains constant as the child matures, but that the efficiency of processing increases, releasing additional resource to support temporary storage. Consistent with this view, Case et al. found in a study of 6- to 12-year-old children that counting spans were highly predictable from individual counting speeds. Furthermore, counting spans were reduced to the level typical of 6-year-old children when adults' counting efficiency was reduced by requiring the use of nonsense words rather than digits to count sequences. It was concluded that the decreased memory spans resulted from the greater processing demands imposed by the unfamiliar counting task, leading to a processing/storage trade-off that diminished storage capacity.

2.04.2.5.3 Time-based theories

The resource-sharing model of working memory has been challenged substantially in recent years. Towse and Hitch (1995) proposed that participants do not process and store material at the same time in complex span tasks as assumed by the resource-sharing approach, but instead strategically switch between the processing and storage elements of the task. Evidence consistent with this task-switching model has been provided in a series of studies that have either varied counting complexity while holding retention interval constant (Towse and Hitch, 1995) or manipulated retention requirements in counting, operation, and reading span tasks, while holding constant the overall processing difficulty (Towse et al., 1998). In each case, the period over which information was stored was a better predictor of complex memory span than the difficulty of the processing activity. This has led to the claim that complex memory span is constrained by a time-based loss of activation of memory items (Hitch et al., 2001).

The consensus view at present is that no single factor constrains complex memory span (Miyake and Shah, 1999; Bayliss et al., 2003; Ransdell and Hecht, 2003). A more complex model recently advanced by Barrouillet and colleagues (Barrouillet and Camos, 2001; Barrouillet et al., 2004) combines concepts of both temporal decay and processing demands in a single metric of cognitive cost that is strongly related to performance on complex span tasks. In this model, the cognitive cost of a processing task is measured as the proportion of time that it requires limited-capacity attentional resources, for example, to support memory retrievals. When attention is diverted from item storage to processing in this way, memory representations cannot be refreshed and therefore decay with time. The heaviest cognitive costs and therefore the lowest levels of complex span performance are therefore expected under conditions in which there is the greatest ratio of number of retrievals to time. Experimental findings reported by Barrouillet et al. (2004) are entirely consistent with this prediction. Using a complex memory span paradigm in which they separately manipulated the rate of presentation of the memory items and the number of intervening items to be processed, complex memory span was found to be a direct linear function of the cognitive cost of the processing activity, computed as a ratio of the number of processing items divided the period over which they were presented. Thus, processing intervals that had relatively high loads (in other words, a relatively large number of items per unit time) were associated with lower span scores than processing intervals with low cognitive loads (low numbers of items per unit time).

2.04.2.5.4 Summary

In this section, a number of alternative theoretical accounts of working memory have been considered. It can be argued that some of these conceptualizations provide valuable specifications of the nature of central executive processes and are not necessarily incompatible with the Baddeley and Hitch (1974; Baddeley, 2000) model. Certainly, the emphasis on time-based loss of information by Towse and Hitch and the ideas of Barrouillet and colleagues concerning cognitive load could readily be accommodated in an elaborated model of the central executive and its interface with the phonological loop. The majority of these alternative approaches also emphasize the role of attention in working memory, a concept given prominence also by Baddeley (1986). However, other claims that working memory is an activated subset of long-term memory and does not exist as a temporary storage medium distinct from preexisting knowledge are less easy to reconcile.

2.04.3 Overview

The ability to hold information in mind for brief periods of time, termed working memory by cognitive psychologists, is an essential feature of our everyday mental life. The purpose of this chapter is to provide a contemporary overview of current theoretical understanding of the cognitive processes

of working memory. According to the influential model advanced originally by Baddeley and Hitch (1974) and revised and elaborated over the subsequent years (Baddeley, 1986, 2000; Burgess and Hitch, 1992, 1999), working memory consists of an attentional controller, the central executive, supplemented by slave systems specialized in the storage of verbal and nonverbal information (the phonological loop and visuospatial sketchpad, respectively). An additional component is the episodic buffer, capable of integrating information from different parts of working memory and other parts of the cognitive system. Each component of the model is limited in capacity.

This relatively simple model of working memory has proved capable of accommodating a wide range of empirical findings. Its fractionated structure has been informed by findings from experimental studies using dual task methods, by developmental dissociations in studies of children, and by evidence of distinct underlying brain from the fields of neuropsychology and neuroimaging. In the area of the phonological loop in particular, understanding of the underlying cognitive processes is sufficiently well advanced to allow the development of a computational model capable of simulating many detailed aspects of verbal short-term memory behavior.

Two components of the working memory model – the central executive and phonological loop – appear to play key roles not only in the temporary retention of information, but also in supporting longer-term learning, particularly during the childhood years. The phonological loop is important for learning the sound patterns of new words in the course of acquisition of vocabulary in native and foreign languages, whereas the central executive mediates academic learning in areas including reading and mathematics. Detailed theoretical accounts of the possible causal roles of working memory in these elements of learning are considered.

There are also several alternative theoretical accounts of working memory that are currently proving useful in guiding further research and understanding in this field. Some of these theories conceive of working memory as the subset of representations in long-term memory that have been activated either automatically via our interactions with the environment or effortfully, by being the focus of a consciously controlled attentional resource. Whereas the role played by attention is acknowledged in almost all current models of working memory, the distinction between models that assume specialized temporary storage mechanisms and those that see working memory as a property of preexisting knowledge representations is a fundamental one, yet to be resolved by empirical evidence. A further common feature of many theories is that time-based forgetting is a crucial feature of working memory.

Research in the field of working memory continues, stimulated by the availability of detailed theoretical accounts that guide empirical investigations of both typical and atypical working memory functioning. There is also increasing recognition that our current understanding of working memory can be put to more practical use, particularly in the fields of education and remediation (e.g., Gathercole and Alloway, in press). In this respect, working memory represents a strong example of how laboratory investigations of basic cognitive processes have the potential to enhance less esoteric elements of our everyday cognitive experience.

2.05 Serial Learning

A. F. Healy and W. J. Bonk, University of Colorado, Boulder, CO, USA

In many activities in everyday life, we are required to learn the serial order of a set of elements. For example, whenever we acquire a new word, we must learn a novel order of sounds. As Lashley (1951) pointed out in his classic paper, the problem of learning serial order is that elementary movements occur in many different orders in different actions. How, then, can an individual who knows the elementary movements in an action learn to produce them in the correct sequence? For example, how can a pianist who knows the notes occurring in a given song learn to produce the notes in the correct order? That is the central problem involved in serial learning.

2.05.1 Concepts

To address this problem, we need to define several important concepts and make some crucial distinctions: Performing a serial task requires subjects to display knowledge of both the elements in the task and their arrangement. The task elements are items, and their arrangement is their order. In discussing serial learning, order is usually based on the temporal sequence in which the items occur, but in some cases order is based instead on the spatial locations of the items. Thus, letters are the items in words, and the letters must appear in a fixed order for a given word to be identified. The words 'tap' and 'pat' have the same items, but their different orders create different meanings. We can describe the order of the items either in terms of their ordinal positions without reference to their relational sequence (in 'tap,' 't' is first, 'a' is second, and 'p' is third) or in terms of their relational sequence without reference to their ordinal positions (in 'tap,' 't' precedes 'a' and 'p' follows 'a').

In cognitive psychology, learning typically refers to the process of acquiring information over time, whereas memory usually refers to the retention (or forgetting) of information. Thus, in the study of serial learning, we are most concerned with the acquisition of order information, but we also need to understand the underlying memory processes that provide the foundation for such learning over time. In practice, assessments of learning typically involve multiple study and test episodes, but assessments of memory usually involve a single study episode followed by a single test. Thus, memory research can be viewed as providing a snapshot of the first stage of the learning process.

2.05.2 Tasks

The original procedure used to investigate serial learning was established by Ebbinghaus (1885/1913).

In this repeated study–test procedure, a list of items is studied and then tested by requiring recall of the items in the order in which they were shown. This procedure is repeated until the subject reaches a criterion of recalling the list without error. Later researchers replaced this procedure with the method of anticipation, in which subjects are shown one item for a fixed amount of time and are then required to anticipate the next item in the sequence. Subsequently, the next item is shown, which provides feedback to subjects as to the correctness of their last response. This procedure continues throughout the presentation of a list, and list presentation is repeated until the subject reaches a criterion, perhaps one time through the list without error. The investigator tabulates how many presentations of the list are required to reach the criterion.

In recent investigations, the focus has shifted from the learning of order information to immediate memory for order information. Consequently, the most popular procedure is that of serial recall. In this case, subjects are given a series of items to study and are then required to recall the entire list in sequential order. Serial recall can be contrasted with free recall, in which subjects are free to report the items in any order they want and do not need to indicate the sequence information in any way. In serial recall tasks, subjects learn multiple different lists rather than the same list repeatedly. Often the investigator includes a delay between the presentations of successive items (interitem interval) or between the presentation of the last item on the list and the recall test (retention interval). Sometimes extraneous distracting items are interpolated during either the interitem interval or the retention interval to prevent subjects from rehearsing (practicing) the items during those intervals.

In the recall procedures, to respond correctly, subjects must remember the items. Another method was developed to isolate memory for order even further by eliminating the need for the subjects to remember the items. Specifically, the items are given to the subjects either in advance or during the trial, and the subjects simply have to reconstruct the order in which the items occurred. For example, for the list ABCDEF the subjects might be told that the items were BFACED, and they would have to rearrange the items into the correct sequence by placing A into the first slot, B into the second slot, and so on. In reconstructing the order, the subjects thus place each item into its appropriate position, perhaps in a horizontal array of slots, but the slots do not necessarily have to be filled in order from left to right. If a left-to-right response is required, the task is serial reconstruction of order, whereas if no constraints on response order are specified, the task is free reconstruction of order, using the same distinction described earlier for serial and free recall.

A new repeated study–test procedure has been developed to investigate both memory for and learning of serial lists, with successive snapshots of the learning process taken until a criterion is reached (Bonk, 2006). This procedure can be viewed as a combination of three common tasks already described: serial learning, serial recall, and serial reconstruction of order. Under this procedure, subjects view a display showing a set of items including both targets and distractors. The targets are then highlighted one at a time to indicate the required sequence. Subjects observe this presentation and then reconstruct the sequence by choosing one item at a time. The items can vary in type, but in the initial study were clip art pictures. The sequences can vary in length, and in the initial study they were from 6 to 15 items long. To respond correctly, subjects must remember both the identity of the target items and the order in which they occurred. A given sequence of target items is shown and recalled multiple times until the subject reaches the criterion of two perfectly recalled sequences in a row.

2.05.3 Results

The most widely cited experimental result in the study of serial order is the serial position function, first described by Nipher (1878; see also Stigler, 1978) for serial recall. To obtain this function, every position in the list is scored separately, and the total number of correct responses at a given position is computed either across repetitions of the list (in a learning paradigm such as the method of anticipation) or across different lists (in a memory paradigm such as serial recall). The function typically takes on a bow shape (like a bow in archery), wherein items at the start and end of the list are remembered better than intermediate items. The advantage for the initial items is the primacy effect, and the advantage for the final items is the recency effect. In serial learning, the primacy advantage is typically much larger and includes more items than the recency advantage, which sometimes includes only a single item. Asymmetrical bow-shaped functions for the initial test of a given list in the new repeated study–test procedure developed by Bonk (2006) are shown in **Figure 1** for each of 10 list lengths. Asymmetrical

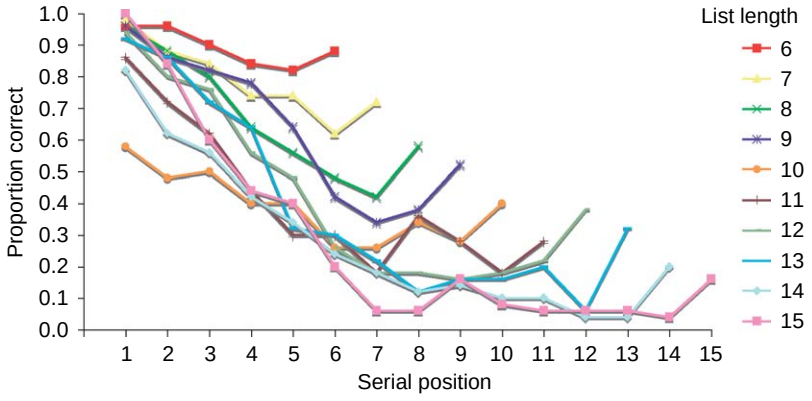

Figure 1 Mean proportion of correct responses as a function of list length and serial position for initial tests in serial learning experiment by Bonk (2006).

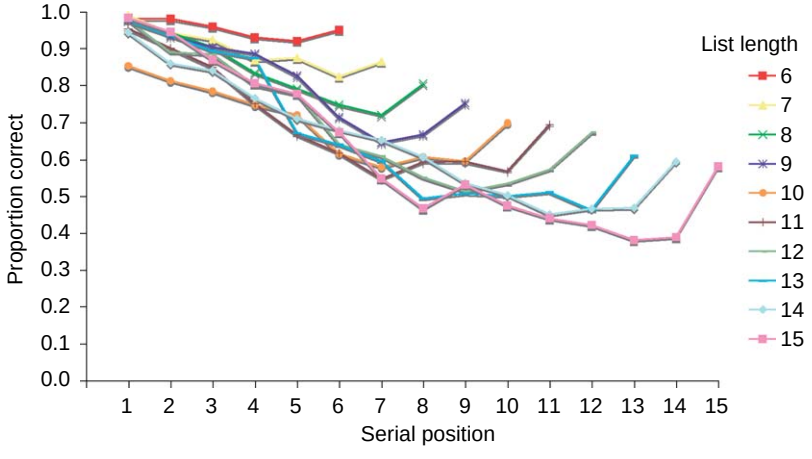

Figure 2 Mean proportion of correct responses as a function of list length and serial position for all attempts through the first perfect recall of a given list by a given subject in serial learning experiment by Bonk (2006).

bow-shaped functions are shown in **Figure 2** for all tests of a given list through the first perfect recall, again for the same 10 list lengths. **Figure 1**, thus, shows curves reflecting serial recall, whereas **Figure 2** shows curves reflecting serial learning. The curves are different, but both show an asymmetrical bow shape. Although the level of performance in serial recall or serial learning may depend on many factors, such as the rate at which the items are presented or the familiarity of the items, the serial position curve typically takes on the same shape when it is normalized. Normalization requires computing the proportion of all correct responses that occur at each serial position of a given list by a given subject. For example, if a subject on a six-item list took three attempts to reach the criterion and during those attempts made a total of 15 correct responses, with 3 of them on the first serial position, the normalized proportion correct for that position would be $3/15 = 0.20$. The fact that the shape of the normalized serial position function is constant across serial learning conditions was first demonstrated by McCrary and Hunter (1953). The normalized functions for the serial learning results of Bonk (2006) are shown in **Figure 3**, again for all 10 list lengths.

Other widely studied results involve the errors made by subjects in tasks requiring serial order. A frequent type of error is one in which the correct item is given but is not placed into its correct position. In a serial recall task, this is a transposition error. Typically, transposition errors occur in pairs because the positions of two adjacent items are confused. For example, if subjects are given the list ABCDEF and they recall ACBDEF, they have transposed a pair of

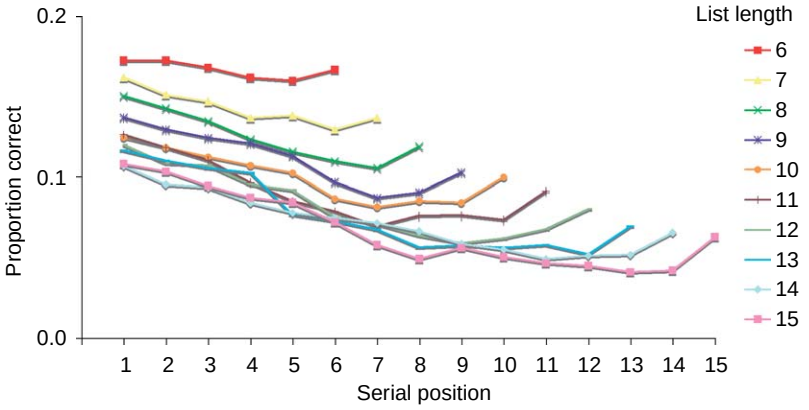

Figure 3 Mean normalized proportion of correct responses as a function of list length and serial position for all attempts through the first perfect recall of a given list by a given subject in serial learning experiment by Bonk (2006).

letters, B and C. Such a paired transposition would result in errors at two of the six list positions, positions 2 and 3. A nontransposition error is any other type of error in this task, such as when an item that did not occur in the list is substituted for a correct letter. For example, if subjects respond with YBCDEZ to the sample list, they have made nontransposition errors at two of the six list positions, positions 1 and 6.

Even with shorter lists, a bow-shaped serial position function is found for serial recall. In a procedure known as the distractor paradigm, items are briefly presented, followed by a retention interval filled with an interpolated task, often consisting of items of a different type, all of which must be read aloud by the subjects. For example, a list of four letters might be presented followed by a variable number of digits, with subjects reading aloud both the letters and digits before they recall the letters in the order shown. This procedure allows the investigators to examine the amount of information remaining in memory after various delays when rehearsal of the information is prevented. Using this procedure and differentiating between transposition and nontransposition errors, Bjork and Healy (1974) found that symmetrical bow-shaped serial position functions were found for total errors at each of three different retention intervals (3, 8, or 18 interpolated digits). These functions, when decomposed into transposition and nontransposition errors, showed a bow shape only for the transposition errors; the functions for nontransposition errors were much flatter, as shown in **Figure 4**.

Transposition errors can be further described in terms of a positional uncertainty gradient, which is a function of the distance between the input positions of the correct item and the item that substitutes for it in the subject's recall response. When the distance is short, the probability of an error is typically larger than when the distance is long. Such error gradients are shown in **Figure 5** for two different conditions in which order information was isolated by telling the subjects in advance which items would occur and using the same set of items on every trial of the experiment (Healy, 1975). The list items occurred one at a time in different spatial locations arranged in a row, with the spatial and temporal positions independently manipulated. In the temporal condition, the items occurred in fixed spatial locations, so only the temporal sequence of the items needed to be learned and remembered. In the spatial condition, the items occurred in a fixed temporal sequence, so only the spatial locations of the items needed to be learned and remembered. The items in this experiment were four consonant letters in each condition. As in the experiment by Bjork and Healy (1974), there were three different retention intervals, with 3, 8, or 18 interpolated digits. These functions show three striking differences in the retention of temporal and spatial order information. First, the decline in accuracy across retention intervals is sharp in the temporal condition but modest in the spatial condition. Second, the serial position function (evident by examining correct responses) is bow-shaped in the temporal condition but not in the spatial condition. Third, the error gradients are steeper in the temporal condition than in the spatial condition.

One specific type of nontransposition error that often occurs is a confusion error, in which a given item is replaced with another item that is confusable

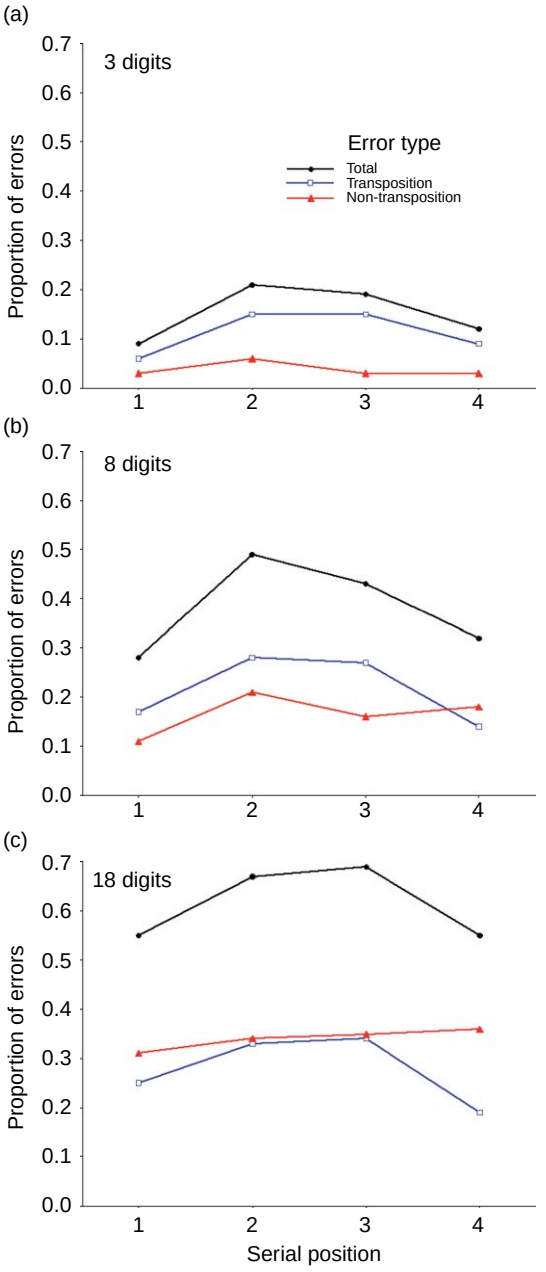

Figure 4 Mean proportion of errors as a function of retention interval (i.e., for 3, 8, and 18 interpolated digits), and serial position for all errors (total) and separately for transposition and nontransposition errors in serial recall experiment by Bjork and Healy (1974).

with it. In our example, a confusion error would occur in the second position if subjects respond with AGCDEF. The confusion error is presumably a result of similarity between the original item and the one replacing it, such as the similarity in sound between the letters B and G in the example. Such an error could be classified as a phonological confusion error. Other types of confusion errors are also possible. For example, if the items were words, the confusions could be based on similarity of meaning rather than sound, in which case they would be semantic confusion errors (e.g., replacing 'cot' with 'bed').

Often a nontransposition error is not based on item similarity but, rather, on positional similarity. Specifically, subjects show a tendency to replace an item in a given list with an item from the same position in an earlier list (e.g., Conrad, 1960; Estes, 1991). For example, if subjects see the list ABCDEF followed by the list GHIJKL and they recall the second list as GHIJEL, they have replaced the item in the fifth position of the second list with the item in the same position of the previous list. This type of error is a serial order intrusion.

Both the serial position functions and the different types of errors give us clues that help us understand the cognitive processes underlying memory for and learning of serial order information.

2.05.4 Theories

2.05.4.1 Classic Theories

The classic theories are largely theories of serial learning because the most popular experimental paradigm used at the time they were developed was the method of anticipation, and this paradigm provided the data that were to be explained by the models.

2.05.4.1.1 Associative chaining

An early description of serial learning was based on an associative chaining model wherein one item in a sequence was linked to (associated with) the next item in a chain (see, e.g., Crowder, 1968). This model was a natural outgrowth of the serial learning task involving the method of anticipation in which each item in the list is explicitly given as a cue for the next item. In our example of the list ABCDEF, the letter A would be linked to the letter B, B to C, and so on. However, even for that task, the simple associative chaining model may not be appropriate, as is evident intuitively from the observation that missing one item in a serial list does not lead to failure to report all subsequent list items. For example, a chaining model may predict that, in memorizing a complete poem, if any word is forgotten then it would be impossible to recall subsequent words in the poem. This particular problem is overcome if there are associative links of

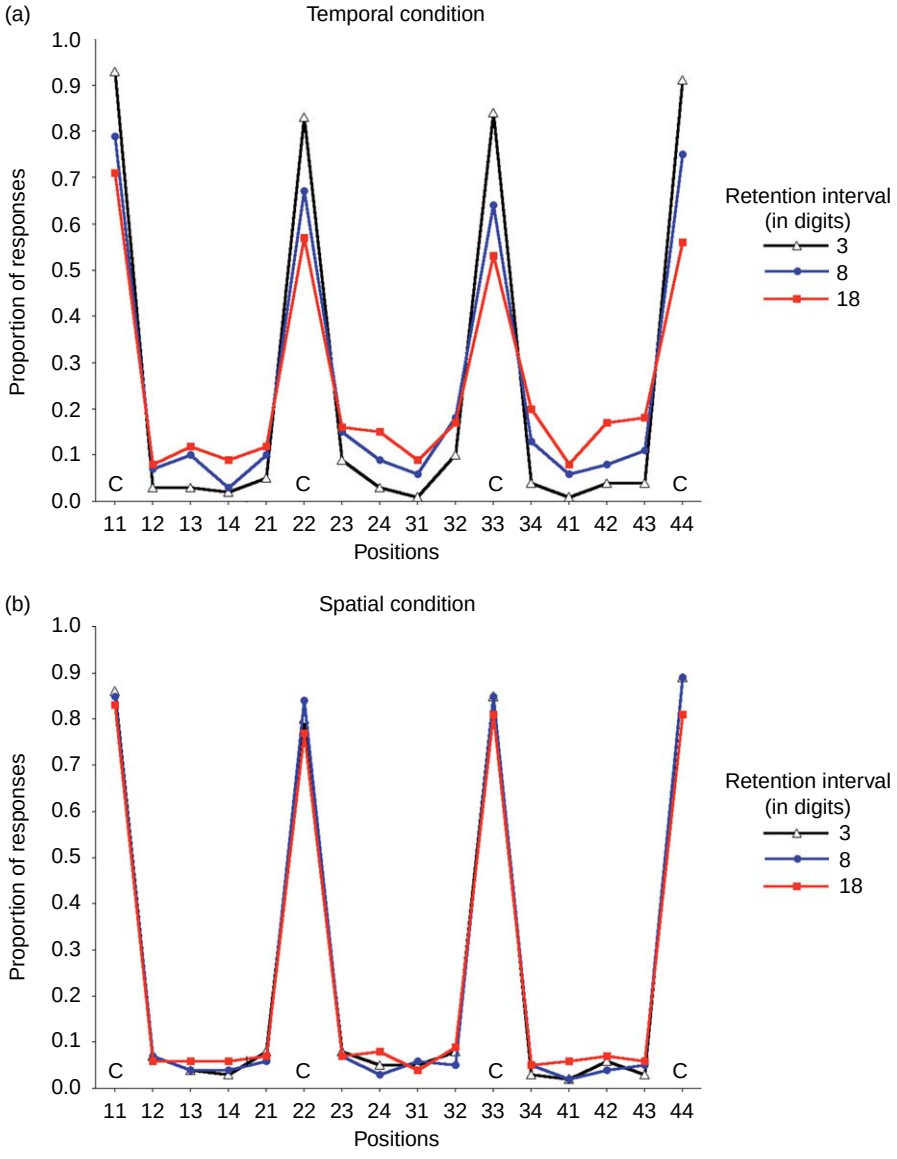

Figure 5 Mean positional uncertainty gradients for temporal and spatial conditions of experiment by Healy (1975). The point plotted for position ij represents the proportion of instances in which the response occurring at position i was the item appearing in input position j of the trial. The label C indicates correct responses.

varying strength among all items in the list, not just neighboring items, with the associations for adjacent items stronger than the more remote associations linking items that are not adjacent in the list. Thus, if a word in a poem is forgotten, subsequent words could still be recalled on the basis of remote associations from earlier words in the poem that could serve as cues. However, even such compound chaining could not overcome other types of evidence against this class of models. For example, in one experiment using the method of anticipation, subjects learned a serial list of adjectives to a criterion of one perfect trial. Then they were given a task to learn a set of paired associates, with experimental pairs formed from adjacent adjectives in the previous list and control pairs formed from unrelated adjectives. Subjects learned the experimental pairs no faster than they learned the control pairs in the paired associate task (Young, 1962), which seems inconsistent with the assumption that in the serial learning task subjects formed strong associations between adjacent items

(but see Crowder, 1968, for counterevidence supporting the existence of such associations).

2.05.4.1.2 Positional coding

Another early description of serial learning is also based on associations between stimuli and responses; it involves a simple positional coding model. In this case, the associations are not from one item to the next but, rather, between a given item and its ordinal position (see, e.g., Young et al., 1967). In our example, the letter A would be associated with ordinal position 1, B would be associated with ordinal position 2, and so on. One version of this theory is a box model (Conrad, 1965), according to which each successive item in a list is entered into a box, with the boxes preordered in memory. Item information in the boxes gets degraded with the passage of time, and at recall subjects output items for each box in turn using whatever information is still available. Transposition errors occur in this model not because of a reordering of the boxes but, rather, because information about an item in a given box is degraded so that the remaining partial information may be consistent with another list item, leading to report of that other item rather than the correct one for that position. This simple model was also refuted by experiments testing it. For example, in a study like the earlier one testing the chaining model, subjects learned, using the method of anticipation, an ordered list of adjectives to a criterion of one perfect trial. Then they were given a task to learn a set of paired associates, in this case with the ordinal position numbers as stimuli and the serial list adjectives as responses. Subjects did not perform as well on the paired associate task, at least on the intermediate items, as they should have if they had in effect learned those associations previously during the serial learning task (Young et al., 1967).

2.05.4.1.3 Positional distinctiveness

A simple but powerful model was proposed by Murdock (1960) to account for the serial position function in serial learning solely in terms of the distinctiveness of the positions. By this model, a given position's distinctiveness is determined merely by comparing its ordinal position value to the values of all of the other list positions. For example, in a five-item list, the difference between the ordinal position value for the first position and the value for the other positions is the sum of $|1-2|$, $|1-3|$, $|1-4|$, and $|1-5|$, which is $1+2+3+4=10$. In contrast, a similar calculation for the third position yields $|3-1|$, $|3-2|$, $|3-4|$, and $|3-5|$, which is $2+1+1+2=6$. Thus, as is also clear intuitively, the first position is more different from the other positions than is the third position. The actual calculation of distinctiveness is a bit more complex because log values are used instead of the ordinal numbers themselves. The use of log values allows the model to account for the finding that primacy effects are typically stronger than recency effects. According to this model, the serial position function should be the same shape for all lists of a given length, even if the lists vary in terms of their presentation time or the familiarity of the items that comprise them. Indeed, as mentioned earlier, normalized serial position functions have the same shape across all experimental conditions (McCrary and Hunter, 1953).

2.05.4.2 Contemporary Theories

Unlike the classic theories, contemporary theories are largely theories of immediate serial memory because the most popular experimental methodology became the immediate serial recall paradigm, and this paradigm provided much of the data that were to be explained by the theories. Thus, the emphasis has shifted from the learning of serial order information to immediate memory for serial order information. The new data by Bonk (2006), which examine serial recall on successive learning trials, provides an empirical integration of serial memory and serial learning results, but little theoretical integration has yet been proposed.

2.05.4.2.1 Perturbation model

An elegant model was proposed by Estes (1972) to account for serial recall performance in the distractor paradigm. Like the classic models, the perturbation model is based on simple associations. However, the associations in this case are between an individual list item and a control element, which represents the given context or environment in which the list was learned. At the core of the model is the concept of a reverberating loop that links the control element to a given list item, with a recurrent reactivation of the list item each time the control element is accessed. Because all the items in a list are associated to the same control element, the difference in reactivation times reflects their input order. The timing of the reactivations, thus, provides the basis for knowledge of the order of the items in a list. This knowledge is assumed to be perfectly stored in memory immediately after the list is presented. Loss of such

information, resulting in failure to recall the items in the correct order, may then occur for one of two reasons. First, the subject may lose access to the control element, perhaps because the experimental context has shifted as a function of time or because of some interpolated, interfering activity. Second, there may be perturbations, or disturbances, in the timing of the recurrent reactivations, presumably resulting from random neural activity. If the timing perturbations are large enough, two adjacent list items may be interchanged so that the later item is reactivated before the earlier item, thus leading to transposition errors in recall. The perturbation process can account for the symmetrical bow-shaped serial position functions found in immediate serial recall of short lists because the likelihood of interchanges resulting from timing perturbations is greater for intermediate list items (which have neighboring items on both sides) than for end items (which have a neighboring item on only one side). This same mechanism easily accounts for the positional uncertainty gradients observed for temporal (but not spatial) order recall, wherein the likelihood of a transposition error decreases as the distance in time increases between the input positions of the correct item and the one replacing it.

After its original formulation, the perturbation model was refined to account for the fact that order information can be viewed as hierarchical (Lee and Estes, 1981). If lists are divided into subsets, perhaps by adding pauses between groups of items, then subjects need to know on which list a given item occurred and in which subset of the list it occurred, as well as its relative position in the subset. According to the refined version of the perturbation model, each item is coded for its placement in this three-tier hierarchy. The hierarchy of codes is repeatedly reactivated, and the perturbation process applies independently at each level, so at each reactivation there is a probability that the relative position of adjacent lists, subsets, or items will be disturbed. This hierarchical perturbation process produces serial order intrusion errors, when an item in a given list or list subset is replaced by an item from the same position in an earlier list or list subset.

2.05.4.2.2 Start-end model

The start-end model (Henson, 1998) was proposed to account for the serial position functions, the positional uncertainty gradients, and the distributions of different types of errors in the serial recall task. At the heart of this model is the observation that the start and end of a list are most salient and therefore serve as anchors, or markers, to code for each item's position in the list (see Feigenbaum and Simon, 1962, for an earlier use of the notion of list end items serving as anchors). Each item gets a two-value code based on the strength of both the start and end markers at that point in the list. The start marker is assumed to be strongest at the beginning of the list and to get progressively weaker for subsequent list items. In contrast, the end marker is assumed to be weakest at the beginning of the list and to get progressively stronger for subsequent list items. Although the end is not evident at the start of the list, subjects anticipate the end (at least when they know the list length), and that expectation allows for the use of the end marker. The model reproduces the general finding that primacy effects are larger than recency effects by giving greater strength to the start marker than to the end marker.

This model makes use of a distinction between types and tokens as a way of representing items. A given item, such as a word, may occur in multiple lists or on multiple occasions in a given list. Each time the word occurs, the item is the same type, but the different instances of the word constitute different tokens. In the start-end model it is assumed that each item token codes both identity and positional information. The identity information specifies the content of that item (e.g., which word has occurred). The positional information is derived from the strength of the start and end markers for that item token. According to the model, the item tokens are unordered in memory; instead, they are ordered at the time of recall. Specifically, at recall the position of a given item is cued by its start and end marker strength values; the identity of the item that matches the cued strength values most closely is recovered and then recalled at that position. Another assumption made by the model is that once an item is recalled, its type is suppressed so that subjects will be less likely to recall a given item type more than once in a trial. This aspect of the model allows it to account for the Ranschburg effect (e.g., Jahnke, 1969), whereby subjects are likely to fail to recall second occurrences of a given item.

2.05.4.2.3 Primacy model

The primacy model (Page and Norris, 1998) is related to both the perturbation and start-end models but was formulated to account for a different set of results. The results in this case are those that formed the basis of Baddeley and Hitch's (1974) model of the phonological loop, which is a qualitative

description of working memory that describes rehearsal processes but does not provide any specific mechanisms for serial recall. Thus, the primacy model can be viewed as a computational version of the phonological loop model (see also Burgess and Hitch, 1999, for an alternative quantitative version of this model). The primacy model does not specifically code position information, but such information is derived at the time of recall from the relative activation strengths of list items. These activation strengths vary as a function of the time when the list items occurred, forming a primacy gradient, with the strength greatest for the first item and declining for successive items in the list. These activation strengths can be thought of as reflecting the degree to which the context defining the start of the list is associated with each successive list item. By this view, the start-of-the-list context resembles both the control element of the perturbation model and the start marker of the start-end model. However, unlike the start-end model, there is no corresponding end marker in the primacy model.

To model the recall process, the primacy model implements the assumption that in a repeating cycle, the item with the greatest activation is selected for recall, and after it is recalled, it is suppressed. Subsequently, the item with the next highest activation is recalled and then suppressed, and so on. During the recall process, the activations for all list items decay exponentially with time. Errors result from the fact that there is noise in the process of selecting the item with the strongest activation (which can be viewed as noise in the perception of the activation strengths), even though there is no noise in the activation strengths themselves. Primacy effects fall out of the model naturally because of the primacy gradient, but recency effects occur because end items can only participate in a paired transposition error in one direction (i.e., with one neighbor), whereas intermediate items can participate in paired transposition errors in both directions (i.e., with neighbors on both sides). Paired transposition errors occur in this model whenever the perceived activation strength of a given list item is either less than the perceived activation strength of a subsequent list item or greater than the perceived activation strength of a preceding list item. Such paired transposition errors also rely on a property of the model called fill in, which is the assumption that when an item is missed in recall because of a transposition it is likely to be recalled in the next position. This model is, thus, consistent with the observation from Bjork and Healy (1974) that transposition errors show a bowed serial position function but nontransposition errors do not. Nontransposition errors typically increase as a function of serial position. To account for this finding, the primacy model assumes that once the item with the strongest perceived activation is selected, the activation is compared to a threshold value. If the activation is above threshold, the item will be recalled, whereas if it is below threshold, it will be omitted and the subject will resort instead to guessing an item, with this threshold comparison subject to noise. Thus, the primacy model can account for nontransposition errors as well as transposition errors.

2.05.4.2.4 OSCAR

A novel approach to explaining serial recall was taken by Brown et al. (2000) in their oscillator-based computational model OSCAR. Oscillators are timing mechanisms that generate continuously changing rhythmic output. Oscillators occur at different frequencies, with high-frequency oscillators repeating more often than low-frequency oscillators. An analogy can be made to the hands in a clock face. The second hand completes its cycle more rapidly than the minute hand, which in turn completes its cycle more rapidly than the hour hand. OSCAR accounts for the learning of order by making use of oscillator timing mechanisms presumed to occur naturally in the mind. In OSCAR, during list presentation, associations are formed between a vector (an ordered series of numbers) representing a list item and a vector representing successive states of the learning context. The learning context is the current state of the dynamically changing internal set of timing oscillators. Thus, OSCAR, like other models, makes use of associations between items and a representation of the learning context. However, in OSCAR, unlike other models, the learning context changes continuously during list presentation. Just as Lee and Estes (1981) postulated a hierarchy of codes in the perturbation model, the oscillators in OSCAR vibrate at different rates, reflecting different levels of a three-tier hierarchy, including item position within a subset, subset position within a list, and list position within a session. Unlike the perturbation model, however, order errors arise in OSCAR solely during the retrieval stage. Specifically, at the time of retrieval, a sequence is recalled by reinstating the states of the set of oscillators that comprise the learning context. Each successive learning context vector is used as a probe recovering the list item vector that is

associated with it. Retrieval errors occur based on the quality of the learning context vector and the extent to which that vector is specific to a particular item. Items occurring close together in time have similar learning context vector values; thus, noise in the retrieval process leads to positional uncertainty gradients like those found for the temporal condition in the study by Healy (1975). This model, unlike some of the others, can thereby explain observed differences between recall of temporal and recall of spatial order information.

2.05.4.2.5 TODAM

Unlike the other contemporary theories reviewed here, which are restricted to memory for serial order, a model by Lewandowsky and Murdock (1989) is designed to account for serial learning as well as serial recall. This theory of distributed associative memory (TODAM) also differs from the other contemporary models in being based on associative chaining. Although, as mentioned earlier, problems had been found for the classic associative chaining model, these were largely overcome in TODAM. A third difference between TODAM and the other models reviewed here is that TODAM provides a more general account of memory, not being restricted to serial order (see Anderson et al., 1998, for another general model incorporating serial recall). A fourth difference is that the memory representations in TODAM are not localized but are, rather, distributed.

Specifically, in TODAM the representations of all list items are stored together in a common memory vector. The numbers making up the memory vector in TODAM represent values of individual features. Successive items are associated using a mathematical operation convolution that blends the constituent item vectors. The resulting convolution is also added to the common memory vector. If all information is contained in a single memory vector, how can the model recover the individual list items when needed? The retrieval mechanism used for this purpose is correlation, which is the inverse of convolution (i.e., it essentially undoes that operation). Thus, a memory probe representing a particular stimulus item can be correlated with the common memory vector to yield another vector that approximates the response item with which it had been associated. Once the approximation to the response item is generated via the correlation process, it must be deblurred (interpreted) before it can be recalled. If the deblurring process yields an overt recall response, the new vector resulting from that response can then be used as a stimulus probe to recover the next item in the list. The deblurring process might not result in an actual overt response. Nevertheless, the recall process can move forward to the next item in the list because the vector approximation can be used as a stimulus for a subsequent response. This implementation allows TODAM to overcome one of the key problems mentioned earlier plaguing the classic chaining model, namely, that missing one item in a serial list does not lead to failure to report all subsequent items. A subsequent version of TODAM (Murdock, 1995) also uses associations between higher-order chunks of items to avoid problems with simple associative chaining models.

To model serial learning occurring across repeated presentations of the same list, in a closed-loop variant of TODAM, the new information added to the memory vector for an item is reduced by the amount of information already present in the vector. This aspect of the model captures the idea that gradually less is learned about each item during successive repetitions of a list.

2.05.5 Theoretical Issues and Conclusions

A variety of theoretical mechanisms have been proposed to account for serial memory and learning, but there is little consensus as to which is the best. The various models differ along numerous important dimensions, such as the relation between item and order information and whether or not position or sequence information is explicitly coded. Some models do not discriminate between temporal and spatial order, whereas others apply only to temporal order. Crucially, most models do not attempt to provide a theoretical integration of serial memory and serial learning results. Thus, despite the theoretical insights and innovations in the five decades since Lashley (1951) first discussed the importance of this problem, we have not yet achieved a full and widely accepted understanding of the processes underlying serial order behavior, which provides the foundation for many activities in everyday life.

2.06 Repetition and Spacing Effects

R. L. Greene, Case Western Reserve University, Cleveland, OH, USA

Coyne (2006) dedicated himself to becoming as good a golfer as he could possibly be. He spent a year in this quest, hitting more than 100 000 golf balls and playing 5418 holes. He found that practice at this skill indeed led to improvement but was frustrated to find out that not all practice was equally effective. The beginning of his regimen led to the fastest improvement, an observation that led Coyne to compare his situation to that of a dieter finding that the first few pounds lost were the easiest. Coyne's observations are typical, as the importance, as well as the limitations, of repetition in the mastery of information or skill can be documented in countless domains (Ericsson, 2005).

That repetition is key to learning but that not all repetitions are equally effective are central observations underlying all serious thought on the topic. The central importance of repetition was recognized by many ancient and medieval thinkers. Hermann Ebbinghaus (1885/1964), who initiated the modern era of memory research, carried out a series of experiments that showed that retention improved as a function of the number of times that information had been studied. Ebbinghaus's theoretical approach assumed the centrality of repetition in the acquisition and strengthening of learning.

The fact that learning and memory are sensitive to repetition is not in question. However, the basis of repetition effects is still far from clear. Boundary conditions where repetition has no effect are particularly interesting in determining why repetition affects retention. A related topic of interest in the literature deals with the temporal distribution of repetitions. Generally, repetitions are more effective if they are spaced apart than if they are massed together (the spacing effect).

Anderson and Schooler (1991) have noted that both repetition and spacing effects are rational; that is, if one were designing an ideal memory system, one might construct it so that it would exhibit both of these phenomena. They pointed out that human memory evolved to manage a huge body of information containing millions of facts and experiences. Expecting perfect retrieval of all these facts is unlikely in the face of our limited physical abilities; it may also be unwelcome because we may quickly find ourselves overwhelmed by the massive amount of information we have stored. A rational memory system would be one where the retrievability of a memory is strongly related to the probability of that particular memory being needed. Repetition would surely be one clue indicating that a particular fact was important. If we had encountered or used a fact numerous times in the past, it would be more likely that we will need it again in the future than if we had only used that fact once. Similarly, when a particular fact or experience had been encountered or used at widely spaced intervals, it is probably more likely to

be used again in the future than a fact used equally often but only in a massed cluster. Anderson and Schooler based their reasoning on theories of information retrieval, which underlie many of the computerized search systems found in libraries or on the Internet. Still, acknowledging that repetition effects and spacing effects are good phenomena for well-designed memory systems to show does not address the issue of the mechanisms that lead to these effects in human memory.

2.06.1 Continuity, Discontinuity, and Repetition

Coyne (2006) found that his golf practice (when not interrupted) led to a steady, albeit sometimes agonizingly slow, improvement in his performance. The seemingly continuous, but always slowing, effect of repeated practice is a ubiquitous finding in the field of learning and memory. The total amount learned increases as a function of repetition, but the rate of learning seems to change systematically across trials. The traditional learning curve depicted as a function of practice demonstrates negative acceleration, with the greatest learning occurring on the first trial. The amount learned on each subsequent trial seems to decline continuously. Eventually, the change in performance as a function of further practice is too small to be measurable. The phenomenon of *registration without learning* (Hintzman et al., 1992; Hintzman and Curran, 1995) is a demonstration of this, with participants showing no evidence of learning more information about the details of a stimulus, even while continuing to register its repeated presentations. Cleary et al. (2001) showed a similar pattern in learning about associations: When presented with word pairs that are repeated many times, participants may note the occurrence of individual items without showing improved associative memory. Because people seem to pay much less attention to later occurrences of repeated stimuli, first impressions become particularly important. Participants may not demonstrate evidence of having noticed small changes that are made to a stimulus after its first presentation (DiGirolamo and Hintzman, 1997). Miller et al. (2004) provided additional evidence regarding which features of a stimulus are most likely to be overlooked; specifically, accidental properties that are not inherent aspects of a stimulus are commonly ignored in later repetitions.

Authors such as Guthrie (1935) and Estes (1955) have long noted that this seemingly continuous improvement in performance does not necessarily mean that the learning process itself must be gradual or continuous. Many learning situations can be broken down into smaller components, and one cannot rule out the possibility that these components may be learned suddenly, possibly as a result of insight. If these components are learned at different times, the seemingly gradual nature of learning may instead reflect the accumulation of mastered components, each of which had been learned in a sudden all-or-none fashion. Distinguishing between a truly gradual learning process and the accumulation of numerous small insights is difficult, and it became common to assume that learning may be either gradual or sudden, depending on the situation and the nature of the participant. Harlow (1949) argued that learning to novel situations may be slow and continuous, but that sudden flashes of insight may occur when learning takes place in a familiar situation.

Rock (1957) was the first to move beyond the general concern that learning curves obscure sudden transitions in performance to an empirical methodology. He developed what became known as the drop-out procedure. He used a paired-associate methodology, in which participants had to learn a list of letter–number pairs. Study trials alternated with test trials, on which letters were presented and participants had to recall the corresponding numbers. After each test, Rock removed pairs that had not been answered correctly on that trial and replaced them with new pairs. Performance in this condition was compared to learning in a control condition, where participants were given the same unchanging list on multiple trials. The major finding was that there was no difference between the drop-out condition and the control condition; both groups mastered the list at the same rate. The fact that replacing old (but not yet mastered) pairs with new pairs did not impair performance led Rock to conclude that pairs were either completely learned or completely unlearned. Rock reasoned that if participants had been acquiring partial information about unrecalled pairs, performance should be impaired if such pairs were replaced by new ones. Because no impairment was found, he concluded that participants had not learned anything about a pair until the trial on which it could be recalled. That is, he argued for all-or-none learning: Rock believed that the fact that performance on a paired-associate list gradually improves across repeated study–test cycles obscures the fact that each pair is either entirely learned or

unlearned, with the number of pairs moving from the unlearned to the learned state increasing across trials.

Rock (1957) acknowledged the fact that there was a potential flaw in his procedure. Some pairs are harder than other pairs. Presumably, the pairs that are not remembered on a particular trial would tend to be the most difficult pairs for that participant. In the drop-out condition, these particularly difficult pairs are being replaced on each trial by new pairs. Because the new pairs are randomly chosen to be added to the list, taken together they would be average in difficulty. Therefore, the drop-out group will end up with an easier list than the control group, which is stuck with the list that had been presented on the first trial. If this methodological flaw is serious, Rock would be mistaken in concluding that this methodology supports an all-or-none interpretation of learning. In later research, Steinfeld and Rock (1968) went to great lengths to argue that this artifact did not invalidate the drop-out procedure, but it is impossible to determine exactly how serious the problem is. Similar methodologies (e.g., that of Estes, 1960) run into analogous difficulties. In a review of this literature that was written just as research on this topic was winding down, Crowder (1976) noted this line of experimentation proved to be inconclusive but was valuable in shaking "the almost axiomatic belief of Ebbinghaus that repetition strengthens a unitary memory trace" (p. 273).

2.06.2 Basis of Repetition Effects

2.06.2.1 Theoretical Approaches

The philosopher Ward (1893) anticipated many of the later developments in theories of repetition effects. He distinguished between functional and atomistic accounts of repetition effects. Functional accounts would assume that repetition affects memory by altering a single location or representation. Every stimulus or experience has a particular trace in memory that is altered when it is encountered again. These alterations have the effect of making information about that stimulus easier to locate. Perhaps the most straightforward way of devising a functional account is to assume that memory traces differ along a single dimension, such as trace strength, so that this sort of approach is sometimes called strength theory. This approach is based on the assumption that repetition influences strength and that stronger traces are easier to remember than weaker traces. Ebbinghaus (1885/1964) seems to have implicitly adopted such a strength position, though his focus was on the strength of associations. Underwood (1969a) developed a somewhat more complex theory in which repetition-based strength was just one attribute that could vary among memory traces. On the other hand, atomistic theories maintain that two occurrences of an item lead to independent and distinct memory traces. Each of these traces would contain information about when it had been formed. Atomistic theories are more likely to be referred to now as multiple-trace theories. The German scientist Richard Semon, whose life and work in the early twentieth century has been described by Schacter (1982), was the first prominent multiple-trace theorist, although the model of memory proposed by the scientist Robert Hooke in 1682 can be interpreted in multiple-trace terms (Hintzman, 2003).

A fundamental difference between functional (strength) and atomistic (multiple-trace) accounts is in whether information about individual encounters with a repeated stimulus is maintained in memory. Functional accounts assume that repetition leads to the strengthening or alteration of a single location so that details about particular occurrences are lost. On the other hand, atomistic approaches claim that every occurrence leads to the formation of a separate memory trace, thereby maintaining the specificity of individual encounters. One class of experimental test of these approaches has focused on this fundamental difference by asking participants to make judgments about details of individual presentations of repeated events (see Hintzman, 2000, for a review of this approach). A pure strength theory would assume that participants would only be able to make a judgment about a stimulus by drawing an inference based on its strength; for example, a stronger stimulus can be assumed to have occurred more recently or more frequently. In contrast, multiple-trace accounts typically assume that each occurrence of a stimulus leads to the formation of a trace that records the context in which it was formed; therefore, participants would have access to detailed information about individual presentations of a repeated stimulus.

2.06.2.2 Judgments of Recency

To see how one might use memory judgments to discriminate between strength and multiple-trace approaches, a simplified account of a recency-judgment task (first developed for this purpose by

Morton, 1968) may be helpful. A participant may be given a list of digits and have to remember which of two test items had been presented later on the list. Imagine that a sequence like 7 5 2 9 1 6 5 8 4 3 is presented, and a participant is asked whether 4 or 5 had been presented later on the list. Note that 4 is the correct answer, but that the alternative 5 had been presented twice. According to strength theory, participants may tend to make the wrong choice because they may mistakenly attribute the heightened strength of the digit 5 to a recent presentation, as opposed to multiple presentations. In contrast, a multiple-trace account would claim that participants perform this task by retrieving occurrences of each digit and attempting to determine recency by examining details of each trace. Flexser and Bower (1974) carried out a systematic investigation of this task and concluded that multiple-trace approaches offered a better explanation of recency judgments. Hacker (1980) reached a similar conclusion by measuring response times in recency judgment.

2.06.2.3 Judgments of Frequency

There are several different ways in which one could test memory for frequency. One method would be a test of background frequency, which refers to the number of times that an event has occurred in one's lifetime. For example, Attneave (1953) studied the ability to make background-frequency judgments of letters of the English alphabet. These background-frequency judgments correlated .88 with the true frequency of occurrence in the English language, demonstrating that people are indeed sensitive to how often letters occur. Howes (1954) showed that people are sensitive to the background frequency of occurrence of words.

For the purpose of distinguishing between strength and multiple-trace accounts of repetition effects, tests of situational-frequency judgment are more useful. The prototypical way of studying situational-frequency memory is to present a list of words, which may be repeated varying numbers of times. At the time of test, list words are shown, and people have to indicate how often each was presented on the list. This sort of information is considered *situational* because participants do not have to remember how often items occurred throughout their whole lives but rather how often they occurred in a particular situation (i.e., on the laboratory list). People under typical testing circumstances are often very accurate, even when not expecting a test (Greene, 1984), leading some investigators to conclude that this sort of frequency information is encoded automatically (Hasher and Zacks, 1979, 1984). Although this claim of automatic encoding of frequency information is unlikely in the face of evidence that strategic factors may have a major impact on this task (Greene, 1984, 1986), all theoretical accounts of repetition effects must address why some information about frequency of occurrence is seemingly stored without intention. Strength and multiple-trace theories offer different explanations for how participants are able to estimate situational frequency. A strength theory would assume that participants access the memory trace corresponding to a test item and then assess the strength of that trace. The judgment of frequency is then based on the strength of that trace. For example, a very strong trace would be evidence that the corresponding item had occurred frequently on the list. On the other hand, a multiple-trace theory would assume that participants try to retrieve as many traces as possible of the test item. Those items that had occurred in the context of the list would then be counted, and a judgment of frequency would be based on that count (possibly after some adjustment to fit the expected ranges).

Results from the frequency-judgment literature tend to favor multiple-trace approaches. Although strength theory would have no problem in accounting for judgments of background frequency, it is not clear how this approach could explain people's ability to offer situational-frequency estimates that are independent of an item's overall background frequency. For example, strength theory would predict that background frequency should always contaminate situational frequency so that people should give higher situational judgments to items that occur more often in everyday life. In reality, situational judgments are largely independent of background frequency, and the slight effect obtained goes in the wrong direction: When situational frequency is held constant, participants give higher situational-frequency estimates to words of low background frequency than to words of high background frequency (Rao, 1983). Accuracy of frequency judgments is better for low-frequency words than for high-frequency words (Greene and Thapar, 1994).

Hintzman and Block (1971) carried out the classic demonstration of participants' ability to come up with specific situational frequencies. In this study, people were shown two lists of words, separated by

a 5-minute interval. Each word occurred zero, two, or five times on each of the lists. These list frequencies were factorially crossed, so that the frequency of occurrence on one list would be completely uninformative as to the frequency of occurrence on the other list. After seeing the lists, participants were asked to estimate situational frequency of occurrence of each test word for each of the lists. The most important finding is that participants were very accurate on this task, so that their estimates of list frequency were chiefly determined by the true frequencies on the list being judged. Frequency of occurrence on the other list had only a small influence. The finding that people are able to make separate situational-frequency estimates for the same item in two lists is awkward for strength theory to explain: If these estimates were based solely on a unidimensional construct like strength, participants would not be able to make up these separate and largely independent estimates. On the other hand, multiple-trace theory would have no difficulty with this pattern, because these estimates would be based on a count of individual traces, each carrying information about the context in which it was created.

Greene (1990a, Experiment 5) carried out an even more extreme comparison of strength and multiple-trace approaches. Participants were given a list of words without being told what sort of test to expect. After the list had been presented, participants were shown a word accompanied by two other words. Participants had to choose which of the two accompanying words had been presented more frequently immediately before the single word. (For example, participants may have seen the word GOAT on the list three times. It may have occurred immediately after the word DIME two times and immediately after WALL once. DIME and WALL occurred elsewhere on the list, so that their total frequencies were equal. On the test, participants could be presented with GOAT, accompanied by DIME and WALL, and asked to pick the word that had preceded GOAT more often on the list. To be correct, they would have to pick DIME.) Participants had to answer this type of question for 36 words. Although this was a difficult test, all participants were able to perform above chance. Clearly, repetitions do more than merely strengthen a trace. Rather, every time a stimulus is presented, it leaves some sort of trace that records the context in which it had occurred.

2.06.2.4 Limitations on Multiple-Trace Accounts

Data from frequency-memory experiments provide strong evidence against the notion that repetition merely strengthens memories. It seems necessary to assume that repetition of stimuli leads to the storage of information that includes precise information about the time or context in which each presentation had occurred. However, this does not necessarily mean that repetition only leads to the formation of multiple traces. After all, it is possible that repetition has multiple effects. For example, it could lead both to multiple traces and to a strengthening of some representation in memory. There is some evidence that multiple-trace theories are not adequate for a complete account of the effects of repetition on memory.

2.06.2.4.1 Effects of repetition on nonrepeated items

A simple and pure multiple-trace account would claim that repeated presentations of an item should have the same effect on memory as presenting multiple once-presented items. For example, presenting 10 words three times each should lead to a functional list length of 30 items.

Let us consider a single once-presented item that may be presented in one of three conditions. In one condition, it is presented along with 10 once-presented words. In a second condition, it is presented along with 10 words, each presented three times, so that there would be a total of 31 presentations on the list. In a third condition, the item is presented along with 30 words presented once, so that there would again be a total of 31 presentations. We then administer a recognition test. We are interested only in recognition of the once-presented item. Recognition will certainly be influenced by the length of the list, but the critical issue would be if length should be defined in terms of total presentations (so that the second and third conditions are equivalent and should be more difficult than the first) or in terms of number of novel words presented (so that the first two conditions are equivalent, with the third being more difficult than the others). If one believes that repetitions act like presentations of new items by creating independent traces, then the second and third conditions should be equivalent. In reality, recognition is not influenced by total number of presentations but by the number of novel presentations so that the first and second conditions are both

approximately equal and easier than the third (Ratcliff et al., 1990). The empirical picture is somewhat less clear-cut in free recall, but even here the effect of repeated presentations does not come close to matching the effect of added novel items (Tulving and Hastie, 1972; Ratcliff et al., 1990). Additional evidence that repetitions do not affect other items in the same way as a comparable number of distinct items was reported by Tussing and Greene (2001). This type of finding suggests that a simple application of the multiple-trace approach to repetition effects is inadequate.

2.06.2.4.2 Superadditive effects of repetition on memory

Waugh (1963) observed that one can use simple laws of probability to derive expectations for memory of repeated items based on performance on once-presented items. Let us assume that two presentations of a repeated item lead to two completely independent memory traces. Recall or recognition of that item would be successful if the participant was able to retrieve one or both of these traces. If we define P as the probability of remembering a once-presented word, then the probability of remembering at least one occurrence of a repeated word should be $(2P - P^2)$ if the occurrences act like purely independent traces. This value can be considered an independence baseline, an indication of how high memory for repeated items should be if retention of separate occurrences was completely independent. Although not all studies find that recall of repeated stimuli significantly surpasses the independence baseline (e.g., Glanzer, 1969), there are numerous examples in the literature in which this has occurred (e.g., Johnston and Uhl, 1976; Goldman and Pellegrino, 1977; Overton and Adolphson, 1979). For reasons that are still unclear, the nature of the memory test seems critical, with performance on repeated items being more likely to exceed the independence baseline on recall tests than on recognition tests (Begg and Green, 1988).

At first glance, any reports of memory for repeated items exceeding the independence baseline might appear to be inconsistent with multiple-trace theories of repetition effects. After all, if multiple presentations of an item lead to the creation of separate traces, shouldn't retrieval of these traces operate just like retrieval of once-presented items? However, this argument is too simplistic. It overlooks the possibility that the memorability of an item might be affected by the fact that there were other occurrences of that item. For example, when a word is presented for a second time on a list, this repetition may remind the participant of the earlier occurrence, leading to further rehearsal and increased retrievability of the first presentation. (There is independent evidence that repeated presentations may lead to such a reminding process; see Hintzman and Block, 1973; Tzeng and Cotton, 1980; Winograd and Soloway, 1985). Thus, one cannot reject the multiple-trace approach simply because recall of repeated words may exceed the independence baseline. Rather, the multiple-trace approach suggests that the probability of recall should be predictable based on the probability of retrieval of the separate occurrences. To test the multiple-trace approach, some way must be found to allow for the experimenter to determine whether the participant is able to recall the first, second, or both occurrences of a repeated item.

Watkins and Kerkar (1985) devised such a study. The general procedure in their experiments was to ask participants to learn a list of once- and twice-presented words. Every presentation was tagged by an arbitrarily selected distinguishing attribute. Participants would be required to recall the words. Then they would be asked to remember the attributes. The goal was to determine whether memory for the items could be predicted on the basis of memory for the detailed attributes associated with particular presentations. Their first experiment can serve as an example of their approach. This experiment required recall of lists, each of which was composed of five words presented once and five words presented twice. The attribute manipulated here was the color of the presentations, with 10 different colors being used in printing the words. After the list was presented, participants were asked to recall the words. They recalled 0.18 of the once-presented words and 0.46 of the repeated words. (Note that recall of the repeated words greatly exceeded the independence baseline.) Then, Watkins and Kerkar attempted to determine whether recall of repeated items could be attributed to retrieval of particular occurrences. To determine how well particular occurrences could be retrieved, Watkins and Kerkar asked participants to remember the color that each word had been presented in, including noting two colors for repeated words. Participants were much less accurate in recalling the colors of repeated words than those of once-presented words. Thus, although people are able to recall repeated words better than would be expected based on recall of once-presented words, they actually remember the

details of each occurrence of repeated words less well than they did for once-presented words. Watkins and Kerkar argued that there is a collective recollection of occurrences, which they called generic memory, that can benefit memory for repeated items separately from retrieval of the particular instances. Watkins and LeCompte (1991) presented further evidence that memory for repeated information can exceed recall of specific occurrences.

Hintzman (2004) had another demonstration that multiple-trace accounts cannot offer a complete account of repetition effects. He took what is commonly seen as the strongest evidence for these accounts, namely, participants' ability to estimate the frequency of occurrence of repeated items. He showed that these judgments of frequency were, in fact, more strongly related to presentation frequency than is performance on a recognition-memory test. Essentially, he dissociated memory for items from memory for how often they occur, although multiple-trace accounts attribute both to a common process (namely, the retrieval of separate occurrences). This finding is inconsistent with a pure strength-theory of repetition effects as well, because such a theory would also attribute the effects of repetition on recognition and frequency judgment to a single process, namely, the strengthening of a single trace for each stimulus. Fisher and Nelson (2006) carried out a conceptual replication of this finding by showing that the size of the repetition effect is numerically greater on frequency judgments than on recognition memory. These results suggest that any one-process account of repetition effects will be insufficient.

Overall, the literature suggests that repetition leads to the creation of separate memory traces, each of which contains information about the context in which it occurred. However, findings such as those of Watkins and Kerkar (1985) and Hintzman (2004) indicate that repetition has additional effects on memory beyond the creation of traces. These additional effects are at present still poorly understood. It is possible that a combination of strength and multiple-trace approaches will be necessary; formal models, such as that of Hintzman (1988), where repetitions create multiple traces that may be combined in various ways at the time of test, may eventually shed light on this. At present, however, we know that simple approaches are inadequate without yet being able to offer a successful complex explanation of repetition effects.

2.06.3 Spacing Effects in Memory

Ebbinghaus (1885/1964) noted that "with any considerable number of repetitions a suitable distribution of them over a space of time is decidedly more advantageous than the massing of them at a single time" (p. 89). This advantage of spaced practice over massed practice became one of the laws of memory formulated by Jost (1897). Spacing of repetitions became a widely used manipulation in studies of learning and memory (Bruce and Bahrick, 1992). Reviews of early research on this topic were carried out by Ruch (1928) and McGeoch and Irion (1952). However, given the wide variety of procedures used, many conflicting results were found, and researchers such as Underwood (1961) despaired of being able to demonstrate consistent and unambiguous benefits of repetition spacing. Melton (1967) rectified this by popularizing a straightforward way of demonstrating the beneficial effects of spacing. With this method, a list of words is presented one at a time to participants. Some of the words are presented two or more times, and the number of intervening items between occurrences of repeated items is carefully controlled. Some repeated words (massed words) are presented twice in a row, whereas other repeated words (spaced words) have one or more intervening words between occurrences. When participants are given a test on their memory for the words, a clear benefit for spaced repetitions over massed repetitions can be demonstrated. Recent reviews have established the advantage for spaced repetitions beyond serious question (Janiszewski et al., 2003; Cepeda et al., 2006). Although this conclusion had to be based on controlled laboratory experimentation, people evidently reach a similar conclusion based on their everyday experiences, as they may choose to devote spaced rehearsals to challenging material (Benjamin and Bird, 2006).

Several distinctions among commonly used terms may be useful. The advantage in memory for a repeated item over a once-presented item is a repetition effect. The advantage in memory for spaced items (repeated items that had their occurrences separated by intervening stimuli) over massed items (repeated items presented consecutively) is a spacing effect (sometimes called a distributed-practice effect). When one looks only at spaced items, any advantage in memory as the number of intervening stimuli is increased beyond one would be called a lag effect. Whether increases in spacing

beyond one or two intervening items hold much benefit in remembering is less clear, although evidence increasingly suggests that this is the case (Kahana and Howard, 2005; Cepeda et al., 2006).

Spacing effects have received a large amount of attention from both theorists and experimenters. One reason why they are seen as particularly important is their wide generality. They may be found in a large number of subject populations, including nonhuman animals (e.g., Davis, 1970; Sunsay et al., 2004), human infants (Cornell, 1980), children (Toppino, 1991, 1993), and the elderly (Balota et al., 1989; Benjamin and Craik, 2001). Also, spacing effects have been found in educational settings for typical course materials, suggesting that the distribution of practice may be a useful way to improve retention without requiring additional time (Dempster, 1988). Bahrick (2005) has argued for the importance of viewing spacing effects from an educational perspective, and it is certainly true that spacing can influence long-term retention of material typically learned in school (e.g., Reder and Anderson, 1982; Rea and Modigliani, 1985; Bahrick and Phelps, 1987; Dempster, 1987; Rawson and Kintsch, 2005; Balch, 2006; Kerfoot et al., 2007).

A wide variety of theoretical explanations have been offered for spacing effects over the years. Although spacing effects may be found in many domains and using many tests, theorists have focused on the literature on human memory for word lists. At least with respect to this memory literature, two classes of explanation have been particularly influential, one emphasizing the importance of encoding and the other emphasizing the importance of retrieval.

2.06.3.1 Deficient-Processing Accounts

Some theorists (e.g., Hintzman, 1976; Zechmeister and Shaughnessy, 1980; Cuddy and Jacoby, 1982) have claimed that repetition spacing influences the processing of the second occurrence of repeated items. Typically, the claim is that massing repetitions leads to deficient processing of the second occurrence, relative to spaced repetitions. Hintzman et al. (1973) showed that repetition spacing seemed to influence memory for the details of the second occurrence, but not of the first occurrence, for repeated items.

This deficient processing of the second occurrence of repeated items may in part be due to involuntary processes akin to habituation; that is, we may not be able to keep ourselves from paying less attention to a stimulus that we had just encountered than one whose previous occurrences were more distant in time. However, it may well be that voluntary, strategic processes play a major role here. Zechmeister and Shaughnessy (1980) argued that, as participants are encoding a list of items, they are constantly deciding how to distribute their rehearsals between the current stimulus and the previous ones. The amount of rehearsal that a participant devotes to an item may be influenced by whether he or she feels that it is already well learned. There would be no point in devoting further rehearsal to an item that has already been mastered. Zechmeister and Shaughnessy found that participants overestimate the degree to which they will remember massed stimuli. They argued that this can lead to participants choosing to devote fewer rehearsals to such stimuli than to spaced items. Bahrick and Hall (2005) proposed a variant of this approach specifically aimed at retention over very long intervals.

There are many sources of evidence that converge on the claim that participants do not adequately encode the second presentation of massed items. When participants are asked to rehearse words aloud, they give fewer overt rehearsals to the second presentations of massed items than to the second presentations of spaced items (Rundus, 1971; Ciccone and Brelsford, 1974). When participants are allowed to pace themselves through a list presented on slides, they devote less exposure time to massed items than to spaced items (Shaughnessy et al., 1972; Zimmerman, 1975). Dilation of the pupil in the eye (a measure that is related to cognitive effort) is greater when participants are seeing spaced repetitions than when they are seeing massed repetitions (Magliero, 1983).

One straightforward test of this voluntary encoding account is to see whether spacing effects are eliminated when participants are not expecting a test on their memory for the material. That is, if participants are not deliberately rehearsing any items for a later test, then they would have no reason to treat spaced and massed items differently. The evidence here is strikingly mixed. Spacing effects are sometimes eliminated when lists are learned incidentally, but the details of the study and testing procedure are critical (e.g., Jensen and Freund, 1981; Greene, 1989, 1990b; Challis, 1993; Greene and Stillwell, 1995; Russo et al., 1998).

A second test for voluntary encoding-deficit accounts would involve an examination of the importance of experimental design. Repetition spacing

could either be manipulated within lists (where participants are given a list containing both massed and spaced repetitions) or between lists (where participants receive a pure list, consisting either only of massed repetitions or spaced repetitions). The vast majority of studies in this area has used the within-list design. The magnitude of spacing effects in this design may be exaggerated because participants may rehearse spaced items during the presentation of massed items. If spacing effects result from an encoding deficit for massed items, you may see a reduction (and possibly a complete elimination) of spacing effects on between-list designs. Unfortunately, the literature on this point is very inconsistent, yielding all sorts of conflicting findings, and it is possible that the details of the design, study instructions, and memory test may be critical (Underwood, 1969b, 1970; Waugh, 1970; Greene, 1990b; Hall, 1992; Toppino and Schneider, 1999; Delaney and Knowles, 2005; Kahana and Howard, 2005).

Attempts to reduce spacing effects entirely to a voluntary deficient-encoding process, while inspiring some supportive results, have failed to present a consistent empirical picture. This has convinced some theorists that at least one other process is needed to explain spacing effects completely (Greene, 1989, 1990b; Braun and Rubin, 1998; Russo et al., 1998). In addition, it has been difficult to see how deficient-processing accounts developed to explain how participants remember intentionally learned lists of words can be easily expanded to cover the range of situations, materials, and subjects that can demonstrate advantages for spaced repetitions.

2.06.3.2 Encoding-Variability Accounts

Encoding-variability accounts of spacing effects make the assumption that the distribution of repetitions affects the likelihood that at least one of the occurrences will be successfully retrieved. Typically, it would be assumed that greater spacings would increase the probability that each presentation of a repeated stimulus would be encoded in a very different way, thereby making it more likely that a participant would be able to retrieve at least one of the occurrences.

One analogy that I have found useful in explaining this approach would be to liken this to the probability of being able to find a particularly important piece of paper. If you want to be sure that you will always be able to find the paper when you need it, you may try to have multiple copies of it. However, it would make no sense to place all of those copies in the same place. Rather, you should scatter the copies around at many different places. Although this would make it more difficult to locate all of the copies, it is assumed that you only need to locate one copy. Similarly, if every repetition of an item leads to a separate memory trace and if one only needs to retrieve one of the traces to remember the item, it would clearly be better if the separate traces are somehow distributed throughout memory.

This notion that repetition spacing influences encoding variability, which facilitates the probability of remembering at least one occurrence of an item, has been expressed in several forms. Landauer (1975) adopted this concept literally. He proposed a model in which memory traces are stored at random locations in a memory system. Traces for the occurrences of spaced items would tend to be stored farther apart than traces for the locations of massed items. If one assumes that only part of the memory space is searched during retrieval, then there would be an advantage for the spaced items.

An alternative way of envisioning encoding variability is with respect to the information with which items may become associated. For example, Glenberg (1979) suggested that interitem associations are critical on many memory tasks, particularly free recall. When two occurrences of a repeated item are presented in massed fashion, the two traces tend to become associated with the same items. In contrast, when the two occurrences are spaced apart, the resultant traces are associated with different items. Glenberg argued that the probability of retrieving at least one occurrence of a repeated item increases with the number of different associations that had been formed. Raaijmakers (2003) showed how this approach can be incorporated into a broader mathematical model of memory.

Gartman and Johnson (1972) pointed out that words can be interpreted in slightly different ways. This is clearest in the case of homographs like IRON or TOAST, where the same pronunciation and spelling pattern would be associated with seemingly unrelated meanings. Even when a word is perceived as having only one meaning, there may be slightly different connotations that could come to mind; depending on the context, the word PIANO could be encoded primarily as a musical instrument or as a heavy object. Gartman and Johnson suggested that repetition spacing influences the probability that each occurrence of a repeated word would receive a

somewhat different interpretation and that this variability in meaning would increase the probability that at least one occurrence could be retrieved. Indeed, Gartman and Johnson reported that recall of homographic words does not show a spacing effect, presumably because different meanings may be invoked even at short spacings.

The notion that some variant of encoding variability underlies the spacing effect has been popular among theorists even in the absence of direct evidence that encoding variability benefits memory at all. Some interpretations of this approach would claim that encoding variability should influence memory for once-presented items; that is, the probability of retrieving at least one of two unrelated, once-presented words should increase as a function of the spacing between them. However, this prediction has been falsified, as spacing seems to have no effect on recall of once-presented words (Ross and Landauer, 1978). Also, direct attempts at controlling the presentation context of repeated items have found that encoding variability typically leads to a decrease in memory performance (Bellezza and Young, 1989; Greene and Stillwell, 1995; Verkoeijen et al., 2004).

Even in the absence of direct empirical support, the concept of encoding variability as at least one component in a theory of spacing effects continues to be popular. One reason is that some variants of this approach can offer a straightforward explanation for an otherwise puzzling finding, namely, the fact that memory for massed items may be superior to memory for spaced items if the test is administered very briefly after presentation. Glenberg and Lehman (1980) presented a particularly compelling empirical picture and proposed a proportionality rule that states that "when the retention interval is short relative to the spacing of the repetitions, performance is negatively correlated with repetition spacing; when the retention interval is long relative to the spacing intervals, performance is positively correlated with spacings of the repetitions" (p. 528). Glenberg and Lehman demonstrated this proportionality rule in free recall, with similar findings being obtained in other memory tasks (Peterson et al., 1963; Glenberg, 1976; see Cepeda et al., 2006, for a quantitative review of this pattern). This advantage for massed items after short retention intervals suggests that it is better to have two occurrences presented in contexts very similar to the testing context rather than to have only one. Although this finding of a massed-item advantage after brief retention intervals is only indirect support for encoding-variability approaches, it has been difficult to develop alternative explanations for this finding.

2.06.3.3 Multiprocess Accounts

Theorists have increasingly abandoned the attempt to reduce spacing effects to a single factor and have instead turned to multiprocess explanations, where spacing influences several aspects of memory (e.g., Glenberg, 1979; Greene, 1989, 1990b; Braun and Rubin, 1998; Russo et al., 1998). For example, Greene (1989, 1990b) has argued that deficient processing of the second occurrence of massed items largely explains spacing effects on tests where cues are provided to participants; such cued-memory tests would include recognition or frequency judgment. On the other hand, free recall is an uncued test because no retrieval cues are explicitly given to participants; some variants of the encoding-variability approach offer a better explanation of spacing effects on this test. This sort of explanation reflects the fact that one can find manipulations that have different effects on the spacing effect found in free recall or cued tests (e.g., Glenberg and Smith, 1981; Greene, 1989; Kahana and Greene, 1993). Still, the details of multiprocess approaches have yet to be worked out satisfactorily, as none has been able to offer a comprehensive account of the literature.

The popularity of multiprocess accounts largely reflects the fact that single-process explanations to date have necessarily left large portions of the literature unexplained. One limitation even for multiprocess accounts is that they have largely been applied only to results from memory experiments using adult human participants. In principle a factor like encoding variability can be applied to nonhuman animals (and indeed the concept owes much to the stimulus-sampling theory developed by Estes, 1955, to explain findings in the animal-learning literature). However, there has been little effort paid to seeing whether one can take theories of the spacing effect developed in the field of human memory and apply them in a fruitful way to other domains, such as animal conditioning or human skill acquisition. Until theorists in this area feel compelled to account for a wider range of empirical data, it will be impossible to claim that we have an adequate explanation of spacing effects.

2.06.4 When Repetition Does Not Improve Learning

Because repetition so clearly is an important factor in learning, it is understandable that we have focused on cases where there is a positive relationship. However, sometimes repetition is ineffective in promoting learning. The classic demonstration of this is the poor memory Americans have for the characteristics of the penny. Although Americans have seen this coin countless numbers of times, Nickerson and Adams (1979) showed that they can have quite poor recollection for its details. They may not be able to recall what words are on the penny or where the date is located. After all, people presumably use the color (brown) of the penny to distinguish it from other coins, so they do not need to attend to its other features. If people are given 15 s to study an unfamiliar coin (the mercury dime, which was in use from 1916 to 1945), they remember its details better than they remember those of the penny (Marmie and Healy, 2004). This illustrates the point that repetition in the absence of attention is strikingly ineffective in promoting learning.

The ineffectiveness of repetition in the absence of attention is also illustrated by the fate of items memorized through maintenance, or rote, rehearsal (e.g., Glenberg et al., 1977; Rundus, 1977). In these experiments, participants have to repeat items aloud over and over. When they are given an unexpected memory test on the rehearsed words, there is at best a very weak relationship between the number of overt rehearsals devoted to an item and later memory (Greene, 1987). Simply repeating an item over and over has little benefit for memory in the absence of attention or more elaborative processing of the material.

Repetition may impair learning if memory is tested for only one occurrence. If an item has been presented in several contexts, it may become difficult to retrieve the occurrence that is being tested. An early demonstration of this (although initially interpreted in a somewhat different way) was the negative part-whole transfer effect reported by Tulving (1966). In this procedure, a control group and an experimental group first learn a list of 18 words and then learn a list of 36 words. In the control group, the two lists are unrelated. In the experimental group, the earlier list of 18 words was then included in the list of 36 words. If repetition inevitably leads to improved memory, then the experimental group should have an advantage over the control group. However, Tulving found an effect in the opposite direction, with the control group outperforming the experimental group. A critical issue here is that there is increased opportunity for confusion between the lists when they overlap. Because participants in the experimental group do not necessarily realize that the 18-word list is entirely contained in the 36-word list, they may have difficulty when they try to restrict their recall to the second list (Sternberg and Bower, 1974). In a similar vein, preexposing some items on a list may impair recognition memory for them, at least in part because participants have difficulty knowing whether the familiarity of the items is due to the preexposure or to presentation on the list (Greene, 1999). Repetition may impair memory when the critical task requires participants to disregard some occurrences of a repeated stimulus.

A striking case where repetition may lessen memory is in serial (ordered) recall of short lists. When participants have to recall short lists of digits or letters, memory is impaired if one item is repeated on the list. This phenomenon, known as the Ranschburg effect, was introduced into the modern psychological literature by Crowder and Melton (1965). Crowder (1968) carried out a systematic manipulation of all possible locations of repeated items. He found that, when the two occurrences of a repeated item occupy immediately adjacent serial positions, recall of the series is enhanced. However, when the two occurrences are spaced apart, recall is impaired, with the greatest decrement occurring when there are two intervening items. The impairment is very localized, with only recall of the second occurrence being negatively affected. The Ranschburg effect is also rather delicate, leading Murdock (1974) to label it the "Ranschburg (non) Effect" (p. 297). Later research has shed light on the boundary conditions of this phenomenon, as changes in the nature of either the instructions given or the nature of the test can eliminate the effect (Greene, 1991). This effect seems to occur because recall of the first occurrence of the repeated item may inhibit output of the second occurrence (Greene, 2001).

2.06.5 Conclusion

Much of the literature on repetition and spacing effects has been carried out in the empirically minded spirit of functionalist psychology, so it is perhaps appropriate that strong conclusions can be

drawn about empirical patterns but only tentative ones about theoretical implications. First, it is clear that the development of learning as a function of repetition is established beyond question in the research literature. Second, performance improves as a smooth, negatively accelerated function of frequency of study, though this does not necessarily imply that all aspects of learning take place gradually and continuously. Third, as a result of repeated practice, we form memories that contain the details of each occurrence and that we can access individually. Fourth, the effects of repetition cannot be reduced merely to retention of these separate episodes, as we seem to form generic memories that capture what these individual presentations have in common. Fifth, the effects of repeated study are enhanced if the study episodes are spaced apart in time. Sixth, these spacing effects are most likely due to a combination of factors, such as deficient processing of massed repetitions and superior retrieval for spaced repetitions. Seventh, repetitions may not always enhance memory, particularly when little attention is paid to a stimulus or when accurate remembering requires access to one particular occurrence of an event.

Although the theoretical implications of repetition and spacing effects remain to be worked out, their practical importance is beyond question (Dempster, 1988; Bahrick, 2005). Admittedly, much of the literature on these topics has followed standard laboratory methods employing word lists and college-student participants, thereby exhibiting the strenuous task reductionism typical of memory research (Crowder, 1985). Still, a meta-analysis carried out by Cepeda et al. (2006) suggested that repetition and spacing effects may influence learning for a wide variety of materials and over long retention intervals. As a wider range of procedures and perspectives are directed at these issues, we may hope to achieve greater theoretical progress in understanding these central manipulations for learning and memory.

2.07 Coding Processes

R. R. Hunt, University of Texas at San Antonio, San Antonio, TX, USA

The questions of what people know and how they come to know it have been a topic of scholarly inquiry forever. At the level of individual knowledge, all that any of us know is represented in memory, and memory representations are just that, representations. Whatever the event may have been, the processes of perception and comprehension yielded a psychological experience, and it is that experience of the event that becomes the memory. In this sense, the memory is a code that represents the original event, but that code is all the knowledge we as individuals have of the event. With these premises, the importance of studying coding processes in memory is obvious. Answers to the questions of what the nature of the code is and how the code is formed are answers to the venerable questions concerning the nature of knowledge.

Widespread interest in issues of coding only appeared with the cognitive renaissance of the 1950s and 1960s. The concept of coding is rarely found in psychology texts prior to 1950, but by 1972, coding was said to be truly central to modern theories of memory (Bower, 1972). In this chapter, we examine the origins

of the concept, which reveal the theoretical function served by coding and the reason for its centrality in modern theory. An overview of the methods used to study coding is provided, as well as some description of factors known to affect the coding process. Finally, two broad metaphors used to describe the memory code will be discussed, along with several specific ideas that represent each of the metaphors. The reader is warned of a major caveat about the discussion, namely, that the effects of variables associated with the memory test will not be described, nor will the theoretical coaction of coding and retrieval be part of the discussion. One must keep in mind that many of the effects described in this chapter are relative to the conditions of retrieval (*See* Chapter 2.16).

2.07.1 The Coding Process

The process of coding is an integral component of many natural and artificial phenomena. Generally, coding can be defined as the transformation of messages, signals, or states from one representational form to another. With this definition, the presence of coding in activities from espionage to metabolism becomes fairly obvious. One might reasonably wonder, however, why phenomena require the apparently superfluous process of changing forms of representation. That is, if the representations denote the same thing, why insert a process to change the form of the representation? Leaving aside esoteric forms of coding for purposes of deception and secrecy, the principal need for coding processes seems to be that the end user cannot work with the original form of the representation, and coding is necessary to transform the original representation into a useable form. Relevant examples here range from the various transformations of energy after it contacts sensory receptors and before it is "used" in the brain to the necessity of transforming a visual experience to linguistic code to inform someone of the experience.

2.07.1.1 Coding from the Computer Model

The meteoric rise in the use of coding as a psychological concept is largely because of the developments in information science and computer technology between 1948 and 1960. Shannon (1948) published a mathematical theory of an abstract communication system, an important component of which was the bits of information transmitted by the system. The theory was written in a general mathematical form such that information could take any conceivable form and be transmitted over any kind of channel. Some psychologists soon realized that the idea could be applied to human information transmission (e.g., Miller, 1956).

Dovetailing with the abstract notion of information transmission was the more concrete model of the computer as an information processor. By 1958, Newell et al. advocated that the mind be described as an information processing system modeled on the workings of computing machinery. Early in the history of computer science, the computer was conceptualized as a general-purpose symbol manipulator, and the insight that the mind could be construed as a symbol-manipulating system (e.g., Newell and Simon, 1972) provided the foundation for the use of a computer model in theoretical psychology. With this foundation in place, the analogy of specific computer functions such as buffers, stores, and retrieval to human information processing, especially memory, was recognized quickly. Among these specific functions was the process of coding.

For the computer, the fundamental process of coding is the transformation of the external input into the representation defined by the machine language. The analogy here to energy transformation in human sensation and perception is patent. For example, the effective energy contacting the visual receptors is electromagnetic energy, but the human brain cannot use this form of energy. The first coding in vision is the transformation from electromagnetic energy to chemical energy at the level of the rods and cones. In turn, the chemical energy is transformed to electrical energy for transmission through the optic nerve for use in the cortex. Less concrete but equally compelling analogies were drawn to cognitive descriptions of learning and memory. By the 1950s, verbal learning researchers knew that some nonsense syllables were more nonsensical than others. Syllables such as FDR, KLM, and CBS obviously were treated differently than JQN, XFV, PGW. The assumption that the nominal stimulus was the functional stimulus had given way to the admission of a proximal stimulus. With that concession, behavioral theory now needed a psychological process of coding to account for the transformation from nominal to proximal stimulus.

2.07.1.2 The Function of a Code in Psychological Theory

Codes serve as representations for some other object or event. Codes carry information, perhaps not in the

precise form specified by Shannon's (1948) theory, but information in the sense of symbolically representing something else. For our purposes, codes are the psychological manifestation of prior experience. The experience can be in the immediate past, in which case we call the code a perception. As the past grows more distant, we refer to the code as a memory. All psychologists agree that behavior and thought are influenced by prior experience, and because the code is the representation of that experience, understanding codes and the processes that produce them looms large for cognitive theorists.

Codes serve another function for psychological theory that is rarely discussed. That is, codes dispel the mystery of action at a distance. To say that current thought and behavior are caused by prior experience begs the question of how something in the past can cause something to happen in the present. The stock answer to this question is that experience changes the individual, but the customized answer includes the form of this change. Different theories propose different kinds of codes, but in all cases, the stored code solves the problem posed by causal action at a temporal distance. The original event does not cause current thought and behavior but, rather, the coded version of that event, which is accessible at the time of the behavior or thought. Not everyone agrees that this use of the code to bridge the temporal gap is a good thing. Watkins (2002), for example, noted that memory has been reified by assuming that a residual of the original experience is maintained over time and that this characterization is unrealistic. Nonetheless, the search for the contents of the memory code has been quite active.

2.07.2 Breaking the Code

On the assumption that the memory code is the proximate cause of the past's influence on current thought and behavior, the question of what is encoded from a given experience has become a popular research agenda in learning and memory. As with many other concepts in science, the memory code cannot be observed directly. Consequently, a variety of methodologies have been developed to infer the nature of the representation of a particular experience. Each method comes with assumptions that allow the inference to follow, and thus it is important to explicitly acknowledge these assumptions. The following discussion is intended to update an earlier review by Tulving and Bower (1974).

2.07.2.1 Transfer Paradigms

The transfer paradigm is a venerable method for studying the effect of prior experience and inferring the nature of the code for that experience. The use of transfer rests on the assumption that the effect of prior experience is proportional to the similarity of the prior experience and the current task. Perhaps the first use of the transfer paradigm to measure encoding and storage was Ebbinghaus's (1964) savings method. The savings score is a ratio of the number of trials required for original criterion learning to the number of trials to reach the criterion on a subsequent attempt. This ratio is assumed to index the stored memory from initial learning in that memory, for the original experience obviates the need for new learning on the second experience. Thus, the goal of the savings method is to determine the amount of the original experience that is available at a later time.

In contrast, contemporary use of the transfer paradigm has focused on the qualitative characteristics of encoding, as attested to by the wide acceptance of the principle of transfer-appropriate processing (Morris et al., 1977). The reasoning is straightforward. If performance on the criterion test varies as a function of the similarity between the test and the prior experience, one infers that the code includes values from that dimension of similarity. As an example, consider an experiment by Jacoby (1983). Subjects studied words for memory either by reading the words or by generating the words from a fragment. Half of the subjects were given a test of recognition memory, and half were given a test of perceptual identification. Perceptual identification requires that words be read under conditions of severe visual degradation. Prior experience with the words facilitates perceptual identification accuracy, but as Jacoby (1983) showed, only if that experience is reading. Generation of the study words produced no positive transfer to perceptual identification, although generation yielded much higher recognition memory than reading. Jacoby's demonstration of differential transfer from reading and generating at study illustrates the use of transfer paradigm to infer the content of the code.

Negative transfer also can be used to infer the contents of the code. An early example is the release

from proactive inhibition (PI) paradigm (Wickens et al., 1963; Wickens, 1970). The basic paradigm involved presentation of short lists of words for immediate recall. The lists were similar on some dimension; for example, all words could be exemplars of the same category. As can be seen in **Figure 1**, performance declined quickly over the first two to three study-test trials. The decline was identified as PI, the cause of which is competition among the codes. The basis of the competition is assumed to be similarity of the codes. Thus, the presence of proactive interference provides a basis for inferring that the code contains information corresponding to the dimension of similarity. The inference is validated by eliminating the similarity on the final list in the series and observing better performance than on the previous trial, the so-called release from PI, which is depicted in **Figure 1** in the shift condition.

Straightforward inferences about the code from the release from PI paradigm are complicated by data reported by Gardiner et al. (1972). They presented different instances from the same category over three study-test trials and observed PI buildup over the trials, as would be expected. On the fourth trial, subjects continued to see instances from the same category but under different conditions. The standard control condition received no special instructions and continued to show PI on the last trial. In another condition, subjects were informed prior to studying the list that the instances were all exemplars of a subcategory (e.g., water birds). Memory improved with these instructions, as would be expected if the dimension of encoding shifts from that of the first three trials. The critical condition is the third condition, in which the special instructions concerning the material were given after study and prior to recall. These subjects also evidenced release from PI, results consistent with an alternative view of the cause of PI buildup and release. That is, PI reflects the increasing ineffectiveness of a cue as more items are subsumed by that cue, all in accord with the principle of cue overload (Watkins and Watkins, 1975). Release from PI then is caused by the availability of an appropriate new cue. Note that in this interpretation, negative transfer in the release from PI paradigm is not informative about coding processes.

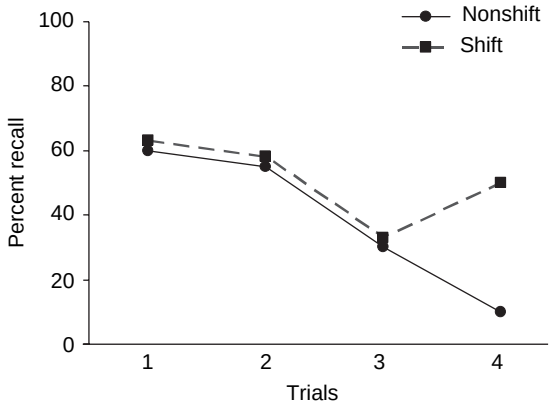

Figure 1 Memory for material from the same category over the first three trials illustrates proactive interference. The shift condition sees material from a different category on the fourth trial, resulting in release from proactive interference. Adapted from Wickens DD, Born DG, and Allen CK (1963) Proactive inhibition and item similarity in short-term memory. *Journal of Verbal Learning and Verbal Behavior* 2: 440–445.

2.07.2.2 Retrieval Cuing

The relative effectiveness of retrieval cues frequently is used to make inferences about the nature of a code. The reasoning is the same as that underlying the use of the transfer paradigm, except that here the appeal is to the principle of encoding specificity (Thomson and Tulving, 1970; Tulving and Thomson, 1973). Encoding specificity states that as a necessary condition for successful memory, the cue must have been present at encoding. If a cue does lead to correct memory, one can assume, based on encoding specificity, that information shared by the cue and its target was encoded originally.

As an example, Nelson et al. (1974) used this logic to investigate semantic and phonetic coding of words. Word lists were studied for memory and then cued for recall by either rhymes or synonyms of the studied words. Half of the subjects who received rhyme cues had studied the words in the presence of the rhymes, and half had studied the words alone. Likewise, half of the subjects receiving synonym cues had studied the words in the presence of the synonyms, and half had studied the words alone. The results showed that recall to a rhyme cue was equally good for words studied in the presence of the rhyme and for words studied alone. Recall in the presence of the synonym cues was much better for the group that had seen the synonym cues at study than for the group that studied the items alone. From these results, Nelson et al. concluded that phonetic information about a word is encoded even when the word

is not modified by a study context. Semantic information corresponding to the synonym is not encoded unless the study context biases that coding process. The results and interpretation make perfect sense, in that words have few alternative sound patterns, whereas the number of nuanced meanings of a word can be large.

The cuing methodology has been used extensively to study the interface between comprehension and memory. For example, Anderson et al. (1976) asked people to study sentences that contained a general noun (e.g., "The woman was outstanding in the theatre"). Later they were given a cued recall test and instructed to recall the last word of the studied sentences. The cue could be the general subject noun (e.g., 'woman') or a specific term that previous norming showed represented the comprehended instantiation of the general noun (e.g., 'actress'). Recall was better for the last word of the sentences when the cue was the particular instantiation rather than the general term that had appeared in the sentence. Using the logic of encoding specificity, Anderson et al. concluded that general terms are comprehended and encoded as particular instantiations rather than as abstract core meaning. This example nicely illustrates the relationship between questions about the memory code and the broad issue of the nature of knowledge. The conclusion from the Anderson et al. study suggests that the meaning of abstract nouns is represented by specific instances of those nouns rather than some abstract meaning that goes beyond the instances.

Using retrieval cues to infer the coded experience is limited to the logic of encoding specificity, namely, the presence of a cue at encoding is a necessary condition of cue effectiveness, not a sufficient condition. The implication of this limitation is that one cannot infer the nature of coding from the absence of a particular cue effect. For example, the declining performance over trials in a buildup of PI paradigm cannot be used to infer a corresponding decline in the encoding of the dimension of similarity across the trials, indeed, quite the opposite inference usually is made. In short, memory performance is affected by factors other than the presence of an appropriate cue. What can be done with some confidence is to infer that particular information was encoded when cue information facilitates memory. Nairne (2002) offers an interesting discussion of the limitations of cue effectiveness as a basis for inferences concerning the encoded trace.

2.07.2.3 Materials Effects

The existence of different kinds of codes also has been inferred from differential effects of material on memory. Perhaps the seminal modern instance of this approach involves comparing memory for a list of pictures versus memory for a list of words that are the names of the pictures. Other things being equal, the pictures will be better remembered than the words (e.g., Paivio, 1971). Paivio and others have interpreted these data as consistent with the idea that at least two classes of codes exist in memory, verbal and imaginal (Paivio, 1995). Pictures can be coded in both forms, whereas words are most likely to be coded in the verbal form, and the multiple forms of code for the pictures confer an advantage in memory performance. Alternatively, Nelson et al. (1976) suggested that the picture superiority effect is not a result of qualitative differences in the code but, rather, to a quantitative difference in the distinctiveness of the sensory code for pictures. Nelson et al. (1977), however, did argue for a difference in the necessity of semantic coding for words and pictures in that pictures require semantic coding prior to phonetic coding, whereas the semantic coding of words is not necessary for phonetic coding. Again, the nature of coding was inferred from the differences in performances for the classes of materials.

Variations in the memory code accompanying manipulations of materials have been used to explain other memory effects, including differences in memory as a function of clinical diagnoses. For example, clinically depressed patients tend to remember negatively valenced words better than positive words, whereas nondepressed people do not show this effect (e.g., Bradley and Mathews, 1983; McDowell, 1984). This effect is eliminated in tests that do not request intentional memory (e.g., Denny and Hunt, 1992; Watkins et al., 1992). Because prior research has shown that meaningfully elaborated codes are better remembered than less elaborated codes on intentional memory tests, these data have led to the conclusion that the encoded representation of negative experiences is more elaborate than the representation for positive experiences in depressed patients. The difference in memory for different types of materials as a function of clinical diagnosis is explained by inferring quantitative differences in the codes. Depressed patients have more elaborate codes representing negative events than do nondepressed people.

A potential problem associated with inferring the type of code from materials effects concerns the decision axis for postulating a class of codes. One would not postulate a qualitatively different class of codes for every dimension along which people can discriminate; otherwise, the kinds of codes would prove practically infinite. What was needed in 1974 (Tulving and Bower) is still not entirely obvious today, and that is a clear set of rules specifying when a differential effect of materials is evidence for different kinds of code. Moreover, care must be exercised to avoid the assumption that labeling material effects as different memory codes has explained anything. Discussing this issue, Tulving and Bower (1974) said, "it is of interest to note that it has not yet been made clear by anyone how the task of explaining memory phenomena is materially aided by the hypothesized existence of different memory stores" (p. 273).

2.07.2.4 Decision Time

Another method used to infer the nature of encoded material is the time taken to respond to queries about the prior experience. The assumption underlying this technique is that response time will be faster if the code contains the information requested by the query. The more inferences from the code required to answer the query, the longer the time will be. A good example of this approach comes from Posner's (1969) research. Subjects were shown two letters in succession, the first of which is the target letter, and the second is the probe. A decision is made as quickly as possible as to whether the probe matches the first target. Various matching rules can be used to instruct the subjects. Suppose the rule is that the two letters have the same name, and the target letter is a capitalized 'A.' The probe can either be a matching capitalized 'A' or one of two nonmatching probes, a lowercase 'a' or a different letter. When 'A' is followed by 'A,' the positive decision is made more quickly than when 'A' is followed by 'a.' The difference in decision latency decreases as the interval between the two letters increases. Assuming that the target letter is held in memory until the match is completed, Posner and his colleagues interpreted this pattern to indicate that the initial representation is visual, thus producing faster matches for visually identical patterns. As the encoding process continues, the visual code is supplemented by a phonetic code, leading to faster responding to the 'A-a' pair at longer interletter intervals.

Reaction time has been used extensively to infer imaginal coding in decision-making tasks (e.g., Brooks, 1967; Cooper and Shepard, 1973; Farah, 1985). As an example, Cave and Kosslyn (1989) showed stimuli consisting of two superimposed rectangles, one drawn in light lines and the other in dark lines. One of the rectangles was drawn vertically, and the other was superimposed diagonally over the first rectangle. The same two objects were used on each trial, although the relative length of the lines in the objects differed from trial to trial. The task was to decide whether the sides of the object drawn in light lines were equal to those of the object drawn in light lines on the previous trial. The principal manipulation was the subject's expectations of the size of the object to be judged and of which of the two rectangles would be drawn in light lines. The manipulation was performed by instructing the subjects that most of the time the same rectangle would be judged on the next trial and that the object would be of the same size as on the preceding trial. These instructions conformed to 75% of the trials. Thus, on 25% of the trials, the size, the object, or both were different from the preceding trial. The time to correctly decide about the targeted rectangle was affected by both expectations. Responses to unexpected objects as well as to unexpected sizes were slower. Considering just the expected object trials, response time increased linearly with the unexpected change in object size. These data indicate that the stimulus from the preceding trial affects performance on the current trial and that this effect systematically varies with the relative size of the stimuli. A reasonable interpretation is that the encoded representation from the previous trial affects performance on the current trial and that representation contains specific size information. That is, the representation is a visual image.

Although studies such as those of Posner and Cave and Kosslyn illustrate that reasonable inferences can be drawn about the nature of the code from decision latencies, one must be aware of the effect of speed–accuracy trade-offs when using latency data. Latencies in most tasks will vary as a function of the emphasis on speed or accuracy, and that trade-off can change the results of an experiment dramatically. Such changes could result in different conclusions about the nature of the code, when in fact the difference is essentially a strategy shift. Moreover, the use of decision latency tends to be limited to material on which accuracy of performance will be near perfect. Thus, the method is not appropriate for new learning or large amounts of to-be-remembered material.

2.07.2.5 False Memories

Memory is not always veridical to the past. People do remember things that did not occur, or at least did not occur as they are remembered. This fact has long been known and has been used as a tool to infer the qualitative nature of the original code. The assumption underlying this inference is that healthy memory is not capricious; rather, errors of commission in memory reflect the content of the coded representation of the probed experience. For example, early studies of false responding in recognition memory showed that synonyms and antonyms of studied words were seductive lures (Anisfeld and Knapp, 1968; Fillenbaum, 1969). The high false alarm rates for these distracters were taken to indicate that the coded representation of the study items was dominated by meaning. The same conclusion was drawn from studies that showed false recognition for sentences that expressed the same idea as studied sentences but were otherwise syntactically different from the studied sentences (e.g., Bransford and Franks, 1971). The coded representation of sentential content seemed to be the abstracted meaning of the sentence.

An important line of research that uses false memory to infer the nature of the code was initiated by studies of inferential processing in comprehension. The idea is that inferences are an integral aspect of normal comprehension and that the information implied in the inference would be part of the coded memory. For example, Johnson et al. (1973) reported a study in which subjects were asked to read several short descriptive stories consisting of two or three sentences. One story was: "John was fixing the birdhouse. He was pounding the nail when his father came out to watch him and help him do the work." The control condition saw the same story except 'pounding the nail' was replaced with 'looking for the nail.' In addition to the actual sentences presented in the story, the recognition test included inference sentences such as: "John was using the hammer to fix the birdhouse when his father came out to watch him and help him do the work." The test instructions were to recognize the sentences that were exactly the same as those presented at study. The group that received the study sentences that invited the tested inferences recognized approximately the same percentage of inference test items and studied sentences. Subjects given the control study sentences made few false alarms to the inference test items. These data are important indications that the coded representation of the prior experience includes the information from the inference, which apparently is indistinguishable from the presented material.

In a similar vein, Deese (1959) reported that people will intrude associatively related words in recall after studying a list of words that are all associated with unpresented words. For example, the study words might include 'sharp,' 'thread,' 'sew,' and 'pin,' but not the word 'needle.' On later recall tests, the probability of recall for the nonpresented associate often is equivalent to the recall of study items. Roediger and McDermott (1995) resuscitated this paradigm, and extensive research has been conducted using the paradigm to study false memories (see Roediger and McDermott, 2000a,b, for a review). A favored interpretation of the intrusions and false alarms that occur in this paradigm is that the critical item comes to mind during study and thus is encoded in the study episode. (*See* Chapter 2.14 for a thorough discussion of false memory.)

Past research has interpreted false memory to be the result of encoding either a general dimension or specific content such as an inference. This interpretation seems reasonable and, additionally, renders false memory less mysterious and capricious in that false memory very often is the product of the normal processes of comprehension of targeted material. One issue concerning inferences from false memory is whether the false memories result from encoding processes or occur at retrieval. For example, false memory of inferences from the Deese/Roediger/McDermott paradigm may be the result of the critical item coming to mind in the presence of targets in recall or recognition. That is, the inference occurs during the test rather than at study. Although this possibility cannot be ruled out entirely, two findings mitigate against an exclusive retrieval interpretation. One is that Roediger et al. (2001) report that false recall is negatively related to correct recall. If the false item were coming to mind as the result of recalling its associates, one would expect a positive relationship between these factors. The second finding is that warnings about false recall are more effective if issued prior to study rather than following study (McDermott and Roediger, 1998; Gallo et al., 2001; Neuschatz et al., 2003; but see McCabe and Smith, 2002, for contrary data).

2.07.2.6 Orienting Tasks

Orienting tasks, usually judgments that the subject makes concerning the to-be-remembered material,

can have a powerful influence on recall and recognition (e.g., Hyde and Jenkins, 1969). With Craik and Lockhart's (1972) levels of processing came a wave of experiments manipulating orienting tasks, all of which assumed that these tasks exert their effect at least in part through specific encoding of a dimension of the material. The logic here is straightforward. If the memory trace is a by-product of perception and comprehension, and the focus of perception and comprehension can be controlled by the orienting instructions, then the qualitative content of the trace can be identified with the dimension specified by the orienting task. For example, Jacoby and Goolkasian (1973) gave subjects lists of word pairs, each of which was related either categorically or acoustically. The orienting task was to rate the degree of the relationship within the pairs. The subjects rating categorical relations recalled more of the items than the subjects who rated the acoustic relationship. The difference in memory is attributed to the nature of the trace (i.e., representations of categorical meaning lead to better memory than sound patterns).

Orienting tasks often are used in conjunction with other methods to infer the nature of the code. For example, Chan et al. (2005) combined the use of orienting tasks and the Deese false memory paradigm to examine the effect of associative versus phonological encoding on false memory. Study lists were either semantically or phonologically related words, and in both cases all the study words were related to a word that was not presented (e.g., 'bed,' 'rest,' 'awake,' or 'sweep,' 'steep,' and 'sleet' are all related to 'sleep,' which itself was not presented). The orienting instructions were to concentrate on the relationship among the words' meanings or among the sound patterns of the words. These instructions were orthogonal to the type of relationship among the words in the lists. The results, which are shown in **Figure 2**, showed an impressive crossover interaction between type of list and orienting task on false memory for the nonpresented items. Considerably more false memory occurred when the orienting task was congruent with the dimension of similarity in the study list. A reasonable interpretation of these data is that the orienting task controls the dimension of encoding and that the critical associate will only come to mind if the study items are coded on a dimension shared by the critical item. That is, if I see *sweep, steep, and sleet*, I will only think about *sleep* if I am attending to the sound of the words.

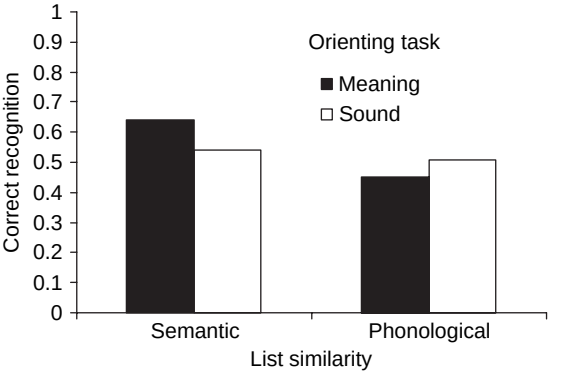

Figure 2 False recognition of critical words as a function of the type of list similarity and orienting task. Adapted from Chan JC, McDermott KB, Watson JM, and Gallo DA. (2005) The importance of material-processing interactions in inducing false memory. *Mem. Cognit.* 33: 389–395.

Despite enormous amounts of research using the technique, we know that orienting tasks alone are not sufficient to identify the content of the code. Leaving aside the possibility that subjects may intentionally focus on dimensions other than that associated with the orienting task, incontrovertible evidence shows that orienting tasks do not control completely the dimension of encoding. For example, Nelson et al. (1979) found that the meaning of a word was encoded in a context that emphasized phonetic features. Hunt et al. (1979) report that visual features of words are encoded during semantic orienting tasks. The encoding of sensory attributes in the course of making a semantic judgment is quite reasonable given that the semantic processing requires sensory input, but this fact complicates the inference one can make about the code following an orienting task.

2.07.2.7 Neural Indices of the Code

A relatively new technique for identifying the code is the use of noninvasive, neural-dependent measures that record brain activity during encoding. The logic of identifying psychological functions from observations of neural dependent measures was formulated in the early 1800s by pioneers such as Gall and Spurzheim, but the development of powerful imaging techniques has made the idea more appealing than ever. A succinct statement of the neuroscientific approach to identifying the memory code begins with the assumption that experiencing an event results in activation of neural pathways that are dedicated to the processing of those types of events.

This activation leaves a trace in the form of altered neural functioning such as increased connectivity. This neural trace will be a critical participant in later memory of the event when activation occurs under appropriate conditions. Using this logic, the trace is identified as the site of the brain activity. To translate the neural code to a psychological code, one appeals to the assumed localization of the psychological functioning (e.g., visual/occipital, auditory/temporal, verbal/temporal-frontal, spatial/parietal, emotional/limbic).

An informative example of the logic underlying the neural identification codes is the study of imagery and memory. A dispute erupted in the 1970s over the nature of the code in memory for an imagined event. The dispute had two aspects. Is the code a modality-specific representation or some more abstract, post-perceptual code (e.g., Shepard, 1978)? And is the mental image a spatial representation or a propositional representation (e.g., Kosslyn, 1980)? Although these appear to be straightforward empirical issues, they proved resistant to adjudication by standard methods of experimental psychology (see, e.g., the following sequence of papers, Kosslyn et al., 1978; Pylyshyn, 1981; Intons-Peterson, 1983).

In the face of this stalemate, some argued that neural techniques are the panacea, "neural measures have the potential to be more decisive on these issues because they provide more direct evidence on the internal processing stages intervening between the stimulus and response in imagery experiments" (Farah, 1995, p. 964). In her reviews of research using various techniques to monitor regional brain activity during mental imagery, Farah (1995, 2006) showed that virtually every study implicates occipital activity in mental imagery, demonstrating that imagery and perception share cortical representations. Moreover, some of these shared cortical representations include spatially mapped areas of the occipital lobe. Thus, if one is willing to assume that the cortical representation is the psychological experience, the neural techniques have resolved successfully what appeared to be an intractable debate about the code underlying mental imagery.

Another interesting example of the use of brain measures to address a question of coding is described by Tulving (1989). The question was, Are there different kinds of codes for knowledge and memory? Tulving reported PET scans of brain activity when the subject was thinking of a recent Sunday afternoon picnic and when thinking of news accounts of French elections. In the best of the Ebbinghaus tradition, Tulving himself was the subject. The results of the scan showed activity in different brain regions when remembering the Sunday picnic than when reflecting on knowledge of the French elections, evidence interpreted to be consistent with the notion that memory and knowledge are represented by different kinds of codes.

Another important line of research using neural techniques was initiated by Wagner et al. (1998). The goal was to identify the locus of brain activity during encoding that is associated with remembered items but not forgotten items. fMRI scans were performed as the to-be-remembered words were presented, and then the scans were backsorted following a recognition memory test to determine what differentiated recognized items from nonrecognized items. Comparing high-confidence hits to misses, greater activity was seen in multiple prefrontal regions and left parahippocampal and fusiform gyri for the hits. Effectively, the conclusion is that relatively high activation in these areas established the code for successful memory. Paller and Wagner (2002, p. 93) have labeled this technique the "subsequent memory paradigm," which yields the contrast between neural activity for successfully remembered and forgotten items. Subsequent use of the paradigm has replicated the original Wagner et al. (1998) results and moved on to issues such as the correlates of coding underlying the subjective experiences of remembering versus knowing (see Paller and Wagner, 2002; Kahn et al., 2004, for reviews).

Research on coding processes that use neural-dependent measures is an exciting development that has produced new information about the brain correlates of learning and memory. However, as with all the other techniques described here, certain cautions are in order if one's goal is to specify as precisely as possible the memory code. Especially important is an issue raised by Henson (2005, 2006) and Poldrack (2006), which is analogous to deductive versus inductive inferences from behavioral data. In the case of behavioral studies of coding processes, a deductive inference would be one in which memory is predicted from a theoretical view of the nature of the code, whereas an inductive inference would be one in which the nature of the code is induced from the behavior. The latter, of course, is the much frowned upon *post hoc* explanation. In the case of the neural measures, the deductive inference is one in which brain activity is predicted from some theoretical idea. Tulving's (1989) study described earlier is an example of the deductive inference based on

neural measures. The hypothesis was that two different kinds of memory codes exist, and the study measured brain activity in the situations that hypothetically activate one or the other of the codes. Notice that the precise regions of brain activity are not critical for the conclusion drawn from the data.

In contrast, the inductive inference, the postulation of a memory code from observation of brain activity, is based entirely on the region of the brain that is activated. Farah's (1995) conclusion that mental imagery is modality specific is based on the assumption that visual perception is mediated by the occipital cortex. Activation of that structure is used to infer visual experience. Not only is the specific brain region important when making these inductive inferences from brain to psychological function but the mapping of structure to function also must be one-to-one (Henson, 2005, 2006; Poldrack, 2006). If any reason existed to assume that the occipital cortex were involved in propositional coding as well as visual perception, one could not infer anything about a particular code from its activation. Thus, if the goal is to specify a particular encoding operation from neural data, one must be able to specify not only what brain area is associated with that operation but also that the brain area is only associated with that particular type of code.

2.07.2.8 Summary of Methods

Memory scientists have been extraordinarily clever at developing techniques to study the nature of the representation in memory. The work is difficult because no direct observation of the memory code is possible, but rather, the code must be inferred from observations of behavior and/or brain activity. The use of indirect inferences to establish the nature of the representation is not at all unique to the question of coding, or even to psychology. It is the same hypotheticodeductive strategy that has led to the postulation of planets and subatomic particles. In contrast, the rules that govern an inference from observations to a specific hypothetical code must be made explicit in each case and examined for their validity.

The challenge confronting the attempt to precisely specify the code in any given circumstance was argued by Anderson (1978). Anderson's point was that inferences about the code are based on data, which in turn were collected under the auspices of theory-driven experiments. That is, a theory predicts some outcome given some setting condition. The problem arises when we realize that a theory postulating a particular code (e.g., a visual image) also assumes some set of processes. Any data explained by this theory also may be explained by an alternative theory that postulates an alternative form of representation (e.g., a propositional code) combined with alternative processes. Anderson concluded that for this reason, arguments about contents of the code cannot be adjudicated by behavioral research. Anderson's only suggested solution was the possibility that neural-dependent measures would become available, and as evidenced by Farah's opinion quoted earlier, some scientists believe that the solution has been achieved in the intervening years. That belief, however, rests on the assumption that the neural measure is a more direct observation of the code.

2.07.3 Factors Affecting the Coding Process

Acquisition and retention of information are determined in part by the circumstances surrounding the initial experience. It is these factors that are classified as the variables affecting encoding. Understanding the effects of these variables is complicated by the fact that criterion performance is affected not only by the coding process but also by the circumstances surrounding the test. Among the major advances in the study of learning and memory is the widespread appreciation for the relativity of the effect of both study conditions and test conditions, each of which constrains the other. Thus, the effect of encoding variables on later performance is relative to the nature of the test. Consequently, in contrast to earlier conceptualizations of learning and memory, we no longer make absolute statements about the general effect of acquisition variables. Nonetheless, the study of factors constituting the encoding environment continues to be a focal area of memory research. In this section, some of that research and its allied phenomena are described.

2.07.3.1 Intent to Remember

Intuitively, intent to remember emerges as a dominant factor affecting later memory, but research on encoding processes has shown that intuition unequivocally to be wrong (e.g., Postman, 1964; Hyde and Jenkins, 1969; Craik and Lockhart, 1972; Challis

et al., 1996). As we shall see, what does matter is the type of processing performed on the material, but trying to remember does not ensure that optimal processing will be engaged. **Figure 3** depicts the results reported by Hyde and Jenkins (1969). Subjects were asked to determine the words' pleasantness, check all of the 'e's in the word, or count the vowels in each word. For three groups of subjects, the orienting tasks were given as incidental memory instructions, and for another three groups the orienting tasks were accompanied by instructions to try to remember the words. As can be seen in **Figure 3**, adding intentional instructions improved performance in the nonsemantic orienting groups but had no effect on the performance following the pleasantness rating task. It is not the intent to remember but, rather, the nature of the processing that is important.

Indeed, an enduring contribution of levels of processing (Craik and Lockhart, 1972) is the acceptance of memory as a by-product of the processes of perception and comprehension of the original experience rather than as the intentional object of processing. After all, how many times during the course of the day does one try to remember, and yet healthy adults can remember most everything that happened yesterday. Furthermore, only occasionally do we know what, if anything, about current experience will be required from memory, rendering intent to remember any part of the experience a gamble against future demands. In light of these considerations, the lack of direct effects of intentional memory is understandable.

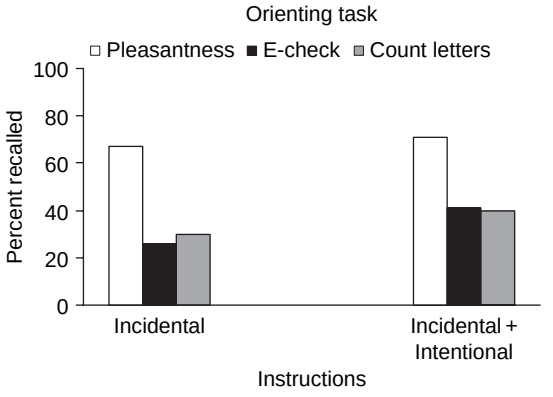

Figure 3 Memory as a function of type of orienting task and intention to remember at study. Adapted from Hyde TS and Jenkins JJ (1969) Differential effects of incidental tasks on the organization of recall of a list of highly associated words. *J. Exp. Psychol.* 82: 472–481.

2.07.3.2 Attention

Coding processes to memory are influenced substantially by both quantitative and qualitative aspects of attention. Qualitative aspects of attentional processing are inferred from the effects of selective attention on memory, and those effects are encompassed by levels of processing. In addition to the effects of selective attention, evidence indicates powerful effects of the amount of attention devoted to encoding. Dividing attention between processing a to-be-remembered event and another activity at encoding comes at a cost to both.

Seminal projects by Baddelely et al. (1984) and Craik et al. (1996) both found that memory was affected negatively by dividing attention at the time of study and also that performance on the secondary task used to divide attention was negatively affected. This research clearly shows that coding processes require attentional capacity. More recent reports (e.g., Fernandes and Moscovitch, 2000; Naveh-Benjamin et al., 2005) have substantiated the earlier conclusion, rendering as apparent the fact that optimal memory for a prior experience requires allocation of conscious processing to that experience. This conclusion only applies to memory tests in which the individual intends to remember, an important example of the caution urged about conclusions concerning encoding without consideration of the retrieval context.

2.07.3.3 Types of Processing

Beginning with Hyde and Jenkins (1969), it became increasingly apparent that memory could be influenced powerfully by asking subjects to perform tasks that focused attention on various aspects or dimensions of the to-be-remembered material. Hyde and Jenkins concluded that the effect of these tasks can be attributed to the "nature of the stored trace" (1969, p. 480). As research intensified, the characteristic of the trace that determined performance took center stage. Hyde and Jenkins had contrasted tasks that required subjects to rate the pleasantness of words, to count the number of 'e's in the words, or to estimate the number of letters in the words. The pleasantness rating task invariably produced better recall, and in contrasting the three tasks, Hyde and Jenkins speculated that the difference lay in the fact that the pleasantness rating task required the words to be treated as meaningful units. This idea would be refined and elaborated by Craik and Lockhart (1972) in one of the most influential papers in the coding literature.

2.07.3.3.1 Levels of processing

Beginning with Estes's (1959) stimulus sampling theory, the notion that objects and events can be conceptualized as multidimensional has been routinely adopted in memory research. Encoding processes function to analyze experience along its various dimensions and select values on those dimensions to represent an experience in memory. The code can be described as the set of these values or features, or alternatively, at a more macro level, the code can be identified with a broad dimension (e.g., phonetic code). Research such as that of Hyde and Jenkins (1969) suggested that encoding semantic features yielded better memory for the event than encoding orthographic features, and Craik and Lockhart (1972) systematized findings such as these with their idea of levels of processing. The idea itself will be discussed later, but the empirical work surrounding the idea uncovered a powerful factor affecting the coding process.

The idea of levels of processing was simple, and the experimental paradigm that it fostered was easily implemented and produced huge effects, factors responsible for dozens of published papers demonstrating the basic effect in the wake of Craik and Lockhart's paper (Watkins, 2002). The effect originally reported by Hyde and Jenkins is that semantic encoding produces superior memory, but the research expanded the characterization to a broad dichotomy between semantic and nonsemantic encoding. The superiority of semantic encoding was demonstrated not only for memory for lists of words, but also for higher-order language constructions (e.g., Perfetti, 1979), and even faces (e.g., Bower and Karlin, 1974). **Figure 4** represents the results of Bower and Karlin's study, in which subjects studied faces by judging their honesty, likableness, or gender. Subsequent recognition memory for the faces was much more accurate following judgments of honesty and likableness. In the wake of the immense volume of literature provoked by levels of processing, one marvels that the basic effect of superior memory following semantic processing remains unexplained (Roediger and Gallo, 2002).

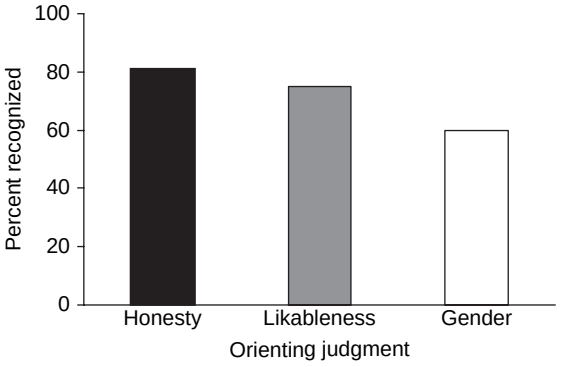

Figure 4 Recognition of faces as a function of judging honesty, likeableness, or gender when studying the faces. Adapted from Bower GH and Karlin MB (1974) Depth of processing of pictures, faces, and recognition memory. *J. Exp. Psychol.* 103: 121–156.

2.07.3.3.2 Self-generation

Slamecka and Graf (1978) convincingly showed that memory for self-generated material is better than memory for externally provided material. This generation effect is operationally distinct from levels of processing in that the generation paradigm requires subjects to generate a word in the presence of highly constraining cues. For example, subjects may be told to generate antonyms of cue words that also fit the letter fragment (e.g., 'hot–c__d'). Other subjects either hear or see lists of the same word pairs and are asked to remember the second member of each pair. Other things being equal, the generated items are much better remembered than the externally provided items.

Similar to levels of processing, generation effects have no consensually agreed upon explanation, and little empirical work currently is devoted to this problem. Nonetheless, generation is a powerful encoding factor. Just how powerful is nicely illustrated in a study by Slamecka and Fevreiski (1983). They arranged a generation list that would yield tip-of-the-tongue states. Subjects were asked to generate words in response to dictionary definitions, and sometimes subjects could not generate the word but would report feeling that they knew that word. The control condition read the definitions followed by the word. **Figure 5** depicts the remarkable outcome, which was that the words that were not generated but were on the tip of the tongue were recalled better that the same word when it had been read.

The generation effect is limited to meaningful material; no generation advantage in memory occurs with meaningless material (Graf, 1980; McElroy and Slamecka, 1982), suggesting a possible connection between the psychological processes mediating generation and levels of processing effects. The generation effect also was eliminated in a study by Donaldson and Bass (1980), in which the subjects in the nongenerate condition were required to judge the quality of the relationship between the cue word and the target. The effect of this manipulation was to

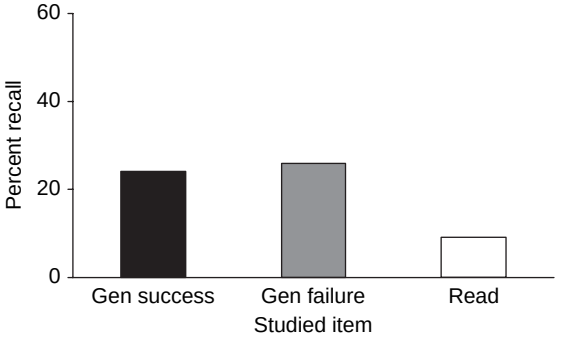

Figure 5 Correct recall as a function of successfully generating, trying but failing to generate, or reading the word at study. Adapted from Slamecka NJ and Fevreiski J (1983) The generation effect when generation fails. *Journal of Verbal Learning and Verbal Behavior* 22: 153–163.

elevate performance in the nongenerate group to the level of the generate group, suggesting that the effect is a result of the attentional focus required by generation.

Begg and his colleagues have made a similar argument based on the premise that the generation effect was the result of impoverished processing of nongenerated items. Begg et al. (1991) demonstrated that generated and read items are equally well remembered if the quality of the processing of the items is equated. For example, if both the generation and read condition are asked to construct images of the words, no difference appears in memory as a function of generation. If both conditions are asked to pronounce the words, the generation condition now shows an advantage in memory. The interpretation of these data entails an important applied message about memory coding; namely, generation requires discriminative encoding processes that transfer to later memory demands, whereas perceptual processing of incoming information may or may not attract beneficial discriminative encoding.

2.07.3.3.3 Organizational processing

Levels of processing and generation research largely have studied memory for unrelated words and have produced descriptions of item-specific coding processes. However, coding of relationships among items has long been known to be important to memory (e.g., Katona, 1940). The modern era of research on organizational coding was launched by Miller's (1956) proposal that discrete elements could be coded into higher-order chunks for storage in short-term memory. The function of such coding was to increase storage capacity by increasing the amount of information in the stored unit. Tulving (1962) later emphasized enhanced retrieval efficiency as the functionally significant impact of organization.

The most straightforward evidence for the importance of organizational processing is found in studies of memory for materials that contain known relationships. For example, word lists consisting of exemplars of known categories are better remembered than random lists, and categorized lists are better remembered when the category exemplars are presented contiguously than when they are presented in random order (Bousfield, 1953; Mathews, 1954). That an active coding process intervenes between list presentation and recall can be inferred from the fact that recall of randomly presented categorized lists tends to come out organized by category. Further evidence of active organization comes from Tulving's (1962) demonstration of subjective organization. Here multiple study-test trials occur for an unrelated list of words, which is presented in a different order on each study trial. Over the trials, a stable output ordering tends to develop – an ordering that is different from the various input orders and is usually idiosyncratic across subjects. The importance of organizational coding to memory has been argued from the almost perfect correlations Tulving found between his measure of organization and free recall.

The dependence of memory on organizational processing also is evident from the phenomena of whole-to-part and part-to-whole negative transfer. Tulving (1966) demonstrated that when subjects learn an initial list to criterion and then are given a second list to learn, half of which comprises the first list items, learning of the second list is impaired relative to a condition that learns an unrelated first list. Similar negative transfer was reported by Tulving and Osler (1967) when the second list consisted of half of the items from the first list. Tulving (1968) suggested that these data indicate the importance of organizational encoding to learning, in that the organization of the first list items interferes with learning (active organization) of the second list. This interpretation subsequently was supported by data showing that positive transfer could be arranged from list 1 to list 2 if list 1 organization is appropriate to list 2 learning (Bower and Lesgold, 1969; Ornstein, 1970).

2.07.3.3.4 Distinctive processing

Laboratory studies promoting the importance of distinctiveness to retention have been reported for over 100 years (e.g., Calkins, 1894), research that parallels the intuition about the memorability of distinctive

events. Despite, or perhaps because of, the intuitive appeal of distinctiveness as a factor at encoding, some confusion surrounds the meaning of the concept of distinctiveness (Hunt, 2006). The most common usage has distinctiveness as a property of events, as in the polka-dot Volkswagen in the funeral procession. In this view, distinctiveness is a property of events, and as such, distinctiveness cannot be explained by appeal to distinctiveness for obvious reasons of circularity. Rather, the standard approach has been to appeal to processes at encoding that entailed a subjective experience, usually of surprise or salience (Green, 1956), which in turn garnered attention in the form of additional processing of the distinctive event (Jenkins and Postman, 1948). In this view, distinctiveness has a quantitative effect on the encoding process.

Interestingly, the standard account of distinctiveness cannot explain the data from von Restorff's (1933) classic paper, which is peculiar because the standard account has been developed largely from data on the isolation effect. The isolation effect refers to enhanced memory for a target item that differs from the other items in the context, which themselves are similar on some dimension. The isolation effect refers to superior memory for the isolated item compared with memory for the same item, in the same serial position of a nonisolated control list. The items of the control list can be either all similar on some dimension or all different. The isolation list conforms to intuitions about what constitutes a distinctive event in that the target item violates the prevailing context. von Restorff was not the first person to use an isolation paradigm, but she was the first person to place the target item early in the list. Her reasoning was that at the early serial position, no context for the list has been established, and the isolate will not be perceived as salient. Nonetheless, the early isolate was better remembered than the corresponding control item. von Restorff's data pose a problem for the standard interpretation of distinctiveness as extraordinary processing attracted by the salience of isolate.

An alternative approach to distinctiveness began as an effort to integrate levels of processing and organization. Humphreys (1976) made the case that optimal encoding of an experience would include both the relationship among the elements comprising the experience as well as information about the elements themselves. Einstein and Hunt (1980) and Hunt and Einstein (1981) were able to demonstrate that the combined effects of organizational encoding and item-specific encoding led to better memory than either alone. Hunt and McDaniel (1993) suggested that the combination of relational and item-specific processing constitutes distinctive processing, using the argument that relational processing refers to processing of dimensions common to all items of an event, and item-specific processing refers to processing of properties of individual items not shared by other items in the event. The combination of relational and item-specific processing then precisely specifies a particular prior item, a description that captures the important discriminative function of distinctive processing. In this view, distinctive processing at encoding is defined as the processing of difference (item-specific properties) in the context of similarity (relational information). Nairne (2006) also has developed ideas about distinctiveness and memory that treat distinctiveness as a psychological phenomenon rather than as a property of events. Nairne's approach defines distinctiveness as the extent to which a particular cue complex specifies a particular event. As with the combination of item-specific and relational processing, Nairne's theory attributes the benefit of distinctive processing to the development of diagnostic information used in retrieval, rather than to quantitative differences in coding processes as specified by the standard treatment of distinctiveness. (For a more extensive discussion of distinctiveness, *See* Chapter 2.09.)

2.07.3.4 Prior Knowledge

Experience within a domain enhances memory for new events within the experienced domain. The more you know about something, the more likely it is that you will remember new information about something (Kimball and Holyoak, 2000). Moreover, this effect is presumed to be largely the result of encoding processes. One line of research leading to this conclusion is the study of experts' memory. Chase and Simon (1973) compared the memory of master chess players with that of novices for various arrangements of pieces on a chessboard. In some cases, the pieces occupied the positions of actual games in play, and in other cases the pieces were randomly arranged on the board. After briefly viewing the board, the subjects were asked to reproduce what they had seen. The experts remembered more than the novices when the boards were based on actual games, but when the pieces were randomly presented, memory was no longer affected by differences in prior knowledge. The superior memory of the experts was explained as the use of prior

knowledge to organize the encoding of a new experience. The experts' advantage disappears outside the domain of expertise, such as with the random arrangement of chess pieces. The results described here for chess apply to other domains, such as bridge, music, medicine, and computer programming (see Ericsson and Lehman, 1996, for a review).

Without disputing the contribution of organizational encoding, evidence has been offered to show that prior knowledge also increases the likelihood of distinctive encoding. Van Overschelde et al. (2005) asked people to remember a list of names of college and professional football (American-style) teams. The list consisted of 10 teams' names. In one case, nine of the teams were professional, and one was a college team, whereas in the other case, all 10 teams were college teams. The lists thus comprised an isolation paradigm. Typically, the isolated item is better remembered than the corresponding item in the all-similar list, an effect attributed to distinctive processing of the target item in the isolation list. Van Overschelde et al. selected people for their experiment who were either knowledgeable about football or not. The result was that the experts recalled the critical item better when it appeared in the isolation list than in the control list, but no isolation effect occurred for the nonexperts. This result suggests that experts encode not only the similarity among items within their domain of expertise but also the differences among these items. That is, prior knowledge seems to influence not only organizational encoding but also distinctive processing.

2.07.4 Characterizations of the Code

A final science of memory will know the neural code for prior experience and have a set of mapping rules to relate that code to the psychological states of memory. Until we reach that final stage, psychological concepts of memory codes will guide our thinking about phenomena of learning and memory. The specific nature of stored information has been characterized in virtually countless ways (e.g., traces, engrams, nodes, images, processes, features, vectors of features, production rules, or logogens). A particular characterization of codes often is driven by the phenomenon under study. For example, research into the effects of learning and memory in problem solving and skill learning often uses a production rule as the code (e.g., Anderson, 1983). What is learned and stored in memory is characterized as an if–then statement in the form of condition–action sequences. This characterization is descriptive of skilled performance in the domain of problem solving in that successful problem solving entails producing a particular action in a particular circumstance. Proposals for particular codes also result from the processing requirements of a theory in which the code is embedded. For example, Neisser's (1967) pioneering theory of pattern recognition proposed that the first step of the recognition process was the analysis of the sensory pattern into units that are stored in long-term memory. These units essentially serve as the data on which processes operate, much as real numbers serve as the database for arithmetic operations. The units used by Neisser were features – a concept that continues to have broad appeal.

Among the myriad descriptions of the memory code, one can detect two general issues that distinguish classes of codes. One of these issues is whether the code should be characterized as structure or process. The structural metaphor perhaps is the more common and more intuitive conceptualization. Here the memory code is a residual, often called the trace, of the prior experience, which is stored in a memory system. The alternative metaphor is that of skill. Here the memory code is represented as a mental process. The skill metaphor is very different from the structural metaphor in that processes are not stored; just as skills are nowhere when you are performing them, memory is nowhere when you are not remembering. These different metaphors lead to interesting differences in memory research, including that on coding, and we examine briefly some of the principle representatives of the two metaphors.

The second general issue concerns the existence of abstract codes; that is, codes for prior experience that are not bound by a particular prior context. The existence of abstract codes has been championed by philosophers as the product of rational thought since at least the time of Plato, and no one seriously studying cognitive processes questioned the reality of abstract codes until quite recently. To some extent, the positions on the abstraction issue are correlated with the first general issue, with the structural metaphor being more compatible with the notion of abstract representations; however, the correlation is not perfect.

2.07.4.1 The Structural Metaphor

Structural analysis of the mind evolved from two important but very different models. The first is

exemplified by Titchener's (1898) admirably clear statement of structuralism, in which of the goal of psychology was modeled on morphology in biology. According to Titchener, the job of the experimental psychologist was to perform "vivisection of the mind which shall yield structural results" (p. 450). The parts of the mind would be revealed by this analysis in much the same way that parts of the body are revealed by morphological analysis. It is precisely this kind of thinking that leads to research attempting to determine the constituents of the memory code that was described earlier.

The second model influencing modern structuralism is the computer. Application of the computer model to human cognition allowed a distinction between structural components and control processes that modeled the distinction between programming commands that are fixed and commands that are contingent on the content. Atkinson and Shiffrin's (1968) theory proposed that certain psychological processes are voluntary (control processes) and that certain structural components of information processing are fixed. The fixed components were memory systems, which are defined in part by the kind of code stored. Thus, coding processes are intimately bound to particular memory systems within a structural analysis. Different structural analyses yield different kinds of codes, as we see in the following discussion.

2.07.4.1.1 Stage theory of information processing

Atkinson and Shiffrin's theory exemplifies the stage analysis of the mind that characterized the halcyon days of information processing. Learning was a matter of transporting information from sensory reception to storage in long-term memory. The trip occurred in three stages. Each stage was a memory storage system, and each system required a different code.

The first stage of processing was the sensory memory store, which theoretically held codes in the form of raw sensory information. Groundbreaking work by Sperling (1960) provided evidence for the existence of a very short-lived memory that contained no meaning, characteristics that fit perfectly with a sensory code. Sperling's work on the visual store was complemented by Darwin et al.'s (1972) report of data suggesting the existence of an auditory store that holds acoustic sensory codes.

The second stage of processing culminated in storage in short-term memory. An important part of the processing was the recoding of the sensory information to its corresponding phonetic form. Evidence for a phonetic code in short-term memory was derived from studies showing interference in memory for short lists of words as a function of phonetic similarity (e.g., Baddeley, 1966). The argument that the code for short-term memory is the sound pattern of the material fit neatly with the importance assigned to rehearsal. That is, rehearsal typically is assumed to be a verbal process, and verbal processes require speech codes.

The final stage of processing was the transfer of information from short-term to long-term memory. Rehearsal was assumed to be the important mechanism of transfer, by which the phonetic code was recoded into its corresponding semantic representation. Again, the evidence for a semantic code in long-term memory was derived from studies showing that semantic similarity interfered with performance on tests of long-term memory (e.g., Baddeley, 1966).

Thus, the stage theory assumed that information processing is characterized in part by coding processes that recoded the information from a previous stage to a form appropriate for storage in the higher stage. In the strongest statement of the theory, the form of the code was assumed to be a structural component, which means that the code has to be in the specified form if the information is stored in the particular system. That is, nothing but a phonetic trace can be stored in short-term memory. Consequently, it is not surprising that research showing that the code in short-term memory could be visual (e.g., Posner, 1969), or even semantic (e.g., Shulman, 1974), raised concern about the stage model. One reaction to the theoretically incongruent data was to revise the model of short-term memory in light of the new evidence on the nature of the code.

2.07.4.1.2 Working memory

The concept of working memory emerged as a revised description of short-term memory (Baddeley and Hitch, 1974) in the wake of the stage model's failure. Working memory is different from the stage model in several dimensions, the most important of which for us is the question of coding. Rather than assume a single store containing a phonetic code, working memory's structure includes three separate storage structures to accommodate three different codes. The structure of working memory includes a phonological loop that stores a phonetic code, a visuospatial sketchpad that stores a visual code, and an

episodic buffer that stores semantic codes (Baddeley, 2000).

Evidence for the independence of the storage systems and their structurally bound codes was inferred from studies of interference. For example, the existence of a phonetic code has been inferred from the interference produced by the phonetic similarity effect (Baddeley, 1966), but this effect can be eliminated under certain circumstances. If the word lists are presented visually and the subject is required to repeat the word 'the' as rapidly as possible during list presentation, phonetically similar lists are remembered just as well as control lists. If, however, presentation of the lists is auditory, the phonetic similarity effect does occur; that is, the phonetically similar list is more poorly remembered than the control list. These data and their interpretation are drawn from Baddeley et al. (1984), who argued that auditory input gains obligatory access to the phonological loop but that visual input requires recoding to a phonetic form. This recoding is performed by the articulatory control process, but that process also is responsible for the production of speech. Thus, rapidly repeating the word 'the' during visual presentation of the list prevents phonetic recoding and storage in the phonological loop. As a consequence, the visual presentation accompanied by interference does not yield a phonetic similarity effect because the words are never coded phonetically.

The existence of a visual-spatial code has been adduced from analogous experiments that involve visual presentation of material accompanied by visual secondary tasks (e.g., Baddeley et al., 1973). In addition, neuroimaging research has offered support for the independent existence of a short-term visuospatial system of the sort proposed by working memory (Smith and Jonides, 1999). The episodic buffer has received little research attention, and at this time no evidence is available concerning the hypothesized code for that system.

The theory of working memory continues to be developed and has provoked a good deal of research, much of it related to the nature of codes in short-term memory. The theory has nothing to say about codes stored in long-term memory, and for the structural view of long-term memory, we turn to the memory systems approach.

2.07.4.1.3 Memory systems

The paragon of modern structuralism in cognitive psychology is the idea generally known as the memory systems approach. Essentially the approach advocates the existence of multiple memory systems in both short- and long-term memory and sets a research agenda of discovering the systems and delineating subsystems. A variety of classification schemes have been proposed, and the one described here is that of Schacter and Tulving (1994; Schacter et al., 2000). Schacter and Tulving outlined a list of defining features for a system that includes the operating rules, the neuroanatomical location of the system, and the type of information stored in the system. The later characteristic is the one of interest to us.

In 1972, Tulving proposed a distinction between what he called semantic memory and episodic memory. Semantic memory stores context-free information that corresponds to knowledge. For example, semantic memory contains information such as 'St. Louis is in Missouri, tomatoes are fruit, Dick Cheney shoots at birds.' These representations are abstract in the sense that the information coded in semantic memory is not constrained by time or space. In contrast, episodic memory stores information bound by its spatial and/or temporal context. For example, episodic memory contains information such as 'I went to the pharmacy yesterday, my wife and I saw Spamalot last Friday, I was told yesterday that John does not like tequila.' Note that the information in episodic memory has a personal as well as a temporal and/or spatial reference. The information stored in episodic memory corresponds to what we normally take to be memory rather than knowledge.

Since Tulving's original proposal, additional memory systems with their associated codes have been discovered. One is the procedural system that contains representations of cognitive and motor skills. These codes are similar to the codes in semantic memory in that they are abstract but differ from semantic memory in the kind of content. The code for the procedural memory literally is the representation of how to do something, like tie your shoes. The procedural code is not readily recoded verbally (try describing how to tie a shoe without using your hands), which is very different from the code in semantic memory. Another recently proposed system is the perceptual representation system. This system contains codes representing the visual and the auditory form of words. For example, the visual form 'cat' is stored in the perceptual representation system as well as a separate code representing the sound of that visual pattern. As with the semantic and procedural codes, the codes in the perceptual representation system do not contain contextually defining information. Unlike those two systems, the perceptual

representation is just that, viz., the modality-specific representation of a word or object. Finally, working memory also is included as one of the components of the system.

2.07.4.2 Summary of Structural Approaches

Memory codes are fundamental to the structural view of the mind in that a defining feature of any theoretical structure is the kind of code it contains. That is, the type code is one of the inherent characteristics of a system, just as skin is an inherent characteristic of mammals. The combination of system and characteristic code then is used as the principal explanation for performance. For example, consider the following situation: Subjects are asked remember a small amount of material but are prevented from rehearsing that material after its presentation and then tested within 30 s of the presentation. Memory for the material will be surprisingly poor (e.g., Peterson and Peterson, 1959). One explanation is that the test drew on short-term memory, which contains a limited duration trace, an aspect of the code contained in short-term memory. As with all metaphors used in science, the structural metaphor not only serves to explain performance but also molds the form of research. Under the structural umbrella, a prominent and respectable research activity is that of identifying and classifying the nature of codes. Thus, much of the research provoked by any of the previously mentioned structural views will be devoted to a description of the memory code. In this function, the structural notion of a memory code has been invaluable for cognitive neuroscience. As mentioned previously, most of the cognitive neuroscience of memory is devoted to identifying brain sites associated with memory phenomena – sites that then are taken to be the brain codes for the prior experience.

2.07.4.3 Process Metaphor

A very different characterization of memory in general and coding in particular arises if mental functioning is assumed to be analogous to a process or skill. The idea is that memory performance is determined by the mental processes operating at the time of an experience rather than by where the memory trace is stored. Craik and Lockhart's (1972) framework, levels of processing, was the seminal impetus for the processing metaphor, and in 1993 it was declared the most successful theory of learning and memory in the previous 25 years (Roediger, 1993). According to its authors, levels of processing "suggested that the memory trace could be thought of simply as the record of those analyses that had been carried out primarily for the purposes of perception and comprehension and that deeper, more semantic analyses yielded records that were more durable" (Lockhart and Craik, 1990, p. 88). Thus, levels of processing assume that the coding process focuses on either the meaning of an event or on nonsemantic properties, such as visual or phonetic features of the event. Attention to semantic features is considered deeper processing, and research has shown time and again that all other things being equal, semantic processing leads to better retention.

The gradual discovery of boundary conditions to semantic processing superiority has led to revisions to the original idea, wherein the central role of depth has been replaced by concepts such as elaborative processing (Craik and Tulving, 1975), distinctive processing (Jacoby and Craik, 1979), and sensory-semantic processing (Nelson, 1979), but the effect of Craik and Lockhart's thinking is manifested in the assumptions these revisions all share with the original view. Chief among these is that coding processes yield a memory trace consisting of qualitative features representing the event. Certain types of traces are more beneficial for retention than others; which type varies with the theorist, but in all cases memory is determined by the qualitative nature of the code. The qualitative nature of the trace is determined by the encoding processes, not by where the trace is stored, as is assumed by most structural theories.

In close temporal and spatial contiguity to Craik and Lockhart's work, a more radical version of the process metaphor began its development with Kolers' (1973) work.

In accord with levels of processing, memory systems played no role in the explanation of performance, but in addition, memory traces of the sort used by structural theories and by levels of processing were shed. The important role of memory traces as conceptual bridges between the past and present was assigned to the psychology processes brought to bear on the current event: The analytic operation of coding the experience becomes what is remembered. The implications of this shift for the concept of coding are far-reaching, as is evident in the following quotation from Kolers (1979):

> On the present view, every encounter with a stimulus elicits a different analysis from every other. . . . In other words, recognition is achieved by virtue of the correlation between the operations carried out on the two encounters with the stimulus event. The more similar the operations, the readier the recognition. But as nothing ever repeats itself exactly, recognition is based on the transfer of skills across occasions and partial correlation. *If the operations that are activated are themselves the record of the stimulus, then as the operations change, the representation of the stimulus also changes; there is no permanent trace of an object, nor even a fixed trace, but skill-developed and occasion-dependent representations.* (p. 383, italics added)

The position expressed here eventually would be known as proceduralism (Kolers and Roediger, 1984). The basic tenet of coding in proceduralism is that the code is the set of psychological processes engaged for perception and comprehension of an event. Levels of processing, in contrast, assumed that these processes produced a trace or code, which was stored in memory. Proceduralism adheres to a much stricter use of the skill metaphor, whereby there is no stored trace or code. After all, where is your typing skill when you are not typing or your adding skills when you are not adding? Rather than assuming a stored trace, the connection between the past and present in proceduralism is represented by the similarity of the psychological processes engaged by the present event to some operations engaged in the past. The more similarity between the two sets of processes, the greater will be the transfer. The metric of similarity includes the modality through which the events are experienced on the reasonable premise that the psychological processes of vision and audition, for example, are different. Thus, one can see that the code for a given event is quite particular and tightly bound by the processing context.

As counterintuitive as the idea is for our intuitions about memory, Kolers (e.g., 1974) offered programmatic evidence for the approach that was sufficiently persuasive to produce important progeny in cognitive psychology. Most notable of these in memory are Roediger's ideas about data-driven and conceptually driven processing and Jacoby's process dissociation theory, both of which take proceduralism's assumptions about coding as foundational.

2.07.4.3.1 Data-driven and conceptually driven processing

The distinction between data-driven and conceptually driven processing emerged as an explanation for dissociations in performance on different types of memory tests. Roediger et al. (1989) argued that these dissociations reflect differences in the processing demands of differences between study/test conditions. The basic assumption is that a particular type of prior processing may be more effective for one type of test than for another. An important example for the development of the data-driven/conceptually driven distinction is the previously discussed research of Jacoby (1983). As a brief reminder, Jacoby asked people to study words under different conditions. In one condition, the words were read without any context. In another condition, the words were generated by the subjects in the context of semantic clues. On a later recognition test, the people who generated the items at study performed better than those who read them – the standard generation effect. However, if the test was to identify visually degraded words, previous reading of the word led to better identification than did previous generation.

Roediger et al. (1989) used Jacoby's (1983) work as the basis for distinguishing the coding of meaning (conceptually driven processing) and the coding of perceptual features (data-driven processing). The dichotomy between semantic and sensory-based codes is not new to our discussion, having been an important component of the stage model, the memory systems, and levels of processing. What is different is that Roediger et al. couched the distinction in processing language. The code for meaning is the psychological processes engaged to analyze the event, and the effect of this prior processing will be revealed only in future circumstances demanding similar analysis of the event. The code created by generating the word 'cat' will not facilitate future demands to read the word 'cat'. In that sense, one can appreciate Kolers' previous quotation to the effect that as the operations change, the representation of the event changes.

The distinction between data-driven and conceptually driven coding has been a powerful stimulant for research and has served an impressive role in classification and organization of memory tests (e.g., Blaxton, 1989; Rajaram and Roediger, 1993). Situations have arisen, however, that resist clean dichotomizing into data-driven and conceptually driven processing. A very simple example is the standard recognition memory test, in which one must process the test item perceptually before a decision concerning its status can be reached. On the face of it, this situation seems to require both

data-driven and conceptually driven processing. The authors of the idea recognized this implication early on: "Tests may involve both types of processes. Indeed, a more useful assumption is to describe two continua, one for each type of processing, to acknowledge that these two modes of processing can be varied orthogonally" (Srinivas and Roediger, 1990, p. 390). The interesting point for our discussion of coding is the realization that characterizations of the trace for an event as exclusively perceptual or conceptual, the very assumption that caused trouble for the stage model, are too simplistic. Advocates of the data-driven/conceptually driven view avoid that mistake by assuming that the code will include both types of information in most all cases.

2.07.4.3.2 Process dissociation theory

Another descendant of Kolerian proceduralism is the process dissociation framework (Jacoby, 1991). Like the memory systems and data-driven/conceptually driven ideas, Jacoby's theory was motivated largely by the challenge of understanding test dissociations. Unlike the other approaches, process dissociation explicitly disavows any effort to identify processes, codes, or systems on the basis of the type of task. Both the memory systems and the data-driven/conceptually driven schemes use the task confronting the subject to identify the type of code that will be required by that task. As research began to discover violations of the prescribed system- or process-task relationship, both the systems and the data-driven/conceptually driven approaches moved to a middle ground: the code for any given event is likely to be mixed. The same data suggested to Jacoby (1991) that these approaches cannot succeed in explaining memory phenomena. The reason is that the explanatory (predictive) power of either approach rests heavily on the ability to identify the theory-specified code representing an event. The primary means for doing so is to assume a code-task purity (i.e., a particular kind of task will recruit a particular kind of code). At best, the inability to identify task-pure codes robs these approaches of some of their precision.

Jacoby's alternative is to specify the nature of the processes as *a priori* rather than identify the operative processes on the basis of task performance. The details of the theory accomplishing this specification are beyond the purview of this chapter, but the assumption about the nature of the code is pure Kolerian proceduralism. Psychological processes are brought to bear on tasks with which we are confronted. These processes vary not only with task demands but also with both external and internal contexts, intent being an important component of the later. In this view, precisely the same process (a.k.a., code) is unlikely to be repeated, a position identical to that expressed in the italicized portion of the quotation from Kolers listed earlier. Consequently, every memory has a unique code in that no two situations engage identical psychological processes.

2.07.4.4 Summary of Process Metaphor

One can conceptualize cognitive activities including learning and memory as analogous to motor skills. Just as particular motor tasks require particular motor processes, so do particular cognitive tasks engage particular processes. In both cases, performance on a task is determined by prior processing as it is related to the task. That is, the effect of prior processing can be either positive or negative. For example, my racquetball game improves with racquetball practice, but my squash game deteriorates as I practice racquetball. The same is true of cognitive tasks. Although it may be that the structural metaphor can encompass all of the memory phenomena marshaled by the process camp, the differences in the metaphors are important influences on research. Three implications of the process metaphor are quite different from anything derived from structural thinking.

Perhaps the least intuitive of these implications is that the influence of the past is not carried by a permanently existing code stored in the system. If learning and memory are thought of as processes, then like typing, or for that matter digestion, memory is nowhere when you are not remembering. Within the process metaphor, the function of the memory code is assigned to transient psychological processes, and research focused on the overlap of processes from one task to another is essentially the process approach to studying the code. However, the vast amount of research sponsored by the structural metaphor aimed at describing memory systems would never occur under the auspices of a process metaphor.

A second and only slightly less counterintuitive implication of proceduralism is that abstract codes of the kind traditionally associated with knowledge do not exist. Take, for example, the following information: George Washington was the first president of the United States. An abstract code for this

information would be stripped of any contextually specific aspects of prior experience with the information, such as when, where, or through what modality the experience occurred. If, however, we adopt a proceduralist's definition (i.e., the code representing an experience is the set of operations that yielded that experience), no representation would be free of context-specific content. The operations producing the experience include those sensory–perceptual processes associated with the modality of processing, and in most cases, it is reasonable to assume that other aspects of the context would influence the encoding operations. The implied lack of an abstract code poses a challenge for proceduralist's accounts of learning and use of concepts, where a concept traditionally is assumed to be distilled from, but not identical to, any particular prior experience. The difference between the abstractionist's and the proceduralist's positions is the venerable difference between rational and empirical knowledge, and it is exciting to see empirical work emerging on this important epistemological issue (e.g., Whittlesea et al., 1994; Heit and Barsalou, 1996; Hannah and Brooks, 2006).

A third implication of the process metaphor extends beyond the issue of coding and is of general importance to conceptualization of cognition. In two different senses, proceduralism is integrative, whereas structuralism leads to modularity. The first sense of integration is that proceduralism need not distinguish various cognitive processes (e.g., perception, memory, reasoning) except on operational grounds for clarity of communication. The aforementioned principles of proceduralism apply regardless of the operational classification of the process, rendering distinctions between such concepts as memory and reasoning unnecessary. The second dimension along which proceduralism is integrative is mind–body dualism. Crowder made this important point by noting that many theories explicitly distinguish between perception and cognition, which he suggests is dualism in a different guise because:

> perceptual skills are considered more legitimately bodily processes than the "mental" cognitive functions such as generation, reflection, and creativity. For example, Tulving and Schacter relegate priming to the activity of the perceptual representation system, as distinct from the episodic memory system. (Crowder, 1993, p. 143)

Taking skill as a metaphor for all cognitive processing, perceptual as well as conceptual, removes any boundary between body functions and mental functions.

2.07.5 Summary of Coding Processes

An enormous amount of research has been directed toward understanding coding processes and their resultant memory representations. The reason for the effort is that the memory code is viewed as the concept that carries the effect of prior experience into the present. In that capacity, the memory code will determine the similarity metric among prior events and between prior and current events. This similarity will determine the types of events that will interfere with each other as well as the effectiveness of certain kinds of cues in the retrieval of particular memories.

All the methods that have been used to infer the memory code are of necessity indirect, based on observations of behavior or brain activity, but the descriptions of the codes inferred from these methods point to three main ways in which the coding process operates. Codes can be a select portion of a complex event, in which case the representation is the portion of the event selected for attention. Codes can be a transformation in the form of the input such as the verbal coding of a picture or the organization of discrete units into a whole. Elaboration is a third form of coding, which yields a representation that contains more than was in the literal physical energy of the original experience. The code resulting from elaborative processing reflects the influence of prior knowledge on perception and comprehension of an event.

Placed in proper context, research on memory coding is an indication of the value of psychology in advancing our knowledge about fundamental questions of mental functioning. This chapter began with the assertion that the problem of knowledge, what can people know and how do they come to know it, is the impetus for coding research. The research has yielded a range of descriptions of particular types of codes that are the fodder for systematic theoretical classification. With that theoretical classification lays the promise of resolution to the perennial issues of the nature of knowledge, issues such as that between abstract, universal knowledge versus particular, contextually bound knowledge.

The resolution has not been achieved, but it is exciting to know that research in psychology has such ambitious aims.

2.08 Mental Imagery

C. Cornoldi, R. De Beni, and I. C. Mammarella, University of Padua, Padua, Italy

2.08.1 Introduction to Imagery and Definitions of Mental Imagery

In our everyday life, during interactions with people and with the environment, a crucial role is fulfilled by the ability to maintain and to recall images (i.e., mental representations including perceptual information). Most of the time, mental images are incidentally activated, such as, for example, when we think back to people's faces or certain episodes of our life. Other times, images are easily retrieved to answer particular questions; for example, people can recall and visualize in their mind how many windows there are in their house and the color of the curtains.

Mental images have always fascinated philosophers; in fact, Greek philosophers such as Plato and Aristotle discussed mental images, the latter considering imagery crucial in both cognition and thinking. Aristotle's theory could be considered the antecedent of the modern analogical imagery view, which maintains a close relationship between perception and imagery (e.g., Shepard and Metzler, 1971; Kosslyn, 1980, 1994). In fact, according to Aristotle, a mental image is an inner representation of real objects, like a copy of real-life scenes. Moreover, medieval thinkers like Augustine and Aquinas gave a central position to imagery in their interpretation of psychological processing from sensation to imagination and memory. Similarly, the British empiricists, for example, Berkeley, Hobbes, and Hume, considered mental images as traces of sensory information. As for more recent times, it is only from the 1970s that psychology reconsidered imagery as a central topic of study (i.e., ever since the advent of cognitive psychology). In fact, behaviorists had failed to consider imagery as a serious topic for experimental investigation because it was not directly observable and thus could not be investigated with a completely objective methodology. The cognitive sciences represented a new era for research on imagery processes. Interest toward mental events was once again a central topic in psychology, and different experimental paradigms were applied to the investigation of higher cognitive processes, such as imagery. Individual reports and subjective introspective experiences were considered objects of interest for experimental psychology, and imagery was included as a legitimate topic of investigation.

In the psychological literature, various definitions and theories regarding mental images were put forward, and most of them were influenced by the interdisciplinary interests surrounding this process. According to Holt (1964), a mental image refers to all the subjective awareness experiences within a

sensory modality, which are not only perceptual. Intons-Peterson and McDaniel (1991) affirmed that mental images might be produced by the interaction between visual representation and a subject's knowledge, suggesting that they are knowledge-based products. Carroll (1993, p. 277) defined imagery as "the ability in forming internal mental representations of visual patterns and in using such representations in solving spatial problems" and proposed a relationship between spatial abilities, visual perception, and imagery. Similarly, Richardson (1999) postulated that mental images are complex mental products, inner representations where information on the actual perceptual appearance of objects can be described and transformed.

Mental imagery is a private and a subjective experience because we cannot observe whether other people have a mental image nor directly know its properties. This implies that its scientific investigation depends on verbal reports and on the phenomenal experience of participants (Richardson, 1980). However, psychological investigation has tried to operationalize or give construct validity to the concept of mental image. For example, according to Paivio (1971), a mental image is defined on the basis of three kinds of operations, that is, (a) by variations in stimulus properties (e.g., high vs. low imagery value), (b) by processing instructions (e.g., instructions to imagine vs. instruction to verbalize), and (c) by individual differences in imagery ability. According to Kosslyn (1980, 1994), a mental image is not simply a phenomenal experience, but a form of internal representation in which information about the visual appearance of a physical object can be manipulated: Visual mental images correspond to short-term memory displays, which are generated from more abstract representations in long-term memory (Kosslyn, 1980; Denis and Kosslyn, 1999). However, the methodological difficulties in the study of imagery have affected a recursive debate between imagery theorists (who support an analogical or pictorial position) and propositionalists (who maintain the existence of an amodal representation, e.g., Pylyshyn, 1973).

2.08.1.1 Debate on the Nature of Representations

The contrast between empirical and rational theories on the acquisition and on the representation of knowledge is recurrent in the history of thinking (e.g., Aristotle against Plato, British Empiricists against Descartes in philosophy and propositionalists against imagery theories in psychology). To summarize, the propositionalists affirm that mental images are epiphenomena, having a symbolic-like format, with no sensorial properties and an explicit explanation of the relations between elements (Pylyshyn, 1973, 1981). According to propositionalists, the representations that underlie the experience of mental imagery are similar to those used in language. The second position, upheld by imagery theorists like Kosslyn (1980, 1994), holds that mental imagery representations are able to depict, not describe, objects; they are analogical representations of objects in our mind and correspond to a quasi-perceptual experience, with a specific modality format.

The initial debate focused on behavioral results such as those obtained by Kosslyn et al. (1978). In the original study, participants were required to memorize a map of an island, where a series of landmarks was drawn, then to imagine the map and to pay attention to one place (e.g., the beach). When the experimenter gave the name of a second place (e.g., the tower) participants had to imagine moving from one place to the other and to press a button as soon as they had reached the second place in their mental image of the map. The results of the study revealed that the further away the second place was from the initial place (the beach), the longer it took for participants to give the response. The conclusion of the authors was that mental images have spatial properties.

The critiques made by Pylyshyn (2002) were as follows: It is not clear whether the results revealed a property of the cognitive architecture or a property of what people know or believe about imagery functioning. Pylyshyn (1981) repeated the experiment by showing participants a map with lights going on and off at the target locations; participants were required to imagine when a light was on and to press a button when they could see it at a second place. Results did not reveal correlations between the distance on the imagined map and reaction times. Similarly, Cornoldi et al. (1996a) found that the distance effect is in relationship to the theories people have about imagery functioning. However, differently from Pylyshyn (2002), they concluded that naïve theories do not simply affect responses but also affect imagery retrieval processes (for a complete debate on these paradigms, see Denis and Kosslyn, 1999).

The debate moved into a new phase when neuroimaging began to be used to study brain activation during mental imagery (see for reviews, Cabeza and Nyberg, 2000; Kosslyn et al., 2001). During mental imagery, some functional magnetic resonance

imaging (fMRI) studies showed an activation of topographically mapped brain areas depicting shapes (see Thompson and Kosslyn, 2000). Furthermore, if these areas are damaged, visual imagery is impaired (Kosslyn et al., 1999). A crucial result to reach the conclusion that imagery involves quasi-perceptual experiences would be if the same visual areas were activated when an object is perceived and when it is imagined. Despite a great number of studies carried out to investigate the involvement of primary visual cortex in imagery, the issue is still open, because results are controversial. In a series of positron emission tomography (PET) experiments, Kosslyn and colleagues found an increased blood flow in Brodmann Area 17 (primary visual cortex) during imagery activity (Kosslyn et al., 1993, 1997); however, other studies with fMRI methods suggest that primary visual cortex is not activated during mental imagery (e.g., D'Esposito, 1997; for a review, see Cabeza and Nyberg, 2000).

In a recent research, Kosslyn and coworkers (Slotnick et al., 2005) tried to disambiguate the long-standing debate on the nature of mental imagery representations and found evidence supporting the depictive view of visual mental imagery. In fact, the authors' contrasting imagery and attention retinotopic maps showed that visual mental imagery can evoke topographically organized activity in striate and extra-striate cortex, in accordance with the stringent criterion required for supporting a depictive theory, as mentioned by Pylyshyn (2002).

Alongside the two opposite positions (propositionalists vs. imagery theorists), intermediate models have been proposed. For example, mental images have been considered as being generated from long-term memory information, thus representing an intermediate format between amodal abstract representations and perceptions. The information in long-term memory would be represented in a more abstract format, whereas conscious mental images would acquire a more sensorial format (Marschark and Cornoldi, 1990). In fact, it is possible that short-term visual memories maintain perceptual detail, but during the integration of information in long-term memory, they lose part of their sensorial properties (Cornoldi et al., 1998).

2.08.1.2 Perceptual and Conceptual Representations: Visual Traces and Generated Images

Cornoldi et al. (1998) proposed a distinction between a visual trace, sharing a large number of characteristics with perception, and a generated image, more dependent on conceptual processes but still distinguishable from an amodal representation. In fact, not only the psychological literature but also subjective experience supports a differentiation between a visual memory based on a recent perceptual experience and a generated mental image. In synthesis, a visual trace is directly received from perception while it happens. For example, when we perceive a shape, we try to maintain it in our mind. In contrast, a generated image is derived from long-term memory information as, for example, when we try to activate an image of our previous car. If the first requires a low degree of attentional control to be kept activated, the latter requires a higher degree of control; moreover, the analogy with perception would be almost complete for a visual trace and only partial for a generated image, and a visual trace would be characterized by sensorial and phenomenic properties and a generated image by perceptual–conceptual properties. It must be noted that a visual trace is also different from a perceptual experience and that, even after short time intervals, a visual experience can be affected by long-term memory reconstructive processes and thus approximate the features of a generated image. The well-known experience of the inability to remember well-known patterns (e.g., the shape and colors of a common banknote, see the example of a 20-euro piece in **Figure 1**) is common to mental images but also concerns recent visual traces.

Figure 1 People are not able to accurately remember the visual appearance of objects, even if they are frequently exposed to them.

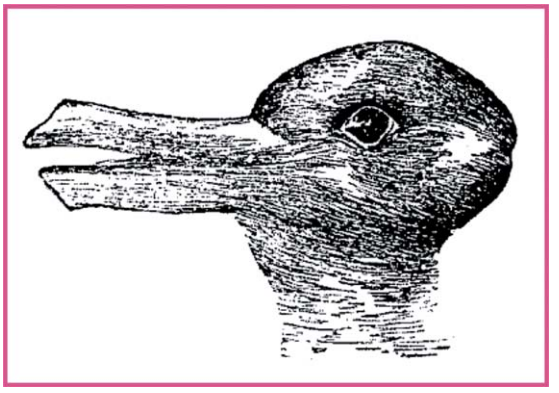

Figure 2 The reversal of a mental image is particularly difficult but can be facilitated by the prevention of verbalization.

The distinction between a visual trace and a generated image can be also used to explain the phenomenon of verbal overshadowing, or the difficulties people meet in the reversal of mental images (Cornoldi et al., 1996b). According to Brandimonte and colleagues (Brandimonte et al., 1992a; Brandimonte and Gerbino, 1993), verbal recoding of visual stimuli occurs almost automatically when pictures are easily nameable; the verbal recoding uses long-term memory knowledge and influences the image of an ambiguous visual stimulus, determining the verbal overshadowing effect. However, if verbalization is prevented, the visual trace still maintains its perceptual properties. If you look at the picture presented in **Figure 2** and then close your eyes, you will explore the experience of a well-established image that cannot be easily reverted. If, for example, a person has in mind the image of a rabbit, that person will have difficulty visualizing a duck, and vice versa.

2.08.2 Different Kinds of Mental Images

Given the fact that mental images are extensively present in human life and respond to different functions, it is not surprising that they appear heterogeneous and may be differentiated. The literature on imagery has proposed a series of taxonomies among different kinds of imagery representations. Richardson (1969), for example, proposed a classification of mental images considering their different properties along the following dimensions: conscious control, phenomenological quality, intentional content, spatial location, and mode. For example, memory images were defined as conscious control phenomena with a quasi-perceptual quality, content related to experience without spatial location and with a potentially amodal format. It is noteworthy that at a higher cognitive level, a distinction can be made between mental images derived from memory and images derived from the imagination. The first refers to all images that we could evoke from memory, such as the image of the Eiffel Tower in Paris. Memory images could differ in vividness, clarity, details, colors, or multisensorial properties. Furthermore, they can be distinguished from fantasy images, created by combining elements stored in memory in new ways, as, for example, in the image of a flying horse. In fact, the creation of integrated images obtained by combining together single images represents a typical mental imagery situation, derived from the classical mnemonic tradition showing that interactive images facilitate the retrieval of an element if the other element is available. **Figure 3** presents an example of interactive image created with the support of fantasy. If the image of a rainbow and the image of a guitar must be integrated in a single interactive image, one could, for example, imagine a natural-looking guitar and a rainbow illuminating it.

The distinction between images from memory and those from the imagination is not rigid because images from memory are not exact reproductions of the equivalent perceptual experiences, whereas fantasy images are created on the basis of features derived from visual experiences. A related distinction refers to common and bizarre images. The first type represents objects, as we know them in the real world; in contrast, the latter are impossible and strange

Figure 3 People trying to include in a single interactive image the images of a guitar and a rainbow could use fantasy to create an effective original representation.

representations of an object. Examples of bizarre images could be a dog smoking a cigar and a man chewing a bone, whereas the corresponding more common image would be a man smoking a cigar and a dog chewing a bone. This distinction has memory implications and has been the basis of mnemonic art. Cornoldi et al. (1988) found that bizarre representations improved memory recall if subjects could evoke the kind of image they wanted. Further studies (Einstein et al., 1989) reported that recall can be influenced by the distinctiveness of materials. They found that in a list of words where all the stimuli were imagined in the bizarre modality, recall was no better than when using common images. When the bizarre and common mental images were generated alternatively in the same list of words, however, the bizarre images produced a better memory performance, indicating that bizarreness *per se* does not produce superiority in memory but needs to be accompanied by another factor, such as distinctiveness.

Other classifications are more focused on the spatial properties of layouts. For example, Kosslyn (1987) distinguished between exact metric coordinates and memory for the relative relation between objects (i.e., coordinate vs. categorical representations; see also Lansdale, 1998). Studies regarding the specialized involvement of different brain structures show that the right hemisphere is important in processing metric spatial information, whereas the left hemisphere participates in processing relative spatial relations (Kosslyn et al., 1989). Other classifications of spatial images refer to the type of processing (sequential vs. simultaneous), to the reference center (egocentric vs. allocentric), and to personal space (peripersonal vs. extrapersonal).

2.08.2.1 General, Specific, Contextual, and Episodic-Autobiographical Images

Can mental images also represent general concepts? The existence of general and prototypical images is an ancient topic of debate. We know that the ability to create a universal or prototypical representation from the analysis of particular cases is a fundamental process in knowledge and conceptual development, but we do not know whether this representation can assume an imaginal format. Radical empiricists (Locke, Hume, Berkeley) denied the existence of general images by arguing that mental images are always based on the representations of specific objects that have been experienced, whereas a general term evokes an abstract idea. From this position two different interpretations developed: one affirming that general images representing the essential properties characterizing the general term (such as a prototypical representation) can be generated, and the other suggesting that general terms are either abstract or refer to an exemplar representation. The distinction between general, specific, contextual, and episodic-autobiographic mental images embraces the first option. The distinction has received support in recent years by cognitive (Cornoldi et al., 1989; De Beni and Pazzaglia, 1995; Helstrup et al., 1997) and neuro-anatomical data (Gardini et al., 2005). An example of a general image may consist of a skeletal representation of the main features of a bird including both coordinate and categorical spatial information. A specific image of a bird should be a particular exemplar of the category (e.g., a canary); moreover, a contextual image refers to an image in which the object or the exemplar is inserted within a context, for example, the canary in the cage. Finally, episodic-autobiographical images correspond with images of single life-episodes connected with an object and having a specific self-reference, for example, my canary escaping from its cage during a sunny day of May. Episodic-autobiographical images involve the retrieval of available episodic traces resulting from autobiographical events. The retrieval of autobiographical memories, even in the absence of specific instructions, seems strictly associated with the activation of mental images (Brewer, 1988).

Cornoldi et al. (1989) investigated the relationship between the generation of different kinds of mental images and memory recall performance. By comparing memory performance for general, specific, and autobiographical mental images, they found that the recall of general and specific mental images did not differ, but autobiographical mental images produced a better recall performance with respect to general and specific ones. De Beni and Pazzaglia (1995) distinguished between self-referred mental images within the personal autobiographical context, in which an individual imagines himself or herself together with the object without a precise episodic reference, and episodic-autobiographical images, representing a specific episode of the subject's life in relation to the object. Episodic-autobiographical mental images increased memory performance with respect to the contextual images but required longer generation times compared with other image categories. This finding could be explained by the fact that the generation of this kind of image requires the

previous generation of a general image. It could also be explained by the fact that the search of a particular episode related to the object must take place, or it might be a result of the richness of details of this kind of image.

According to Cornoldi and coworkers (Cornoldi et al., 1989; De Beni and Pazzaglia, 1995) (see **Figure 4**), the mental image generation would start with the retrieval of a global shape information of the object (which can be used to generate a general image) and be subsequently enriched with details, for example, those of a particular exemplar belonging to the category of an object, or contextual information when an object is imagined in a particular context or with reference to characteristics of a familiar type of an object, thus creating the conditions for generating, respectively, a specific and a contextual image. In contrast, the generation of episodic-autobiographical mental images would undergo a different generation process directly involving the retrieval of the image from the episodic-autobiographical memory store.

In an fMRI study, Gardini et al. (2005) provided anatomical support for the results repeatedly observed in cognitive studies. The researchers, in fact, investigated the neural correlates of general and specific mental images from concrete nouns. Results showed different brain activities for both types of images; in particular, general images activated right frontal areas to a greater extent than specific images, whereas specific ones mainly activated the left-superior frontal region and the right thalamus, demonstrating that general images involve brain areas associated with the generation of global images differently from the specific images, requiring additional support from areas in charge of retrieving visual details.

2.08.3 Models of Mental Imagery and Memory

Most of the authors studying imagery agree with the idea that not only do the generation and the recall of mental images involve memory systems, but also their maintenance and transformation require temporary systems or subsystems of memory devoted to the treatment of visual and spatial information.

In the following paragraphs, we focus on three different approaches to the relationship between mental imagery and memory. We describe the models of Paivio and Kosslyn, and we discuss the potential role played by the visuospatial working memory system in maintaining and elaborating visual and spatial representations.

2.08.3.1 Paivio's Dual-Code Theory

To explain the effectiveness of imageability in predicting memory performance, Paivio (1971) proposed two different categories of processes that people can use when they encode information: images and verbal processes. He proposed studying mental images by observing the influence of imagery on memory performance, starting with a series of studies on nouns

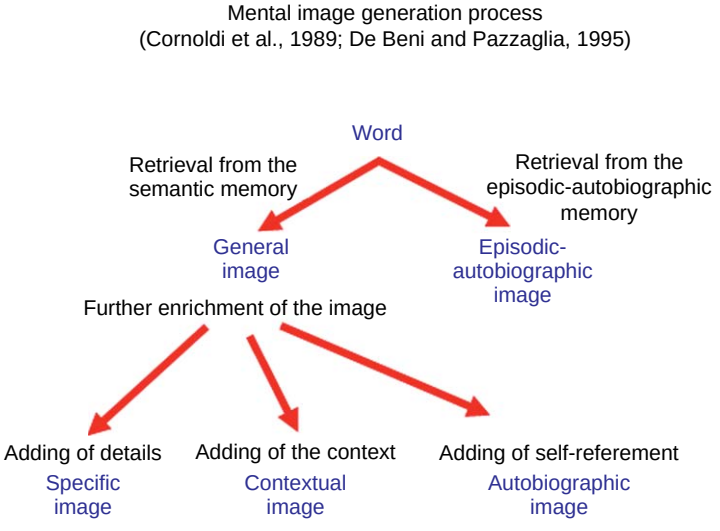

Figure 4 The generation process of mental images (Cornoldi et al., 1989; De Beni and Pazzaglia, 1995).

and paired-associates recall. Paivio et al. (1968) examined the implications of different indexes of verbal stimuli such as meaningfulness (i.e., the number of verbal associations that a word would elicit in a given period of time), concreteness, the extent to which words refer to a tangible object, imagery value (which refers to the ease or difficulty with which words prime a mental picture), and familiarity for memory performance. Results obtained by Paivio et al. (1968) demonstrated that imagery value and concreteness were strongly related to recall, and meaningfulness and familiarity did not produce an effect on recall when the imagery value was controlled for. A particular result, concerning paired-associate recall, was that concrete-abstract pairs were recalled better than abstract-concrete pairs. The result was interpreted on the basis of the assumption that a prior image can represent an appropriate imaginal tag for subsequent information.

Paivio (1971) proposed a dual-coding theory of mental processing (see a schematic representation of the theory in **Figure 5**). The theory assumes that cognitive behavior is mediated by two independent systems specialized for encoding, transforming, storing, and retrieving information. The verbal system is responsible for the encoding and processing of verbal material and the nonverbal for encoding nonverbal input, such as images. The kind of encoding that a stimulus undergoes depends on three types of variables, that is, the nature of the material (high vs. low imagery value), the instructions given to the participants, and their imagery abilities. Paivio's model (1971, 1978) identifies three levels at which information might be processed. The first is the representational level, where the sensory trace activates the appropriate symbolic representation in long-term memory: The logogens are the basic units in long-term memory for verbal stimuli, whereas the imagens represent the basic units for imagery material. The second is the referential level, where symbolic representations in one system activate corresponding representations in the other system. These interconnections are assumed to be involved in naming objects or in creating the image of an object. In particular, referential connections between the two processes are activated when one kind of information (verbal or imagined) activates the other system. In this case there is double encoding. According to the theory, nouns with high imagery value are subjected to double encoding. "The increased availability of both codes increases the probability of item recall because the response can be retrieved from either code" (Paivio, 1971, p. 208). Finally, the associative level involves associative connections among both verbal representations and images.

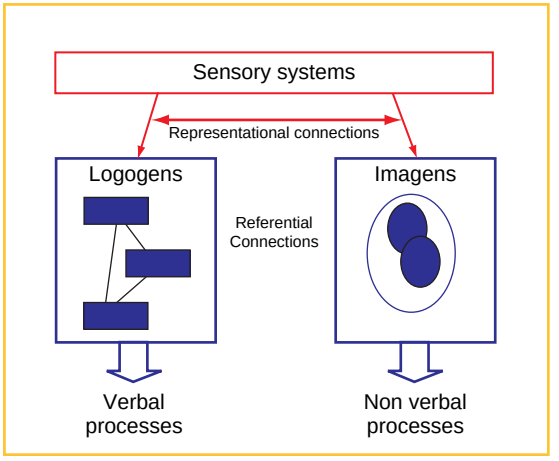

Figure 5 A graphic representation of Paivio's (1971) Dual-Codes Theory.

2.08.3.2 Kosslyn's Visual Buffer

Kosslyn (1980, 1994) proposed a computational model of image generation and provided a description of the functional structures supporting this process. His model is valid for both imagery and high-level visual perception, considered to share structures, functions, and properties. Imagery is a multicomponential process, involving a series of different processes, like image generation, maintenance, inspection, and transformation. Mental generation involves the activation of an image using long-term memory information, inspection of the different parts of an image, and arrangement of the details of an image (Kosslyn et al., 1992, 1995). Mental images do not correspond to simple visual memories but are the result of a multicomponential process that assembles the different parts together and generates a new representation.

Kosslyn's model (1980) was created based on an analogy with computer graphics. Computer graphic files store information in a compressed and nonpictorial form; when they are displayed, they are translated into a mathematical map (bitmap), which specifies the color of each pixel (tiny dot) on the screen. Kosslyn suggested the involvement of two kinds of deep representations: image files containing information regarding the perceptual characteristics

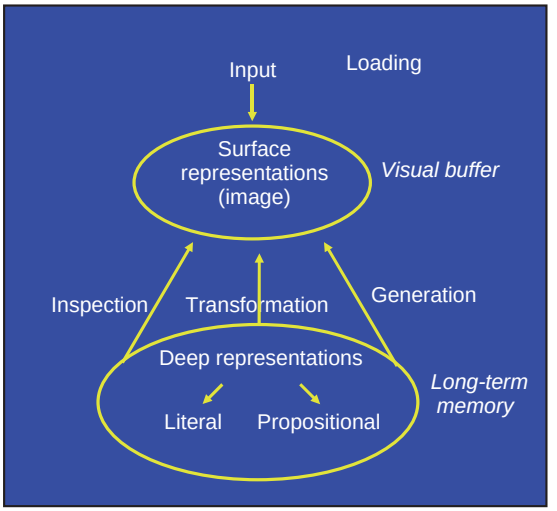

Figure 6 Schematic representation of the interaction between long-term memory and visual buffer (Kosslyn, 1980).

of the skeletal image of objects, and propositional files containing abstract descriptions of objects and their parts expressed in a propositional format (see a schematic representation of the model in **Figure 6**).

Mental imagery activity can be distinguished in a series of processes. For example, the PUT process arranges parts into an image, the FIND guides the top-down search in associative memory, and the PICTURE is responsible for the activation of stored visual representations. However, a different set of processes is hypothesized to be involved in the inspection and transformation of images: REGENERATE refreshes and sharpens the existing images, LOOK FOR searches for a named part within the existing images, SCAN repositions the image by means of a linear transformation, ZOOM increases the resolution of the image, and so on. A critical component of Kosslyn's model is the Visual Buffer, which is considered to be a short-term memory system with spatial properties (x, y, z coordinates, adjacent cells, etc.) located in the occipital lobe. In fact, the images are generated in the visual buffer either on the basis of information loaded by perception or on the basis of information stored in long-term visual memory (see **Figure 7**). In 1994, Kosslyn revised the model in his book *Image and Brain*, addressing the importance of seven basic components:

- The visual buffer, which holds spatially organized patterns of activation;
- The attention window, which focuses on the information in the visual buffer selected for further processing;

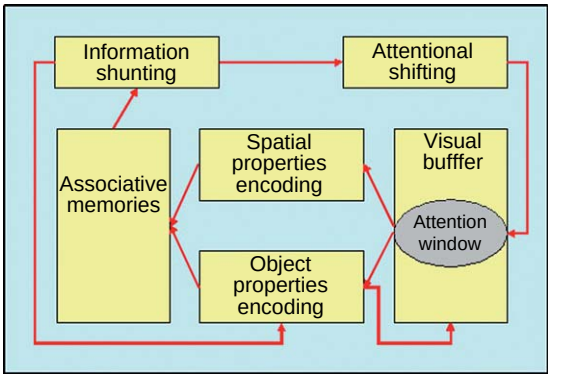

Figure 7 Processes interacting with the visual buffer (Kosslyn, 1994).

- The object properties encoding system, analyzing the physical properties of an object;
- The spatial properties encoding system, which analyses the spatial location of an object;
- The associative memory, containing information about the physical and conceptual properties of the objects;
- The information shunting, which uses stored information to collect further information about an object with top-down processes; and
- The attention shifting mechanism, which shifts the focus of attention from a specific location to a different one.

2.08.3.3 The Visuospatial Working Memory Approach

A partially different approach to imagery was adopted by other researchers, based on the idea that there is a memory system involved during the generation, maintenance, and manipulation of visual information and mental images. The visuospatial working memory (VSWM) approach (Baddeley, 1986; Logie, 1995) to imagery shares many characteristics with the visual buffer system postulated by Kosslyn (1994). However, experimental studies and research paradigms within this framework have followed different directions. The first studies with implications for the link between visual imagery and VSWM were carried out by Brooks in the late 1960s. In particular, in a 1968 study, participants were required to visualize a block capital letter and, following its contour, to answer 'yes' if the corner they mentally followed was on the bottom or the top of the figure and 'no' if it was inside the figure. Moreover, participants could

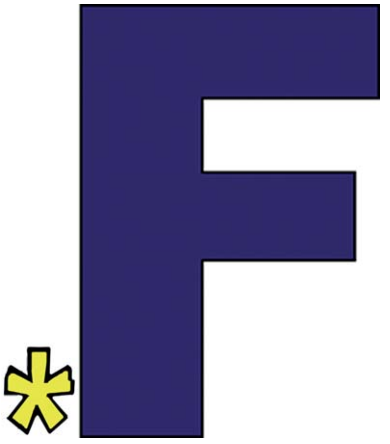

Figure 8 An example of a mental imagery scanning task used by Brooks (1968): People are invited to mentally move along the contour of a capital letter and decide about the properties of its corners.

respond either vocally or by pointing to the letters Y and N on a sheet (see an example in **Figure 8**).

Starting from the bottom left-hand corner (indicated by the yellow asterisk) and going in the direction of the arrow, the correct responses would be: yes-yes-yes-no-no- and so on. Brooks (1968) observed that participants performed worse when responding by pointing to the letters on a sheet than when giving a verbal response, whereas the opposite happened when they had to scan a sentence rather than an image. Brooks concluded that the visualization of a block capital letter involves different cognitive resources than those used to point to printed words on a sheet. These results were consistent with the view that there is a specialized cognitive system able to process visual inputs and to generate and retain images.

The original working memory model proposed by Baddeley and Hitch (1974; Baddeley, 1986) is a nonunitary system comprising three separate components. The central executive has attentional functions and coordinates the activities of the two slave systems, the phonological loop, which maintains and processes verbal information, and the visuospatial sketchpad, in which visual and spatial information are maintained and processed by two different, but complementary, visual and spatial subcomponents (Della Sala et al., 1999). Salway and Logie (1995) attempted to examine the role of working memory and of VSWM, in particular in imagery tasks, by using several kinds of interferences on a single main imagery task. Specifically, they analyzed the effect of random generation (usually interfering with the central executive component), articulatory suppression (interfering with the phonological loop), and spatial tapping (damaging VSWM) on the performance of the Brooks matrix and a verbal task (1968). Participants were asked, in one condition, to imagine placing consecutive numbers in consecutive squares of a visualized matrix; in the second condition, they had to retain a sequence of consecutive words, for example, 'good, bad, slow,' and so on, placing them in a set of nonsense sentences that were to be retained without the use of any form of visual image. Results showed that articulatory suppression damaged the second (verbal) condition, that spatial tapping disrupted the first (spatial) condition, and that random generation interfered with both tasks in an important way. In 1995, Logie suggested a revised model of the VSWM involving a passive visual store (i.e., the visual cache) and an active rehearsal mechanism (i.e., the inner scribe). The visual cache provides a temporary store for visual information (color and shape), whereas the inner scribe handles information about movement sequences and provides a mechanism by which visual information can be rehearsed in working memory.

Within the classic multicomponent model of working memory, there is a debate as to whether mental imagery, having a specific visuospatial format, involves a working memory component, which maintains the specific properties of the information (i.e., the visuospatial sketchpad) or whether it also requires central processes, such as those involved in the central executive system. In the modified view of VSWM (e.g., Logie, 1995), in fact, the generation of an image appears to be the prerogative of the central executive, whereas the retention of its visual and spatial properties may be the responsibility of a temporary store, such as the VSWM system.

On this basis, we could also wonder whether there is a potential overlap between the concepts of VSWM and Kosslyn's visual buffer. From Logie's point of view, if the central executive is responsible for imagery generation and manipulation, it would also host the visual buffer controlling the operations involved in imagery maintenance. Kosslyn's processes acting on the contents of the visual buffer such as GENERATE, ZOOM, SCAN, and so on, could be seen as procedures activated from long-term memory and also operated by the central executive. However, in this case, specific modal processes, in Kosslyn's model clearly attributed to a specialized system, would be included in the amodal activity of a Central System. Moreover, the visual buffer

would contain the visual properties of the image, the information about its location, and any semantic information associated with the image, but these operations would better match the operations of the visuospatial component of working memory.

Within this context, Bruyer and Scailquin (1998), using the dual-task paradigm, analyzed which working memory component is involved in the generation, maintenance, and transformation of mental images, demonstrating that both spatial tapping and random generation interfere with the generation of mental images, but only spatial tapping damages the maintenance of mental images, whereas random generation produces major interference on the transformation (i.e., rotation) of mental images. The difficulties in associating mental imagery with a specific working memory component could be overcome within a continuity model, which assumes that control can be involved at different degrees. In this framework, the VSWM processes may be distinguished according to the degree of controlled activity (see **Figure 9**); in particular, at a lower level, a simple recall of previously acquired information is required, whereas at the higher level, an elaboration of information to produce an output different from the originally presented stimulus is involved (Cornoldi and Vecchi, 2000, 2003). According to this view, a plausible specification of the imagery tasks along the continuum could involve maintenance, inspection, generation, selection, combination, and transformation, respectively ordered on the basis of the active control required (see Cornoldi and Vecchi, 2003).

Another crucial issue in VSWM concerns the nature of the components and of the type of representation maintained in memory. In fact, although there is converging evidence supporting the multicomponential nature of VSWM, there is no agreement on the number and identity of its components. A great number of neuroanatomical data, starting from the work of Ungerleider and Mishkin (1982), has supported the distinction between a spatial and a visual component, for example, by focusing on a where system or on a dorsal stream, processing spatial information, and on a what system or on a ventral stream, processing the features of perceived objects. Another fractionation in VSWM processing was suggested by Pickering et al. (2001), who distinguished between a static format of the generated representations (e.g., a matrix in which locations are presented simultaneously) and a dynamic format (e.g., a matrix in which locations are presented one at a time). A similar distinction was made also by Pazzaglia and Cornoldi (1999) between spatial-sequential and spatial-simultaneous processes: A spatial-sequential task requires recalling spatial positions presented in a sequential format, whereas in a spatial-simultaneous task, participants have to recall positions presented simultaneously. Pazzaglia and Cornoldi (1999) distinguished between these two spatial components and a visual one in which participants have to memorize objects with different shapes, colors, and textures.

2.08.4 Paradigms in the Study of Mental Imagery and Memory

Mental images are mental representations, which, just like thoughts, are not directly observable. As Richardson (1969) stated in the early days of the

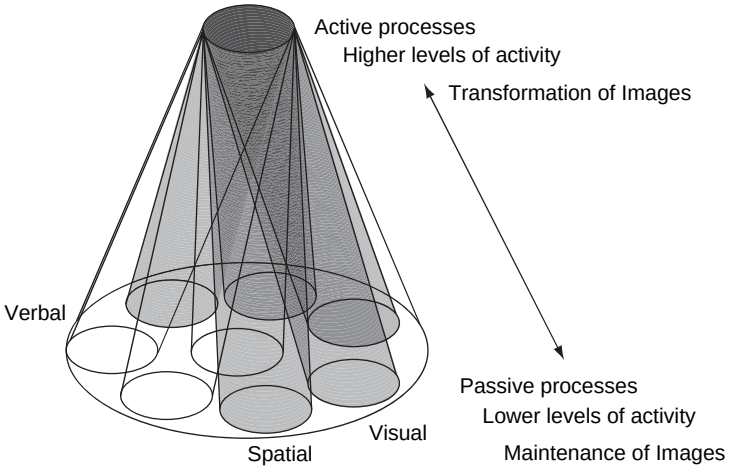

Figure 9 The continuity model of working memory: Mental imagery involves different portions of working memory differentiated according to the type of content and the degree of control (Cornoldi and Vecchi, 2003).

renaissance of research in this area, the problem regarding mental image investigation is to find a valid method to measure imagery. In fact, from the early days of cognitive psychology, this problem has been at the center of psychological questions concerning imagery. In the present state of research, different methodologies have been developed and applied to the imagery domain, offering the possibility of further investigating this phenomenon.

2.08.4.1 Cognitive Paradigms of Mental Imagery Processes

Within cognitive psychology, imagery has been investigated mainly in two different ways. The first examines mental imagery as a dependent measurable variable. It studies qualitative and subjective aspects of imagery and the extent to which mental images are similar to the physical objects that are being imagined. The latter concerns the use of mental images as independent variables (manipulated by researchers) in which observable aspects are reflected in behaviors, and especially in the performance obtained by participants (Richardson, 1999). In this paragraph we focus on the direct study of imagery processes, whereas in subsequent paragraphs, we examine the implications of two main manipulations of variables related to imagery (i.e. materials and abilities).

Studies directly focused on mental imagery representations and processes have used a large range of different paradigms. A few of them have been based on the examination of the subjective imagery experience, as, for example, when people are invited to rate the vividness, or other properties, of their mental images. For example Cornoldi et al. (1992) studied which characteristics influence a vividness judgment; Baddeley and Andrade (2000) examined which manipulation depresses mental imagery, inferred by decreases in the experience of vividness.

A problem with the use of subjective experience ratings is that they are affected by the criterion people use to decide whether or not their image is of a high quality. Since Galton's (1883) first started using vividness ratings to find people with different imagery abilities, the problem has been to decide to what extent vividness ratings describe differences in representations and to what extent they describe differences in criteria. For this reason, the majority of studies focusing on the properties of mental images have also used more objective criteria, such as time, effects of the experimental manipulations, verbal descriptions of the results of imagery processes, drawings, and external ratings (for a review, see Pearson et al., 2001). For example, in the mental pathway task, people are invited to imagine a matrix with a series of cells (e.g., a simple 5×5 board), imagine following a pathway on the board in correspondence with the verbal instructions given (go left, down, etc.), and point, on request, to the position reached at the end of the instructions on a corresponding blank matrix. This task has been particularly successful in studying the strengths and deficits of mental imagery processing in totally congenitally blind individuals (e.g., Cornoldi et al., 1991).

The chronometric study of mental imagery has produced the main experimental paradigms in the field. The most popular paradigm is surely represented by the so-called mental rotation tasks, derived from the traditional psychometric literature on spatial abilities testing, requiring a decision of whether two figures are differently oriented examples of a single figure, or if one of them is actually different (typically its mirror image) from the other. In a series of very influential studies, Shepard and coauthors (e.g., Shepard and Metzler, 1971) reconsidered the method and manipulated the angular variation between the two pictures (see examples in **Figure 10**). They found that the time necessary for giving a response was a function of the rotation angle, showing how the decision was not based on a consideration of the properties of the object (feature x is on the right of feature y, feature z is above feature y, etc.), which would not have been affected by the rotation angle but was based on a process of mentally rotating one figure to see whether it perfectly matched the other one.

There are many other examples of chronometric studies of mental imagery. For example, in the preceding paragraphs, we provided examples of image generation tasks, such as images generated from a verbal label, and mental scanning tasks (e.g., scanning an island or a capital letter). In fact, in the popular taxonomy of mental imagery processes, generation, scanning (and inspection), and transformation represent three classic cases. A fourth case is

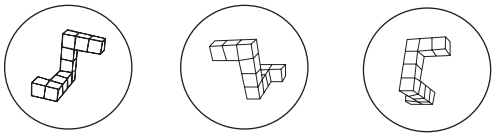

Figure 10 Examples of pictures used for a mental rotation task: People must decide as quickly as possible if the two figures are identical or mirror images.

imagery maintenance, which can be studied either with the classic paradigms of visual memory or with reference to subjective experience (people are invited to press a button when they realize their image is vanishing).

In the field of imagery transformation, the quality of the image can be directly derived from the verbal response of the individual. For example, in a mental subtraction task, people must generate an image from the visual exposure of a drawing and then a subsequent image from the visual exposure of a part of it; their task is to subtract the second image from the first and report the verbal label of the resulting image (see **Figure 11**). Brandimonte et al. (1992b) found that the performance in this task is facilitated by the block of verbalization.

Other studies focused on different types of mental synthesis, where participants are required not only to maintain and combine different images but also to produce a different image unrelated with the single primitive images. This particular case, given the novelty and the potential originality of the final result, has also been considered an example of creative imagery. Finke and his colleagues (Finke et al., 1989) asked subjects to carry out a series of transformations on imagined figures mediated by verbally presented instructions. The transformations were designed so that the final pattern would resemble a familiar object, as in the following example of the task: Imagine a B, now rotate the B 90 degrees to the left, then add a triangle below the rotated B, and finally report what the resulting pattern looks like (see **Figure 12**).

A different and more recent example of an imagery transformation task was suggested by Vecchi and Richardson (2000), who devised the jigsaw puzzle test, considered by the authors as an active VSWM task, because participants must hold in mind the arrangement of the puzzle pieces and actively mentally manipulate their combination. In fact, the task requires that the puzzle be solved by moving the pieces only mentally, without actually touching or moving the pieces in question (see an example in **Figure 13**). Drawings represent common, inanimate objects derived by Snodgrass and Vanderwart (1980), with a high value of familiarity and of image agreement. Each puzzle is numbered, and participants give their responses by writing down the corresponding number of each piece on a response sheet.

The study of imagery processes can also be based on a fractionation of complex processes into more simple ones and on the individuation of measures tapping the most simple components, as illustrated by a series of studies by Postma and coauthors. In an analysis of memory for locations, Postma and De Haan (1996) separated the object location memory into three processes: the first process requires encoding metric information and the coordinates of a particular object located in the environment; the second process, called object-location binding, requires linking the object's identity to its position; and finally, the last process integrates the first two mechanisms and combines metric information with object identity and location (Kessels et al., 2002a,b).

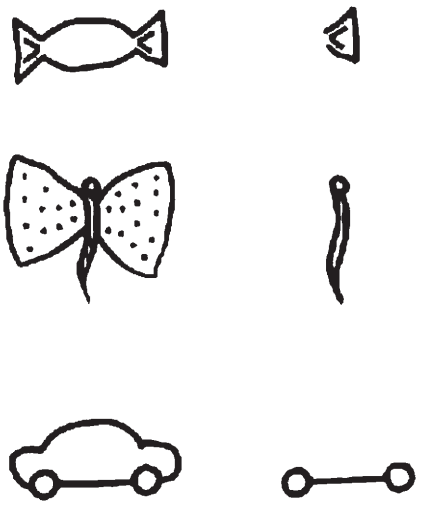

Figure 11 Examples of stimuli used for mental subtraction tasks: People, after exposure to the visual stimuli, must imagine the subtraction of the second part from the first and decide which is the resulting pattern (in this case a fish, a papillon, and a cloud).

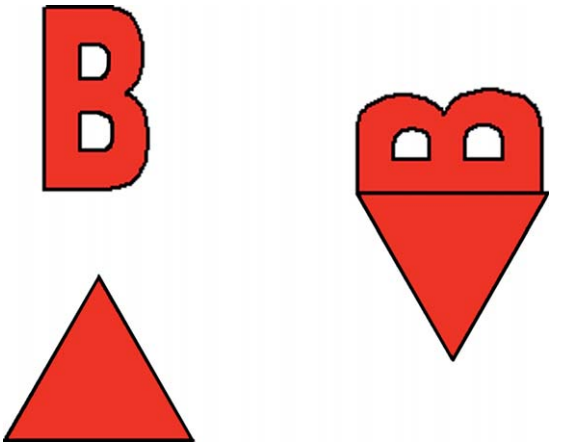

Figure 12 Example of a creative synthesis task.

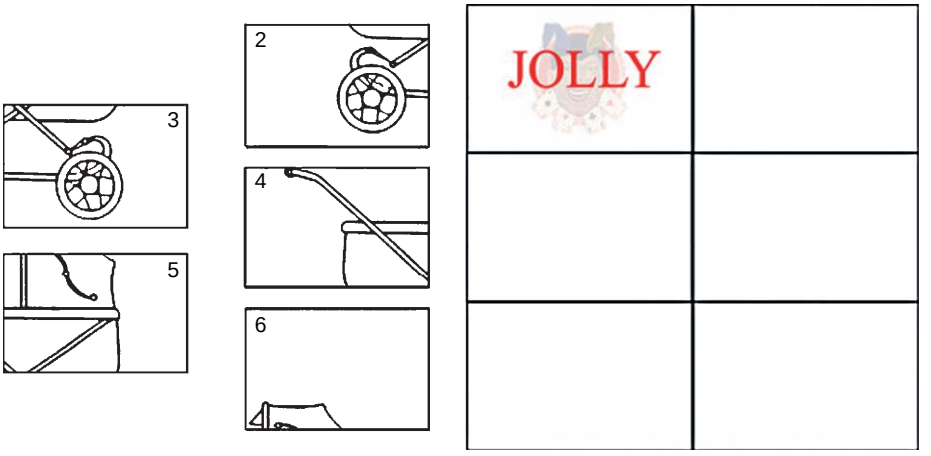

Figure 13 Example of an item derived from the jigsaw puzzle test (adapted from Vecchi and Richardson, 2000).

2.08.4.2 Neural Implications

Neuropsychological paradigms have also been useful in the study of visuospatial imagery. They offer data that have increased, in many respects, our knowledge of mental imagery processes and representations. In particular, the study of single cases has revealed important dissociations and relationships. For example, Bisiach and Luzzatti (1978) reported evidence that a unilateral neglect disorder, which usually causes patients to ignore the left half of the visual field, can also result in deficits in mental imagery. They offered the example of Milan's famous Piazza del Duomo: A patient with an unilateral neglect in front of the cathedral will typically ignore the left part of the square, but – in the case of Bisiach and Luzzatti's patient – the same experience happened in the area of a mental imagery representation. In fact, invited to imagine being in front of the cathedral, the patient was not able to describe its left part. This difficulty was not related to a preceding perceptual difficulty, nor to the particular characteristics of the square, because – when invited to imagine the square giving his back to the cathedral – his imagery block involved the other side of the square (i.e., the side accurately described when facing the cathedral).

Deficits can also be purely confined to visual imagery (Beschin et al., 1997). Farah et al. (1988) reported the case of a patient who had perceptual abilities and object recognition preserved. He was also able to copy drawings correctly and to draw objects from memory, but he could not correctly answer sentences requiring imagery for verification, for example, "An elephant is larger than a mouse." Goldenberg (1989, 1992) demonstrated that patients with left temporo-occipital lesions were unable to take advantage of imagery instructions in verbal learning tasks.

The study of severe neuropsychological patients has been integrated with the study of groups of individuals hypothesized, for different reasons, to have specific difficulties in visuospatial working memory or in mental imagery tasks (for a review, see Cornoldi and Vecchi, 2003). Examples of these groups are blind individuals (e.g., Cornoldi et al., 1991; Cornoldi and De Beni, 1988), children with nonverbal/visuospatial learning disabilities (Cornoldi et al., 1999; Cornoldi and Guglielmo, 2001; Mammarella and Cornoldi, 2005), elderly people (Vecchi and Cornoldi, 1999; Richardson and Vecchi, 2002), and individuals with specific genetic syndromes (Lanfranchi et al., 2004).

With the development of more sophisticated brain-mapping techniques, the study of imagery has taken further steps forward. In fact, from the pioneering work of Roland and Friberg (1985), who studied the variations of cerebral blood flow on the basis of the visualization of familiar routes, a great number of imagery studies have been carried out with neuroimaging techniques. Some of the questions research has tried to answer are: How do differences in brain activation inform us about the nature of different kinds of imagery? What kinds of brain areas are activated during generation, maintenance, and transformation of mental images? Does mental imagery share common cortical structures with perception, memory, or motor control?

Neuroimaging methods can be classified into two main groups: electromagnetic techniques, such as MEG (magneto-encephalography) and ERPs (event-related potentials), which have excellent temporal

resolution but poor spatial resolution, and techniques, such as PET and fMRI, which have good spatial resolution and coarse temporal resolution. It is noteworthy that although neuroimaging techniques can identify regions associated with a cognitive task, they cannot determine which of these regions are crucial for performing the task. For this reason, neuroimaging findings may be complemented with data provided by experimental and neuropsychological methods.

A central issue in the field of imagery is whether those visual areas involved when an object is perceived are also involved when an object is imagined. For example, Kosslyn's theory (1994) predicts activation during mental imagery activity in early visual processing regions (i.e., striate and extrastriate cortex). A series of experiments by Kosslyn and colleagues (Kosslyn et al., 1993, 2001; Kosslyn and Thompson, 2003) provided support for similarities between visual perception and visual imagery; other studies, however, have suggested that primary visual cortex is not activated during visual imagery (Roland and Gulyas, 1994; D'Esposito et al., 1997; see Cabeza and Nyberg, 2000 for a review). Roland and Friberg (1985) asked subjects to visualize the successive view along a route in a familiar environment. The task induced blood flow increase in the superior prefrontal cortex and, in particular, in the superior occipital cortex, the postero-inferior temporal cortex, and the postero-superior parietal cortex. These associative regions are also activated during processing of visual information. However, the authors did not find an activation of the primary visual cortex. According to Kosslyn et al. (1995), the right hemisphere is responsible for generating mental images from memory, whereas the left hemisphere is advantaged in the generation of visual mental images (see also Trojano and Grossi, 1994).

Charlot and coauthors (1992) selected high- and low-imagery participants and involved them in a task requiring the conjugation of abstract verbs (verbal task) and in a mental exploration of a memorized spatial configuration (imagery task). Their results revealed different patterns of activation for high (left-sensory motor cortex in the verbal task and left temporo-occipital cortex in the imagery task) and low imagers, who showed less differentiated increase of their cerebral activity. In Mellet et al.'s (1995) study, participants were required to inspect and memorize a map of an island with six landmarks. The cerebral blood flow was recorded as the participants performed either perceptual (the subjects were shown the map and asked to scan from landmark to landmark) or imaginal scanning of the map (performing a mental scan without looking at the map). The results revealed a common network of cerebral areas, in particular, bilateral superior external occipital regions, reflecting the processes involved in the generation and maintenance of visual images, and the precuneus (left internal parietal region), reflecting the scanning process. In this study, the parietal regions were involved in an imagery process with a spatial component. This latter result is consistent with the already mentioned hypothesis (Ungerleider and Mishkin, 1982) of a distinction between a dorsal stream (spatial system), running from the occipital to the parietal cortex, involved in the perception of spatial locations, and a ventral stream (visual system), running from occipital to the infero-temporal cortex, involved in the recognition of objects. The results obtained by Mellet and colleagues (1995; see also Mellet et al., 1996) revealed that the spatial system is engaged in both mental scanning of visual images and mental scanning of mental images.

2.08.4.3 Imagery Value

In the study of the indexes of verbal materials best predicting memory performance, imagery value has usually resulted as the best predictor (Paivio, 1971), whereas the effects of item frequency/familiarity and associative value/meaningfulness resulted in weaker results and were partly explained by imagery value. This result was interpreted by Paivio (1971) as proof of the dual-code theory; in fact, a high-imagery-value item (e.g., the word 'train') evokes both a verbal and an imaginal encoding, and the double encoding enhances enhance the probability to get back the item. On the contrary a low-imagery-value item (e.g., the word 'range') only evokes a verbal encoding and thus has a poorer trace and a reduced probability to be recovered. Paivio (1971) also assumed that pictorial material has, by definition, a high imagery value and thus, if verbalizable, has the highest probability of having a double encoding; in other words, the picture superiority effect (better recall of the verbal label of a presented picture than of the corresponding presented word) should be caused by the same reasons that explain the superior recall of high-imagery words with respect to the recall of low-imagery words. However, this conclusion raises a series of perplexities (for a review, see Cornoldi and Paivio, 1982; Marschark and Cornoldi, 1990) because high-imagery verbal material differs from low-imagery verbal material in many respects only partly related to the use of mental imagery.

Different paradigms have been used to analyze the specific effects of mental imagery on the recall of high-imagery-value materials. For example, in a dual-task paradigm, participants are presented with a main task, which in this case can involve the retention of the high-imagery-value material. Simultaneously, they are also required to perform a secondary task, most of the time tapping one of the working memory components. (Some studies that have employed the dual-task paradigm have been presented in the preceding paragraphs, e.g., Salway and Logie, 1995; Bruyer and Scailquin, 1998). In a series of studies (e.g., Colpo et al., 1977), we simultaneously presented words, either with high or low imagery value, and pictures, and we found that the memory for high-imagery-value words was selectively impaired, suggesting that high-imagery words and pictures relied on the same type of resources.

A different paradigm concerns the manipulation of instructions. In general, specific instructions encouraging the use of mental imagery enhance memory with respect to instructions encouraging the use of a non-imagery strategy (e.g., repetition); furthermore, this effect seems to interact with the imagery value of the material, although the latter effect is not always clear (for a review, see Richardson, 1999).

2.08.4.4 Individual Differences in Imagery Abilities

The study of mental imagery has often used an individual differences approach, as already anticipated in the section concerning neuropsychological evidence. Also, within normal populations (i.e., in the absence of severe deficits), imagery ability differences can be observed. Actually, some of the tasks used for measuring spatial abilities require the maintenance and the manipulation of mental images, as in the case of tasks requiring mental rotation or the mental transformation of parts (mental folding, mental assembly, etc.). The traditional preference for imagery transformation tasks over other spatial tasks in the psychometric assessment of spatial abilities seems to result from the fact that the imagery transformation tasks involve a high degree of control and are thus central and related to the central structures of intelligence; however, at the same time, they maintain specific spatial features and are not only theoretically but also empirically distinguishable from other high-control tasks tapping verbal functions (Cornoldi and Vecchi, 2003).

Individual differences found with the use of objective measures are related to independent measures obtained with neurological (e.g., Charlot et al., 1992) and cognitive procedures. An example of this relationship is represented by the ability of solving ambiguous figures (Cornoldi et al., 1996). For example, Mast and Kosslyn (2002) found that the ability of rotating images was highly associated with reports of image reversals subsequent to an 180-degree rotation of a figure, whereas other imagery ability measures were not.

In the mental imagery field, the repertoire of differential measures has been enriched by many other measures, including subjective ones. Despite their methodological limitations, the self-report measures have been largely used and have produced a series of different tools. For example, the VVIQ test (Marks, 1973) requires that a person imagines, with either open or closed eyes, a scenario (e.g., a sunset) and reports how vivid his/her image is. The imagery ability is directly inferred by the sum of the values given to the different activated images. There have been concerns regarding the value of this subjective measure, voiced from different sides, but there is evidence that in some cases it may be a useful method (for a review, see McKelvie, 1995). For example, a VVIQ score may be predictive of the performance in a task requiring the memorization of visual objects. However, there is evidence that in some cases other types of subjective reports may have better predictive power. In particular, Graham and Morris (2003) suggested that a lack of a relationship between subjective measures and performance could be because they tap different components of mental imagery. To investigate this, the researchers administered two spatial tasks and two different self-report questionnaires to a group of subjects. One self-report, the VVIQ, mainly involved subjective visual experiences derived from long-term memory, whereas the other included items of the same kind used in the spatial tasks. They found that only the latter items predicted spatial performance, whereas there was no relationship between VVIQ and objective measures.

2.08.5 Educational and Other Applied Implications

The role of mental imagery in human cognition, for example, in reasoning, comprehension, and creativity, has been illustrated in several studies (Paivio, 1971; Richardson, 1999). This evidence suggests that training to effectively use visualization processes could enhance cognitive performance in many areas.

A well-known example of how mental imagery can be used in an educational context is represented by imagery mnemonics. This point was already emphasized by ancient Greeks and Romans, who stressed the importance of using mnemonics to improve learning. However, in the history of culture and education, the attitude toward mnemonics alternated between moments of enthusiasm, resulting from the enhancement of memory, and criticisms, resulting from the artificial connection between memory content and memory cues. For example, Cicero and Giordano Bruno were in favor of mnemonics, but Erasmus and Montaigne were not (Yates, 1966). Despite these different views, there is general agreement that mnemonics enhance memory and that they rely largely on the use of mental imagery (for a review, see Higbee, 1988). One key principle of imagery mnemonics is the creation of interactive images, which facilitates the retrieval of an element when the element imagined in interaction is available.

Mnemonics can be distinguished into two categories according to whether they rely on a specific rule or they require the prior creation of a cues file, and both categories of mnemonics very often rely on the use of mental imagery. Mnemonics based on a rule are of many different types. In the chaining mnemonics, people form a series of interactive images by combining in pairs the sequence of items. For example, given the sequence 'radio, cat, window, salad, etc.,' one could form the interactive image of a radio turned on by a cat, then a subsequent image of a cat jumping onto the windowsill, a window placed above a bowl of salad, and so on.

Another rule-based mnemonic that has received a lot of educational uses is represented by the keyword technique, mainly used for the study of foreign languages. The technique requires people to give a concrete imaginable meaning to the foreign word by associating it with a word in their own language with a similar sound. They then form an interactive image including the images of the new word and the word corresponding to the real meaning of the foreign word. The example given in **Figure 14** shows how a person could remember the Russian word 'likor' for 'battleship'. His first task would be to find an imaginable word similar in sound to the Russian word 'likor,' for example, Lincoln or liquor. The second task would be to create an interactive image including, for example, Lincoln and a battleship. As the two elements are very different in size, the person could use a zooming process to give a name to the small individual represented on the deck of the battleship.

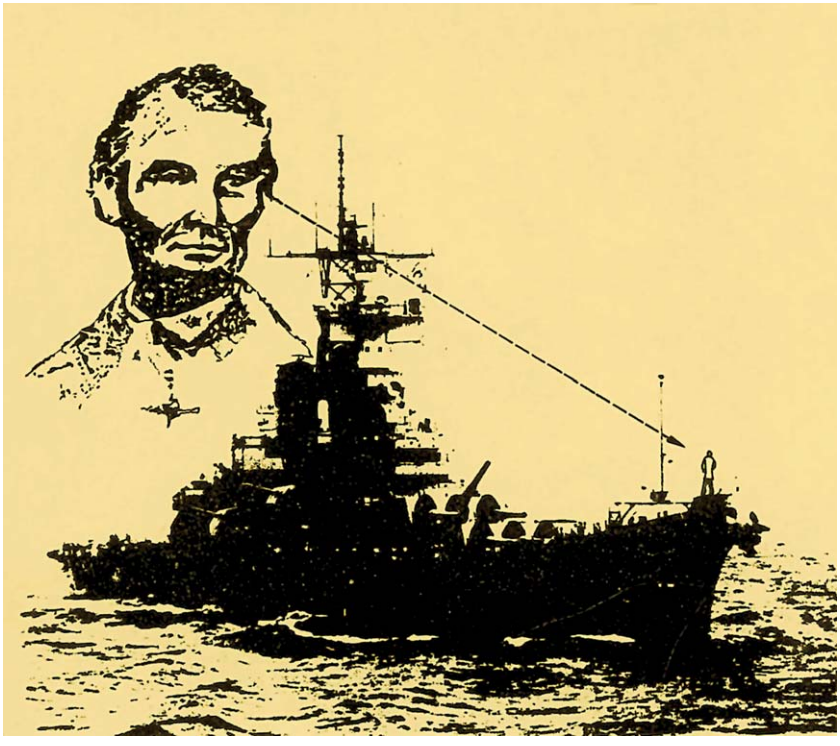

Figure 14 Example of the use of the key-word technique to learn a foreign word ('likor' for 'battleship').

Despite the fact that imagery mnemonics can be considered artificial and distinguished from mnemonics based on semantic associations, in many cases the two components can act together. The example given in **Figure 15** represents this possible synergy. In fact, a child trying to memorize the patterns illustrated in the matrix could simply rely on the semantic associations between items (e.g., a dish and a bowl can stay together), or the more effective rule of categorical clustering (a hen, a duck, a chicken, and a rabbit are all animals). However, the child could also take advantage of the memory of the visual form of the represented objects and the possibility of imagining them in interaction (a farm scenario with the animals, a bowl above a dish, etc.).

Mnemonics based on a cues file requires people to have already created a file containing a series of organized images that will be imagined in interaction with the new to-be-remembered material. At retrieval, the well-known cues file will be used for retrieving the new information memorized in interaction. Expert memorizers have always given preference to this category of mnemonics because it offers the possibility of storing huge amounts of material. There are reports of experts who created files of thousand of cues, either organized around spatial layouts or (more often) organized sequentially in correspondence with the number sequence. The most well known mnemonic based on a cues file is represented by the loci mnemonics, where people use landmarks arranged along a well-known pathway as cues. The example given in **Figure 16** is adapted from the illustration given by Lindsay and Norman (1977) in their psychology handbook, where the pathway was in fact the route followed by Donald Norman to reach the Department of Psychology of the University of California at San Diego, starting from his home. The first landmarks selected by Norman were in sequence: (a) his own home, (b) the bay, (c) the train railway, and so on. Having to memorize a sequence of words, Norman could associate them with the sequence of landmarks (e.g., a radio left close to the gate of his home, a cat looking at a boat in the bay, a broken window on a train). If required to remember the sequence of words in perfect order, people using the loci mnemonics have no

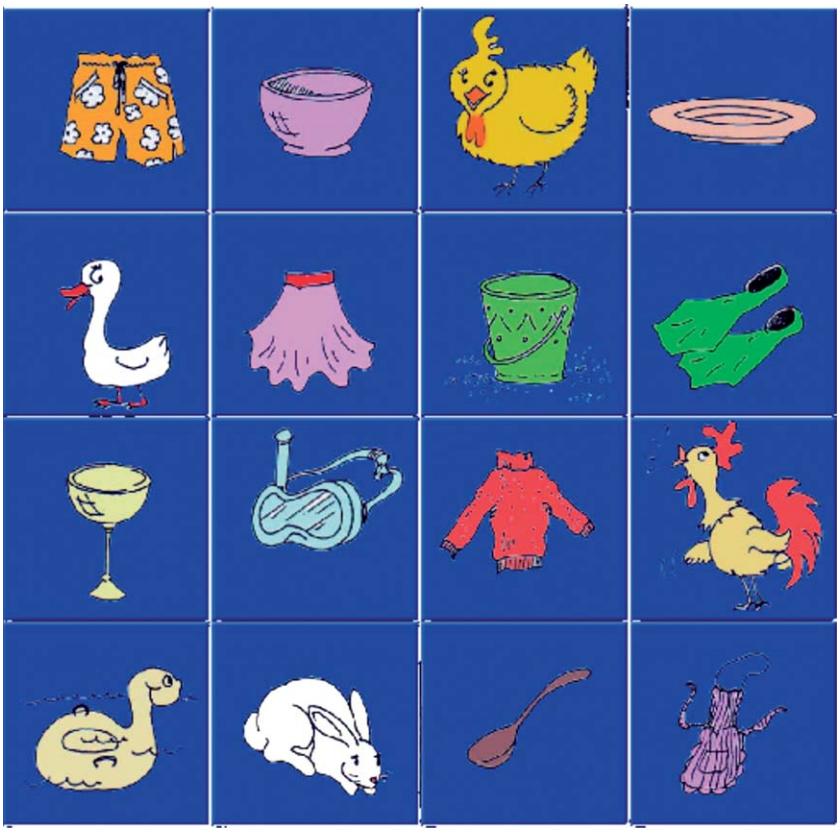

Figure 15 Example of memory material that can take advantage of both semantic and mental imagery strategies.

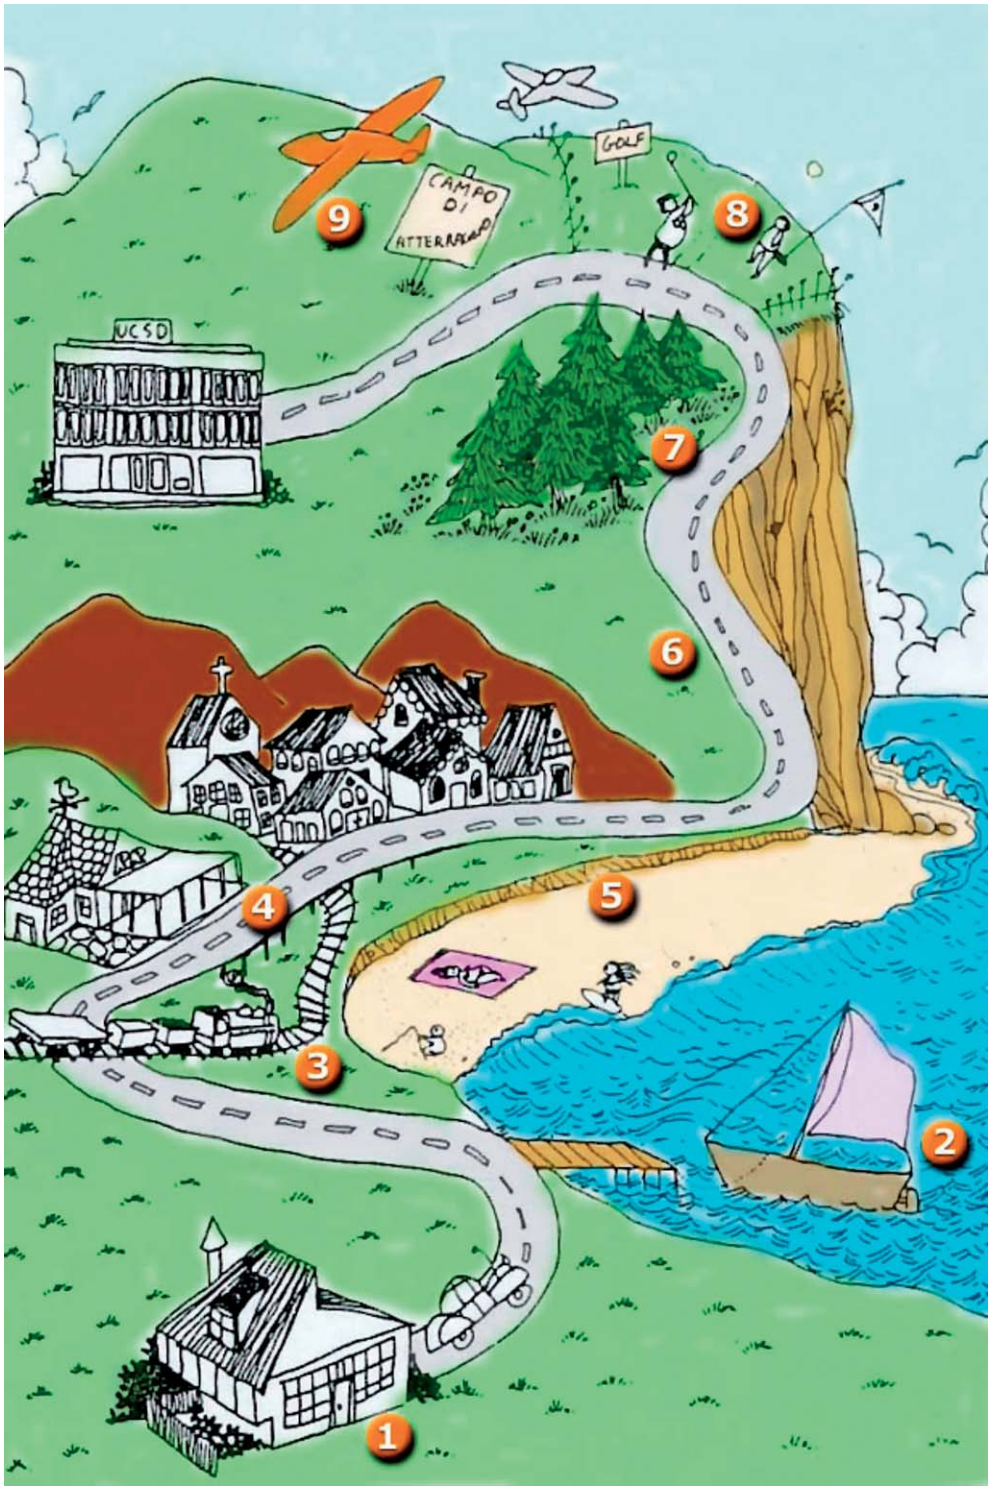

Figure 16 An example of figure employed for using the loci mnemonic. Adapted from Lindsay PH and Norman DA (1977) *Human information processing,* 2nd edn. New York: Academic Press.

problems in retrieving their well-known route with its landmarks and thus retrieve the elements imagined in interaction with their landmarks.

A critique advanced against the loci and other imagery mnemonics is that they can be successfully used for memorizing isolated arbitrary series of items but do not offer an advantage in memorizing meaningful texts. However, there is evidence that loci mnemonics can also enhance memory for texts, although its advantage is more evident when a text is orally presented than when it is written, because of the competition of visual processes involved in imagining and reading (Cornoldi and De Beni, 1991).

2.08.6 Concluding Comments

Mental imagery represents a very relevant part of mental life. Because of its pervasiveness, internal status, and complexity, its study raises a series of methodological problems and requires differentiations and specifications. In this chapter we described mental imagery with reference to different approaches and theories. In particular, we illustrated the debate between prepositional and imagery theorists and the efforts devoted to distinguishing between different imagery processes and representations. The classical problem concerning the extent of the analogy between visual perception and visual mental imagery may find a response in the consideration of the differences from images directly derived from experience and images generated from long-term memory information. Furthermore, the consequences resulting from the use of different types of long-term memory information can be examined within the approach distinguishing between general, specific, and other types of mental images. However, many issues in the field, for example, the dynamic nature of mental images, their role in different life activities (like creative processes, thinking, meditation, and so on), and the study of individual differences, appear still in need of further research developments.

2.09 Distinctiveness and Memory: A Theoretical and Empirical Review

S. R. Schmidt, Middle Tennessee State University, Murfreesboro, TN, USA

2.09.1 Introduction

My memories appear as a varied landscape, with fields and trees and distant mountains. I can distinguish each blade of grass at my feet, I see the individual veins on the leaves on a nearby tree and the brown corrugated grain of the tree's bark. Farther away, the blades of grass are lost in a field of green, and the trees on the hillside are marbled clumps of color. However, I can clearly see a lone tree in the middle of a distant field. On the horizon I can see the blue haze of the mountains, occasionally interrupted with an outcrop of white rock. I know the mountains must be covered with trees, but I cannot separate one from another. The clarity of my memories, like the clarity of my perceptions, appears to be determined by both distance and contrast. In this manner, contrast, or distinctiveness, is a fundamental concept in any theoretical treatment of memory.

Theory and research concerning distinctiveness and memory have long and fascinating histories that have been recounted in detail elsewhere (see Wallace, 1965; Schmidt, 1991; Hunt, 1995). These histories unfailingly begin with Hedwig von Restorff, a postdoctoral assistant in Wolfgang Köhlers's laboratory. von Restorff was one of the first to argue that the Gestalt perceptual principles applied to memory traces (Geissler, 2001). Principles of organization and the perception of figure and ground lend themselves nicely to the clarity of memory for that metaphorical lone tree in the field. von Restorff (1933) argued that "the rules according to which the

reproducibility of items is a function of the structure of the list are consistent with the laws governing whether individual parts in the field of vision remain independent or integrated into a perceptible whole." (Von Restorff, 1933: p. 323) The perception of a single "figure in a whole" (or tree in a forest) is impaired because it becomes a part of the whole. The perception of a tree in a field does not suffer from such interference (Von Restorff, 1933: p. 327). Studies of the von Restorff effect and distinctiveness effects in general can be seen as attempts to understand the good memory for the metaphorical lone tree.

In the following pages, I provide a summary of theoretical and empirical treatments of the concept of distinctiveness in memory research. I begin with a few of my own organizational principles, followed by three theoretical perspectives on distinctiveness in memory. Then I provide a rather long catalog of empirical phenomena that roughly fit under the distinctiveness umbrella. I conclude with a cautionary note concerning the usefulness of distinctiveness as a theoretical construct.

2.09.2 Organizing Principles

Imagine that I am looking at a giant oak tree at the height of fall colors. My visual field is completely filled with the image of the tree, and every leaf on the tree, save one, has turned bright red. The green leaf stands out in this perceptual field. There is nothing unusual about a green leaf; it gains its distinctive character by virtue of its context. In contrast, I do not recall ever seeing a purple polka-dot leaf on a tree. Perhaps a purple polka-dot leaf on a tree would be distinctive in any context. Note that individual leaves on a tree full of purple polka-dot leaves would not stand out from one another. However, the tree as a whole would stand out in a typically green forest. Thus, when one tries to define the distinctiveness of an experience, one must consider the domain, or to push the metaphor, the field of view.

Toward this end, researchers often distinguish between context-dependent, or primary, distinctiveness and absolute or secondary distinctiveness (Schmidt, 1991). Primary distinctiveness (from W. James's primary memory) is defined relative to the immediate context or, for example, a list of words in a memory experiment. For example, a tall tree in the middle of a field of grass stands out in its immediate context, and a single word printed in red stands out in the context of a list of words all printed in black. Secondary distinctiveness is defined with regard to the previous history of the observer and to experiences stored in long-term or James's secondary memory. Examples of secondary distinctiveness might include seeing a purple polka-dot tree or reading the sentence: The banker floated across the puddle on a newspaper.
