Volume 1 Learning Theory and Behaviour

Volume 2 Cognitive Psychology of Memory

Volume 3 Memory Systems

Volume 4 Molecular Mechanisms of Memory

FOREWORD

A comprehensive reference work on learning and memory could not be better timed than this. During the second half of the twentieth century, the study of learning and memory moved from a descriptive science largely based on the pioneering behavioral analyses of Pavlov, Thorndike, Watson, Skinner, Kamin, Rescorla, and Wagner to a new mechanistic science of mind that combines these brilliant behavioral studies with an analysis of the underlying neural mechanisms, first in a regional manner by Milner, Tulving, Mishkin, Squire, Schachter, and Morris, then on the cellular level, and finally on the molecular level.

The challenges that now face the field are outlined by the five great pioneers in the study of memory – the editor-in-chief Jack Byrne and the editors of these four extraordinary volumes: *Learning Theory and Behavior*, edited by Randolf Menzel; *Cognitive Psychology of Memory*, edited by Henry Roediger; *Memory Systems*, edited by Howard Eichenbaum; and *Molecular Mechanisms of Memory*, edited by David Sweatt. The challenge faced by the contributors to these volumes was to combine the molecular mechanisms with the other three levels in order to provide a coherent, systematically and intellectually satisfying understanding of learning and memory. This is central to the new science of mind. Since memory is the glue that holds our mental life together, the topics covered by these four volumes are central to and paradigmatic for all aspects of the neurobiology of mental life, which has as its goal the understanding of all mental processes in neurobiological terms. Indeed, it is the plasticity of the brain that is the key to understanding the continuity of all mental function. The goal for each of these four volumes was to bridge the subdisciplines concerned with the various forms of memory into a coherent science. The chapters of each of these volumes succeed admirably in doing just that. As a result, this rich and rewarding reference work will serve as a superb framework for the decades ahead, a reference that will provide both the student and the working scientist with the intellectual background necessary to understand and function effectively in the study of learning and memory.

PREFACE

Learning and Memory: A Comprehensive Reference is the most authoritative set of volumes ever produced on learning and memory and represents the state of the science in the early 21st century. The study of learning (the process of acquiring new information) and memory (retention of that information for future use) has intrigued philosophers and writers for centuries because our memories and plans for the future consolidate who we are, and disruption of these processes dramatically interferes with our daily lives. The fascination with learning and memory is not limited to the humanities, but has been the subject of intense scientific research. Psychologists are concerned with elucidating the features of learning and memory processes and systems, neurobiologists seek to determine the neuronal mechanisms of learning and memory, and neurologists and psychiatrists focus on research and treatment of failures or disruptions in learning and memory.

The study of learning and memory represents a scientific field that has matured at all levels – from the discovery of the protein chemistry and molecular biology of the cellular events underlying learning and memory, through the delineations of the properties and functions of neuronal networks, to formulating and testing the psychological and behavioral neuroscientific theories of learning and memory. In addition, many basic research findings have applied implications on such diverse fronts as education, legal issues hinging on eyewitness testimony, learning disorders in children, memory disorders following brain damage, and declines in memory in older adults.

The volumes in this *Comprehensive Reference* are the result of a meeting in London in July of 2005 where the editors planned the massive work of consolidating all facets of the study of learning and memory. We collected nearly all the topics (albeit from many different disciplines and directions) that we considered constituted scientific approaches to learning and memory and proceeded to parcel the topics into four volumes, resulting in *Learning Theory and Behavior* edited by Randolf Menzel; *Cognitive Psychology of Memory* edited by Henry Roediger III; *Memory Systems* edited by Howard Eichenbaum; and *Molecular Mechanisms of Memory* edited by David Sweatt. This was a formidable task, not only because of the richness and diversity of the subject matter, but also because we needed to logically place topics in the appropriate volume. Although some of the decisions may seem arbitrary, and indeed there is overlap both within and between volumes, each editor ended up with a set of coherent topics that they could organize and introduce in a logical manner.

With approximately 40 chapters per volume, it is no surprise that the editors cover an unusually wide range of intellectual territory or that there is a difference in interpretation by some authors. The organization is a significant editorial challenge and investment in and of itself. However, it is the editor's selection of authors, and the ensuing scholarship on learning and memory from different perspectives, that make this series unique. Authors were identified and invited based on their expertise on a particular topic, and their contributions represent a marvelous compendium of research in learning and memory. The chapters in this series not only represent scientific strength and breadth, but also range from learning at the synaptic level to a systems level approach, and include studies of remarkable learning capabilities in a variety of invertebrates and vertebrates, including human beings.

The first volume in the series, *Learning Theory and Behavior* edited by Randolf Menzel, consists of 38 chapters and sets the tone for the interdisciplinary and comparative approach to the study of learning and memory. He introduces the volume by emphasizing both the value and the limitation of the comparative approach in natural and laboratory settings, stressing that we need information from the behaving animal as well as the neuronal

structures in order to understand the processes involved in information storage and retrieval. Several chapters review progress from using animal models, including worms, molluscs, insects, rodents, birds, and nonhuman and human primates. In addition, concepts such as planning, decision-making, self-awareness and episodic-like memory, usually reserved for human beings, are discussed at several taxonomic levels. The final chapters take an engineering perspective and describe synthetic approaches, including modeling neuronal function and developing a concise theory of the brain.

The second volume, *Cognitive Psychology of Learning* edited by H. Roediger, is comprised of 48 chapters on various aspects of cognitive ability and the underlying neuroscience. The basics of attention, working memory, forgetting, false memories, remembering vs. knowing, the process of recognition, and episodic memory are covered. In addition, topics that are often not included in "memory" volumes deservedly receive attention here, e.g., learning of concepts and categories, learning of perceptual and motor skills, language learning, and implicit learning. This volume also covers memory processes throughout the human lifespan and includes chapters on individual differences in memory ability, both subnormal (learning disabilities) and supranormal (performance of mnemonists and experts in particular domains). Finally, chapters on applied aspects of memory research, dealing with such topics as eyewitness identification in the legal system and applications of research to educational issues, are included.

Volume 3, edited by H. Eichenbaum, consists of 29 chapters which represent a "progress report" on what we know about memory systems and their relationship to different parts of the brain. *Memory Systems* returns to a comparative approach of learning and memory. This volume introduces the concepts of multiple memory systems, and many chapters discuss in extensive detail the different features of declarative memory and their underlying brain structures. Procedural learning in humans and other animals is addressed, and a short section details the involvement of hormones and emotions on memory retention or loss. Finally, changes in memory systems associated with aging, disease processes, and drug use are addressed.

The final 42 chapters in Volume 4, *Molecular and Cellular Mechanisms of Memory* edited by J.D. Sweatt, represent a review of the state of the science of what we know at the systems, cell, and molecular levels on learning and memory formation, as well as providing a look at the emerging and future areas of investigation. Once again, this volume covers an impressive amount of information derived from studies at many taxonomic levels, from molecular associative learning mechanisms, through an array of studies on synaptic plasticity, to the cell level of fear conditioning.

The centrality of learning and memory to our daily lives has led to intense analysis by psychologists and neurobiologists for the past century, and it will undoubtedly remain at the forefront of research throughout this new century as well. It is our intention that this set of volumes will contribute significantly to the consolidation of this field, and it is meant as a resource for scientists and students interested in all facets of learning and memory. No other reference work covers so wide a territory and in so much depth.

Learning and Memory: A Comprehensive Reference would not have been possible without the tremendous work of the Editorial Board, who identified the topics and their authors, and reviewed each contribution. Special thanks also go to Johannes Menzel, Senior Acquisitions Editor at Elsevier, for supporting the project and Andrew Lowe and Laura Jackson, Production Project Managers, and Joanna De Souza, Developmental Editor, for ensuring that the production schedule was maintained.

1.01 Introduction and Overview

R. Menzel, Freie Universität Berlin, Berlin, Germany

1.01.1 Introduction

The central question of behavioral neuroscience is: What is the source of information that creates and controls perception, reaction, and action in animals and humans?

Since Plato and Aristotle, Western philosophy has found two opposing answers that still guide our thinking today. Idealism proposes preexisting information unfolding as the organism develops, whereas empiricism states that all information is gathered by the interaction of the organism with the environment. As behavioral science developed into its modern form in the second half of the nineteenth century, these two philosophical approaches provided the epistemological framework for two different experimental approaches to animal behavior. Ethology emphasized the preexisting information inherited from the evolution of the species, whereas behaviorism, including Pavlov's physiology-driven approach, focused on collecting information through perception and action. Reference to idealism and empiricism gave these two opposing approaches a strong theoretical backbone, turning anthropomorphic descriptions of behavior and pure collections of observations into hypothesis-driven science. Ethology benefited from Darwin's theory of evolution that provided a conceptual framework for the accumulation and transmission of information, while behaviorism gained from the strength of laboratory-based experimentation and suitability for formal descriptions (*See* Chapters 1.03, 1.06). Although the history of the two behavioral science disciplines is a success story, we also know of their limitations and their failure to capture the breadth of behavior. The dualistic (and initially exclusive) conceptualization of the two forms of information that drive behavior is not adequate to explain brain functions. Regardless of the source of the information stored in the brain, it is expressed in properties of the brain, the wiring of neurons, and the communication between them. The two historical disciplines in behavioral science also failed to develop concepts that included brain functions. Ethology relied too heavily on simple-minded models of brain function, whereas behaviorism eliminated any reference to the brain.

In the end, behavior needs to be explained by underlying body functions, with the brain as the most important player in this game. Where are we now in such an attempt? This volume deals with behavior, theory, and system functions of the brain. Although cognitive neuroscience and the "emergent new science of mind" (Kandel, 2006) offer novel levels of integration between behavioral science and neuroscience, we still have a long way to go. The chapters in this volume should contribute to this exciting endeavor.

1.01.2 Biology of Learning and Memory: The Value of a Comparative Approach

Learning from experience is a property embedded into the survival strategies of all animals living in natural surroundings. Animal species live in different ecological niches, are equipped with different sensory and motor capacities, and communicate differently with other individuals of the same species and with other species (*See* Chapters 1.17, 1.20, 1.21, 1.22, 1.26, 1.31). They also come with different nervous systems, which can be large or small, and some are highly centralized, while others have several rather separate ganglia. There is no one model animal for this research

endeavor, and different animal species have different advantages. One species can be reared more easily in the lab, another has a better-worked-out toolbox of molecular genetics, another provides for large and identifiable neurons or allows recordings from multiple neurons simultaneously over long periods of time, while another has already been analyzed in a wide range of behavioral tests. The main goal of this research is to unravel the general rules and species-specific adaptations in selecting relevant information, adding it to existing knowledge, storing it such that passing time does not eliminate it, and making it available for better-adapted behavioral acts in the future. Comparative studies provide the tool for identifying generalities and specificities.

Observing animals in their natural habitat can suggest relevant research questions (*See* Chapters 1.17, 1.20, 1.21, 1.22, 1.23, 1.25, 1.26, 1.29). While we have ideas about what is worth observing and measuring, we need to be open-minded about unexpected outcomes, as these are often the discoveries that propel research. Food-storing behavior in birds and mammals (*See* Chapters 1.22, 1.23), communication via gestures and/or sound (*See* Chapters 1.16, 1.17) or by ritualized movements in bees (*See* Chapters 1.12, 1.25, 1.29), learning during courtship in *Drosophila* (*See* Chapter 1.28), and navigation (*See* Chapters 1.20, 1.21, 1.25, 1.26) are examples, and many more will be described in this volume. The animal species studied are varied: Worms (*Caenorhabditis elegans*; *See* Chapter 1.32), mollusks (*Aplysia, Limax, Lymnea, Hermissenda*; *See* Chapter 1.30), cephalopods (octopus, *Sepia*, *Loligo*; *See* Chapter 1.31), insects (*Drosophila*, *See* Chapter 1.28; the honeybee *Apis*, *See* Chapters 1.12, 1.25, 1.29), rodents (e.g., mice, rats, squirrels, chipmunks, deer mice, Merriam's kangaroo rats; *See* Chapter 1.22), birds (e.g., Clark's nutcrackers, Eurasian nutcracker, marsh tits, black-capped chickadees, pinyon jays, Mexican jays, Western scrub jays, willow tits, crested tits, many song-learning bird species, the oscines of the Passeriform birds; *See* Chapters 1.17, 1.22, 1.23), and primates (chimpanzees, orangutans, macaques, vervet monkeys, baboons, capuchin monkeys, and pygmy marmosets; *See* Chapter 1.16), including human beings. Each of these species provides us with the opportunity to discover novel ways of solving similar problems brought about by an ever-changing environment and to unravel general strategies by comparison.

The transition from the natural habitat to the laboratory is an essential step in hypothesis-driven behavioral research, but is by no means a simple step (*See* Chapter 1.11). We cannot expect to get full control over the animal, which is sometimes a misleading assumption in some of the behavioral studies (*See* Chapters 1.03, 1.06, 1.10, 1.18). However, the history of an individual's experience can be traced more accurately in the laboratory, and the proper control experiments can be established. The chapters in this volume provide ample evidence for successful transition from the natural environment to the laboratory.

Often an additional and more critical step is required. Animals need to be constrained for physiological measurements, or they are genetically manipulated to isolate cellular components of neural function. It is essential to remember that constrained animals or genetically manipulated animals are no longer the living creatures that we observed in their natural environment, and they are not even those seen in the laboratory behavioral tests. It might not matter so much whether a nutcracker caches a nut in the bark of a tree or in a plastic Lego building block, but it will make a great deal of difference whether a chimpanzee learns to move between tree branches or is sitting in a training chair connected to amplifiers while performing stereotypical arm movements. It is true that in most cases we do not yet have alternatives attempting to relate neural function with behavioral performance, but while presently there are no better experimental tools of neural recording, we must not forget the distance between the natural conditions and the experimental surroundings where we collect data.

Invertebrates such as the nematode *C. elegans* (*See* Chapter 1.32), the mollusks *Limax* or *Aplysia* (*See* Chapter 1.30), the fly *Drosophila* (*See* Chapter 1.28), and the bee *Apis* (*See* Chapters 1.25, 1.27, 1.29) are of particular value in laboratory settings since the transitions from natural to laboratory to experimentally interfering conditions presumably impact them less. Intermediate transition steps from natural to laboratory conditions can be made more easily, and the behavior of these invertebrates appears to be controlled more strongly by innate components. Nevertheless, transgenic nematodes and flies are not normal animals with just one isolated function that has been modified. It is, therefore, very advantageous that transgenes in *C. elegans* and *Drosophila* can be switched on and off rather quickly, and even more important, can be genetically rescued, which allows us to test the isolation of the targeted effect very carefully. Transgenic mice are by far more complicated to analyze, and special care must be taken in interpreting their behavioral alterations.

Many questions about learning and memory cannot be moved into the laboratory, and these may often be the particularly interesting questions (*See* Chapters 1.16, 1.22). This has two consequences: (1) The data are correlational in nature as control groups often cannot be studied or serve as partial controls and animal manipulations are very difficult or impossible, and (2) recording brain functions is difficult or impossible. These limitations should not reduce our efforts to collect data under natural conditions, as these data are essential for future laboratory studies and for comparative studies in humans.

A comparative approach should include human beings, and the motivation of many animal studies is to better understand humans. This is justified if appropriate caution is taken and the general limitations of a comparative approach are observed. Both ethology and behaviorism carry their historical burdens regarding inappropriate generalizations between animals and humans (*See* Chapters 1.03, 1.10), but cognitive neuroscience offers tools and strategies that help to guide such comparisons. If processes and mechanisms have been identified that apply across animal species, they are less likely to be species-specific adaptations and can safely be generalized to humans (e.g., cellular and molecular processes of neural plasticity as discussed elsewhere in this work, or basic rules of associative learning (*See* Chapters 1.05, 1.06, 1.09, 1.10, 1.11, 1.18)). The involvement of homolog brain structures for related forms of learning and/or memory formation are strong hints for homolog function. The hippocampus (e.g., in the case of spatial learning and episodic-like memory) and the amygdala (e.g., in fear learning) are two examples, and many more will be found in the chapters of this volume (*See* Chapters 1.14, 1.15, 1.21, 1.22, 1.23). Comparison between animals with very different brain structures (e.g., mammals and insects) is much more difficult, and often no more than analog functions can be assumed (e.g., navigation according to a geometric representation of space, different forms of memories according to their time course, and susceptibility to experimental interference).

One of the most important and controversial issues related to comparison between animals and humans relates to language and self-awareness (*See* Chapters 1.15, 1.16, 1.23, 1.37, 1.38). Although language acquisition has deep biological roots, the relation to nonverbal or acoustic communication in monkeys is not yet understood (*See* Chapter 1.16). The neural requirements of self-awareness exist in animals (*See* Chapters 1.37, 1.38), but it is not clear whether additional neural functions are required for the human form of self-awareness. The case of episodic memory, as discussed in several chapters (*See* Chapters 1.21, 1.22, 1.23), is a particularly interesting example because essential features of knowledge about what happened, when it happened, and where it happened exist at different degrees of complexity in many animal species (e.g., in the honeybee; *See* Chapters 1.12, 1.25, 1.29). Food-storing birds appear to relate these memories to themselves and appear to expect to find food at that location in the future (*See* Chapter 1.23), showing a capacity that is close to personal recollection in humans. Salwiczek et al. (*See* Chapter 1.23) call this memory episodic-like and see a gradual, rather than a principle, difference with the introspective experience of mental time travel in humans. This pragmatic approach might be exemplary in the sense that other human mental functions could also be broken down into additive features, which could then be tested for their existence in animals in various combinations and complexities. However, the demonstration of the existence of the components does not prove that the full function of a cognitive faculty as observed (or personally experienced) in humans exists in a particular animal species. Nevertheless, the strength of this approach lies in the assumption that there are no categorical differences between animals and humans, and gradual differences can be traced to different performances according to the complexity of the elements found. An example could be dance communication in honeybees (*See* Chapters 1.12, 1.25, 1.29). The bee communicates a location, and depending on the context, the dance might indicate a feeding place, a water or resin resource, or a new nest site. Although the communication process is symbolic and has a vocabulary (although a very reduced one) and a form of syntax (context-dependence), it does not qualify as a language because it lacks essential features, for example, semantics and grammar. One might call it language-like, as one might categorize other symbolic indexical forms of communications, but the point is that a research program can be set up by this decomposition strategy which allows scientists to search for the related neural processes of the components rather than the mental faculty as a whole. It appears to me that a similar research strategy is proposed by Changeux and Dehaene (*See* Chapter 1.38) in their attempt to decompose conscious processing and learning. They propose a unified or global workspace for the neural synthesis of past, present, and expected experiences. Such research approaches are promising because they

avoid the epistemological deadlock connected with the preoccupation of a categorical separation between animals and humans (MacPhail, 1998) or the assumption of equality between the animal mind and the human mind (Griffin, 1984).

1.01.3 Theories, Processes, and Mechanisms

Animal learning theory has been a rich research area over the last 60 years or so, and we may ask whether some of its concepts might join with physiological studies for a better understanding of the underlying processes. Theories derived from associative forms of learning have been elaborated the most (*See* Chapters 1.03, 1.06, 1.09, 1.10, 1.18), and it appears that three concepts are most useful in a search for functional implementations: associative strengths, associability, and prediction error (Dickinson, 2007).

1. Associative strength between two elements (stimulus or response) depends on the history of experience and the stimuli/responses involved and controls both acquisition and retrieval of memory. Although different behavioral theories compete for the best way of capturing the essence of associative strengths (e.g., Rescorla and Wagner, 1972; Pearce and Hall, 1980; Bouton, 1994; *See* Chapters 1.03, 1.06, 1.09), it is not yet clear whether unidirectional or bidirectional associations predict the relations between the elements. Neuroscientists are more than prepared to absorb this concept and translate it into processes of neural plasticity. Donald Hebb (1949) proposed such a neural implementation, and it is widely accepted that synaptic strength is closely related to associative strength (*See* Vol. 4). Long-term potentiation and long-term depression are processes that are based on the accurate timing of neural activity in the pre- and postsynaptic elements of neural nets (*See* Chapter 1.34).

The coincidence of spike activity as a means of modulating synaptic efficiency appears to play a role not only between pairs of pre- and postsynaptic neurons, but also in networks of many neurons. Singer (*See* Chapter 1.37) points out that coherence of spike activity is an essential feature of cortical nets in up- and downregulation of learning-related neural plasticity. It will be important to show that spike synchrony in biological networks is an emergent property similar to artificial networks (*See* Chapter 1.34) and to establish the causal relationship between these global network characteristics and learning. Since small networks composed of identified neurons do not depend on spike coherence in a global sense to establish associative changes in synaptic efficacy (e.g., in mollusks; *See* Chapter 1.30), it will be interesting to search for additional qualities of synchronizing neurons. Such additional qualities could lie in the fact that the three components of memory (formation, retrieval, and consolidation) are so tightly connected that only under conditions of synchronized activity are all three memory components activated. New contents can only be stored in distributed brain regions which jointly reorganize the network according to the new information.

2. Associability is another concept developed in behavioral learning theory that promises to be useful in neural studies. The concept captures the properties of the stimuli and/or outcomes that determine associative strengths as they are reflected in the salience of the stimulus, the predictability or surprise value of a stimulus, or the outcome. Cognitive dimensions of operant learning (*See* Chapters 1.06, 1.10) or perceptual learning (*See* Chapter 1.07) involve attention as a critical parameter of learning (*See* Chapter 1.13), a parameter that can be traced to particular structures (e.g., cholinergic projections from basal ganglia, amygdala, and the septohippocampal system).

3. Prediction error: Learning theories state that learning occurs as long as the outcome of a behavior is not fully predicted, and thus the deviation of the expected from the experienced outcome changes the current associative strengths. Behavioral theories differ with respect to their assumption of whether the error affects associative strength directly (e.g., Rescorla and Wagner, 1972; Mackintosh, 1975) or indirectly (Pearce and Hall, 1980). The implementation of the prediction error into machine learning (Sutton and Barto, 1990) has been very successful (*See* Chapters 1.34, 1.36), and strong neural correlates exist: for example, the neural properties of reward neurons (dopamine neurons of the mammalian ventral tegmentum (Schultz, 2006) and octopamine VUMmx1 neurons in the honeybee brain (Hammer, 1992; Menzel and Giurfa, 2001)).

When dealing with learning, several chapters in this volume draw their underlying concepts from both behavioral and neural data to document that the strongest expectations for an understanding of processes and mechanisms come from collecting experimental data from both behavioral and neural studies (Dickinson, 2007). How far will such a hybrid theory and understanding lead us?

Forty years ago, Kandel and Spencer wrote a seminal paper entitled "Cellular neurophysiological approaches in the study of learning," calling for a novel approach in translating basic psychological concepts of learning into strategies for the search for their neural implementations (Kandel and Spencer, 1968). Less than 20 years later, Hawkins and Kandel (1984) presented a first review on their finding on *Aplysia* associative and nonassociative learning and derived neural components comprising a cellular alphabet of learning (*See* Chapters 4.01, 4.02). This strategy has turned out to be most successful in localizing in space and time neural events induced by learning. It appears that the associative events are distributed, multifaceted, and dependent both on innate predispositions and earlier learning. *Drosophila* provides a particularly carefully studied case (*See* Chapter 4.07). Different neural structures are involved in learning the same odor by reward or punishment, and short- and long-term memories of the same content reside in different neural nets. Localizing the memory trace is an important step in a functional analysis.

A major unresolved issue in both behavioral and neural studies is the relationship between learning with and without external reinforcing or evaluating stimulus. As pointed out above, concise behavioral theories have been developed for Pavlovian and instrumental conditioning, but perceptual learning (*See* Chapter 1.07), navigational learning (*See* Chapters 1.12, 1.20, 1.25), and interval learning (*See* Chapter 1.19) provide cases in which no obvious external reinforcer may be present. Is associative learning a special case of a more general form of learning (the learning of temporal sequences; *See* Chapter 1.12), or is every kind of learning associative? Does an internal reinforcer provide the evaluating function in the latter forms of learning? Learning theory has not settled the debate, and it might well be that functional analysis will show that internal reinforcing circuits are active at the proper time when animals learn by observation. An important component in such forms of learning is attention (*See* Chapters 1.13, 1.36), as is assumed in a modeling study of navigational learning in the honeybee (Montague et al., 1995).

Only selectively attended stimuli are learned. Most importantly, modulatory circuits that appear to be involved in coding evaluating stimuli also participate in selective attention. It will be necessary to build conceptual bridges between the concept of associability as developed in theories of associative learning and the evaluating property of directed attention as described in observational learning. Further advances will only be made with the combination of behavioral and neural approaches.

1.01.4 What Is Memory and What Is a Memory Trace?

The many facets of memory are reflected in the many terms used to capture them (*See* Chapters 1.02, 1.04). Are there 256 different kinds of memory, as Tulving (1972) asked? Irrespective of whether we divide up memories according to time, cellular mechanisms, brain structures involved, categories of contents, type of learning, or type of retrieval, we always imply that memory directs behavior via the process of retrieving information. As pointed out at the beginning of this chapter, brains are equipped with information before, and independent of, acquired information. Thus the content of memory provides a knowledge base for behavioral guidance (including perception, planning, expecting, and thinking), and splitting it up may obscure the basic and unifying property of memory. One question that needs to be asked, then, is: How do we go about measuring the knowledge stored in memory? We do not know, and this ignorance might be one of the reasons why so much emphasis is placed on the need to define memory by retrieval processes (*See* Chapters 1.02, 1.04, 1.12, 1.14, 1.15, 1.24). As long as measurement of memory content is based only on retrieving it from memory, we will not be able to separate stored memory from used memory.

Nadel (*See* Chapter 1.04) quotes from Aristotle's *Ars Memoria*: "It has already been stated that those who have a good memory are not identical to those who are quick at recollecting. But the act of recollecting differs from that of remembering, not only chronologically, but also in this – that many of the other animals (as well as man) also have memory, but of all that we are acquainted with, none, we venture to say, except man, shares in the faculty of recollection." Indeed, the distinction between memory and recollection is multifaceted (*See* Chapters 1.02, 1.04, 1.05, 1.14, 1.15, 1.24), and one of the most important distinctions relates to memory formation versus memory retrieval. Behavioral measures, as well as human subjective introspection, reach memory via retrieval, but the postlearning reactivation process can work only if learning left traces in the form of an engram. Since the process of memory formation is

not directly accessible to behavioral studies, it has been seriously questioned from a behavioral analytical perspective, in terms of whether it makes sense to distinguish between memory as an entity independent of retrieval (*See* Chapters 1.04, 1.05). The notion of a physical memory trace, independent of its use, however, is a central presumption in neuroscience. Indeed, only when neurologically related interference procedures were introduced into memory research did a clear separation between memory formation and memory retrieval become possible. The key discovery in this context was the consolidation process.

Does a memory exist if it is not retrieved? This question is addressed in several chapters in this volume, and rather diverse opinions are expressed. If the knowledge stored in memory does not guide behavior, a behavioral biologist cannot know whether memory exists (and may thus define memory by its retrievability). But a neuroscientist cannot help but assume that the knowledge stored in memory continues to exist during time periods when it is not retrieved, because the physiological measures of memory are independent of whether the animal performs the corresponding behavior. The concept of memory consolidation is essential in this debate. Hermann Ebbinghaus (1964) described a fast and a slow component in forgetting, and William James (1890) proposed that these may be related to two forms of sequential memories: Primary and secondary memory. The concept of consolidation as a time-dependent process following learning was introduced by Müller and Pilzecker (1900) on the basis of their finding that new learning interfered with the formation of recently acquired memory for short, but not for long intervals. At this stage of analysis, a separation between an internal, time-dependent, and self-organizing process of memory formation and retrieval of memory was not possible, but when experimental interference was introduced and neurological cases of retrograde amnesia were analyzed, strong arguments in favor of an independent engram-building process could be presented (*See* Chapters 1.14, 1.15). However, the situation is not as simple as was believed (*See* Chapters 1.04, 1.05). For example, amnesia-inducing procedures could have led to competing learning processes. Irrespective of the unresolved questions in separating memory formation and memory retrieval processes, the body of evidence is overwhelming, proving that neural traces are indeed induced by the learning process independent of retrieval, and consolidation has a physical basis in the structuring and restructuring processes of neural net properties.

Procedures interfering with ordered neural activity or cellular metabolism during periods of consolidation induce retrograde amnesia. Memory gets better over time, even when it is not used. Sleep phases strengthen the consolidation process (Born et al., 2006) and are related to repetition of content-specific patterns of neural activity (Wilson and McNaughton, 1994). It appears to me that the debate about the nature of the memory trace (*See* Chapter 1.04) will continue as long as we cannot read the encoding processes and directly measure knowledge stored in neural nets. Once we can show these in suitable animals such as *Drosophila*, we will probably discover that, in addition to the constructive processes of reactivating memory and using its content, there is an essential component that exists independent of the reactivation process. Whether we like to call this lasting component memory is a question of definition.

Reactivation of memory leads to new learning and its subsequent consolidation processes (*See* Chapter 1.09). Only recently has neuroscience become interested in the mechanistic aspects of extinction learning and memory formation. The phenomena subsumed under the term reconsolidation provide case studies (*See* Chapters 1.24, 1.27). Reconsolidation refers to the effect that retrieving memory may lead to cue-dependent amnesia if the retrieval process is followed by treatment with an amnestic agent. What are these learning and reconsolidation processes? Does reactivation indeed make the old memory trace vulnerable to amnestic interference, indicating that new learning overwrites old memory, or do the learning processes involved in memory reactivation induce parallel consolidation processes that reflect the addition of a new memory trace to the existing one? The ongoing debate reflects the same dilemma addressed above. Our inability to measure knowledge as stored information directly restricts our mechanistic analysis to global and indirect arguments. Once again, behavioral analysis needs to be combined with fine-grained neural analysis addressing the critical question much more directly at the level of the neural elements of the engram.

What might be a suitable strategy toward a direct reading of knowledge? A first step should be to develop criteria that allow us to identify and localize a memory trace. Heisenberg and Gerber (*See* Chapter 1.28) address this question by defining four essential requirements of a memory trace:

1. Neuronal plasticity occurs in particular neurons that are localized and identified, and these neurons are essential for a particular kind of memory.
2. The neuronal plasticity in these neurons is necessary for this particular memory context.
3. Memory cannot be expressed if these neurons cannot contribute during retrieval.
4. Memory cannot be established if these neurons do not receive the required input for the memory content to be stored.

Note that this checklist of experimental procedures does not yet provide us with access to information stored in the memory trace, but we can hope that in a next step a localized and thus-characterized memory trace will be accessible to the really important question of how neural circuits encode and store particular pieces of information. So far only one organism, *Drosophila*, offers the opportunity to localize and characterize a memory trace at the level of cellular resolution, and, indeed, in applying this strategy to rather small neural circuits it was found that traces for short-term memory of an olfactory discrimination task and long-term forms of the same memory content appear to be localized in different, probably partially overlapping neural circuits. Furthermore, it was found that memory traces of appetitively or aversively evaluated stimuli of the same kind occupy different but partially overlapping neural circuits (*See* Chapter 1.28).

A whole battery of highly sophisticated molecular–genetic tools are available to measure the spatial–temporal patterns of memory traces in selected neurons and neural nets of the *Drosophila* brain (Keene and Waddell, 2007). Reading the dynamics of the neural elements during the learning process (i.e., consolidation and retrieval under conditions in which the animal tells us via its behavior whether it perceives, attends, and retrieves) will help us understand at least part of the knowledge stored in memory. How close are we then to direct knowledge reading?

Localizing and characterizing the memory trace by applying correlation analysis is the mainstream of the neuroscience approach today (*See* the volumes edited by Sweatt and Eichenbaum). Correlating elemental with system properties is an important step in any mechanistic analysis. The next step will be to establish closer, possibly causal, links following the strategy outlined by Heisenberg and Gerber (*See* Chapter 1.28). The tools also exist for the worm *C. elegans* (*See* Chapter 1.32) and are becoming available step by step for other species (e.g., the mouse). The hunt for direct knowledge reading will be embedded in a concerted approach to understanding the workings of neural nets and the brain as a whole.

1.01.5 The Engineer's Approach to Learning and Memory

Engineers compose and biologists de-compose, so a combination of these two strategies should be favorable to the study of a complex system such as the brain. Constructive thinking in theoretical neuroscientists is inspired by rules derived from behavioral studies (e.g., Hebb's rule), by the morphology of brains and the connectivity patterns of neurons (e.g., the matrix-like connectivity in the hippocampus), by the functional properties of neurons (e.g., synaptic plasticity), and by theoretical concepts developed independently from, but motivated by, thoughts about how the brain might work (e.g., autoassociative or attractor networks). Our volume contains chapters dealing with all of these aspects (*See* Chapters 1.33, 1.34, 1.35, 1.37, 1.38). Irrespective of the intellectual pleasure one experiences when thinking about theoretical neural nets, one might ask how the joint efforts propel our understanding. I see the following points that are also well-illustrated in the respective chapters:

1. Hypothesis-driven research like ours requires well-formulated concepts and hypotheses. Theories developed for neural nets shape these concepts and allow us to formulate predictions (*See* Chapters 1.33, 1.35).
2. The analysis of the vast amounts of data collected by anatomical, electrophysiological, optophysiological, and molecular studies requires the contribution of theoretical neuroscientists to extract relevant information and interpret it (*See* Chapters 1.34, 1.37).
3. There exists no concise theory of the brain. Global brain functions need to be constructed from elemental and network functions and implemented into a model (e.g., the neuronal workspace model of Changeux and Dehaene; *See* Chapter 1.38).

At any of these levels of a modeling approach, one has to decide what is considered an essential feature and which of the many characteristics of the neurons, their connectivity at the local and the global level, are implemented or not. Should one use simplified integrate-and-fire neurons or Hodgkin-Huxley-type neurons? Should the model care about the real gestalt of neurons or not? How seriously should one take the

neuroanatomical data on local and global connectivity? These and many other decisions are hard to make, and different choices produce serious debates about the suitability of these models. There are many measures of suitability: Are experiments stimulated, predictions offered, and interpretations of data supported or rejected? Five chapters (*See* Chapters 1.33, 1.34, 1.35, 1.37, 1.38) provide a range of examples where strong arguments can be presented for the suitability of the respective models and experimental approaches are suggested. Other examples are given in Vol. 4 that deal with small neural nets partially composed of identified neurons (*See* Chapter 1.30). Indeed, small biological neural nets (e.g., the stomatogastric ganglion in the lobster) have been successfully modeled, and the models in the electronic version were directly hooked up with the biological neural net to analyze the contribution of certain cellular properties (Golowasch et al., 1999). These approaches have been applied in the search for the neural implementation of operant learning in the buccal ganglion of *Aplysia* (Brembs et al., 2002; Vol. 4; *See* Chapter 4.10).

Given the technological advances with the expression of light-driven conductances in specified neurons (e.g., channel rhodopsin), similar analyses will be possible (e.g., in *Drosophila*; *See* Chapter 1.28), which emphasizes the need for theoretical concepts and models of the respective networks.

Ultimately, models of neural function should also predict behavioral outcomes. Singer (*See* Chapter 1.37) makes the case for the role of spike synchrony and oscillatory spike patterns in memory formation. Koene and Hasselmo (*See* Chapter 1.35) formulate predictions for the role of theta rhythm in the hippocampus for memory formation and retrieval, and Rolls (*See* Chapter 1.33) explicitly characterizes the properties of the autoassociative network of the hippocampus for behavioral phenomena such as completion and graceful degradation. It is to be expected that the success of the combined theoretical and experimental approach will make modeling an indispensable part of the search for the memory trace.

1.01.6 Conclusion

Curiosity-driven behavioral studies, theory-guided laboratory behavioral experiments, and modeling of neural functions define a unique workspace in the search for the engram. Joining forces will help, and the chapters presented here will hopefully facilitate communication between these disciplines. The task is indeed demanding, because the goal will not only be to localize and characterize the memory trace, but to measure the knowledge stored in the memory trace independent of and in addition to the behavioral read-out process.

1.02 A Typology of Memory Terms

H. L. Roediger, III, F. M. Zaromb, and M. K. Goode, Washington University in St. Louis, St. Louis, MO, USA

1.02.1 Introduction

The English language provides us with the term memory to denote several interrelated ideas, such as 'the power of the mind to remember things' or 'something remembered from the past; a recollection' (both quotes are from the Oxford American Dictionary). These definitions of memory are fine for everyday conversation and communication, but scientists interested in studying the biochemical, neural, or psychological underpinnings of this topic have found the need to describe many distinctions about memory that laypeople do not use. Such a need is further underscored by a growing interest in interdisciplinary approaches to the study of human memory (*See* Chapters 3.05, 3.06, 3.14) and in adapting cognitive research paradigms to the study of nonhuman animal learning, an area that has developed largely in isolation of the human memory research tradition (e.g., Wright, 1998; Wright and Roediger, 2003; *See* Chapters 1.04, 1.13, 1.14, 1.15, 1.21, 1.22, 1.23). This chapter is intended to explain the meaning of some of the most popular terms that have been contributed to the literature.

We aim to paint with a fairly broad brush and not to get involved in matters such as whether one term (say, implicit memory) is to be preferred to another term (indirect memory), although buckets of ink have

been spilt on these matters. Rather, we intend to provide general definitions and meanings of terms without defending them as theoretically critical (or not). In this sense, the chapter is descriptive rather than theoretical, although we fully understand that by choosing one's terms and their definitions, one implicitly adopts a theory.

How many types of memory are there? In the early 1970s, Tulving wrote: "In a recent collection of essays edited by Norman (1970) one can count references to some 25 or so categories of memory, if one is willing to assume that any unique combination of an adjectival modifier with the main term refers to something other than any of the references of other such unique combinations" (Tulving, 1972: 382). Tulving added two more terms (episodic memory and semantic memory) in that chapter. Yet more important for present purposes, Tulving continued to keep a list of memory terms as he encountered them. Thirty-five years later, Tulving (2007) wrote another chapter entitled "Are there 256 different kinds of memory?" which was the number of combinations of the adjective + memory sort that he had collected by that time. The list goes from abnormal memory (at the beginning), through terms such as diencephalic memory and false memory, then on to rote memory and sensory memory, and finally, at the end of the list, to working memory. (There are 250 others.)

We hasten to add that we are not going to cover 256 kinds of memory in this chapter. We aim to provide a lexicon of some of the primary terms that readers will find in the four volumes of *Learning and Memory: A Comprehensive Reference*. We have tried to weave the terms together in a loose sort of story, so as not to provide just a glossary with a long list of terms and definitions. The story is one conception of the varieties of memory provided elsewhere (Roediger et al., 2002). We try to give a verbal definition of each type of memory we chose to include, as well as a practical example of how the type of memory might operate in a person or other animal, and we usually point to a paradigm by which this type of memory is studied, to provide kind of an operational definition.

The reader will notice that in some cases the same memory term (e.g., episodic memory) may refer to a process, entity (e.g., memory trace), system, mental state of awareness, or type of cognitive task, depending on the context. Such linguistic flexibility can easily lead to confusion, so we attempt to distinguish among different uses of each term where appropriate. The index of the book can be used to glean other uses of the term. In addition, semantic confusion can easily arise from the types of metaphors employed to describe a memory concept. Most cognitive psychologists use a spatial metaphor in which memories are conceived as physical entities stored in a mind space, and the act of remembering involves searching through the mind's space in order to retrieve the objects of memory (e.g., Roediger, 1980; Tulving, 2000; *See* Chapters 1.04, 1.05). In contrast, others have proposed nonspatial metaphors that make analogies to concepts such as strength – memories are comparable to muscles whose strengths are directly related to performance on memory tasks (e.g., Hull, 1943); construction – the act of remembering involves constructing memories from available information (e.g., Bartlett, 1932); depth of processing – memory is a by-product of the level of perceptual analysis (Craik and Tulving, 1975; *See* Chapters 1.07, 1.08); or auditory resonance – memories are like notes played on piano keys or individual tuning forks resonating (e.g., Wechsler, 1963; Ratcliff, 1978), to list but a few. To reiterate, we do not mean to provide exhaustive coverage, but rather to paint with broad strokes and to represent the way memory terms are used by cognitive psychologists and others.

We begin with consideration of some general distinctions made among types of memory. We then turn to the idea that it is useful to catalog memories by their time course in the system (from brief sensory memories, to short-term conscious memories, to various sorts of long-term memory). Most work has been devoted to the various types of long-term memory that have been described, so this is the focus of the next section of the chapter. Inevitably, given our organization, there is a bit of repetition because we needed to cover the same term (say, episodic memory) in more than one context.

1.02.2 Broad Distinctions

This section of the chapter is devoted to consideration of several broad distinctions among forms of memory. We consider the issue of explicit and implicit memory, conscious and unconscious forms of memory, voluntary and involuntary retention, intentional and incidental learning and retrieval, declarative and procedural memory, and retrospective and prospective memory.

1.02.2.1 Explicit and Implicit Memory

Explicit memory refers to cases of conscious recollection. When we remember our trip to Paris or

recognize that some words occurred in a recent list, these are instances of explicit memory. In cases of explicit retention, people respond to a direct request for information about their past, and such tests are called explicit memory tests. On the other hand, on tests of implicit memory, people are asked to perform some task, and the measure of interest is how some prior experience affects the task. For example, take the simple case of the word elephant appearing in a long list of words. If subjects are given a recognition test in which they are instructed to identify words studied in the list (and to reject nonstudied words), then their choice of elephant as a studied word would represent an instance of explicit retention. However, if a different group of subjects were given the same set of words to study and then were given a word stem completion test (with instructions to say the first word that comes to mind to the word stem ele_____), then this would constitute a test of implicit memory. The relevant measure on this test is priming, the greater probability of completing the stem with elephant rather than other plausible words (element, elegant, electricity, etc.) when the word has been studied than when it has not been studied. For example, the probability of producing elephant to the word stem might be 10% if the word had not been studied in the list and 40% when it had been studied, which would constitute a 30% priming effect. One reason for believing that these two measures represent different forms of memory is that they can be dissociated by many experimental (and subject) variables.

Graf and Schacter (1985) introduced the terms explicit and implicit memory to the field. Explicit retention refers to most typical measures of retention that psychologists have used over the years (recall, recognition, and their variations), whereas implicit memory refers to transfer measures when people may not be aware of using memory at all (Jacoby, 1984). Some writers prefer the terms direct and indirect memory for this contrast, because explicit tests measure memory directly, whereas implicit tests are indirect measures. Schacter (1987) offers a fine historical review of concepts related to implicit memory.

1.02.2.2 Conscious and Unconscious Forms of Memory

Conscious and unconscious forms of memory refer to the mental states of awareness associated with remembering the past. Attempts to describe human memory in relation to consciousness hearken back to the early introspective tradition of experimental psychology and the writings of Wilhelm Wundt, Edward Titchener, and William James (e.g., James, 1890/1950), as well as the psychoanalytic tradition and especially the well-known writings of Sigmund Freud (e.g., Freud, 1917/1982). Less well known is the fact that in the very first experiments on memory, Ebbinghaus (1885/1964) devised a relearning/savings technique for measuring memory that could detect unconscious knowledge. In fact, Ebbinghaus preferred savings measures over the merely introspective techniques of recall and recognition, because these latter tests cannot, almost by definition, measure memories that are not conscious (Slamecka, 1985).

In contemporary studies of memory, conscious recollection refers to the subjective awareness of remembering information encountered in the past, a process that is likened to the experience of mentally traveling back in time (Tulving, 1985). Tulving has also termed this state of awareness autonoetic (self-knowing) consciousness. In contrast, a noetic (knowing) state of consciousness is the type of awareness associated with retrieving previously learned information, such as a geographical, historical, or personal fact, without recollecting details about the place and time in which that information was originally acquired. For example, noetic consciousness might characterize the experience of a person being asked to name the capital of Canada and who, after thinking for a bit, responds "Ottawa" without remembering when he or she last encountered or originally learned this fact. Autonoetic consciousness, on the other hand, is reflected by the person's ability to think back to and re-experience an episode, such as a visit to Ottawa.

Conscious recollection may be intentional and effortful, or it may occur without the intent to explicitly remember information relevant to a given memory task, as is the case with involuntary conscious recollection (e.g., Richardson-Klavehn et al., 1996). This term refers to the fact that one may suddenly be remembering some event from the past without ever having tried to do so. In some cases of patients with damage to the frontal lobes, they may experience confabulation, or the experience of conscious recollection occurring for events that never occurred. The patients believe they are having memories, but in many cases the events are preposterous and could not have occurred. Such cases are extremely rare yet do occur.

Unconscious retention may be observed in performance on tests of implicit memory where individuals indirectly demonstrate their prior exposure to the test material under conditions in which they do not consciously recognize the material. Tulving has referred to the state of awareness associated with unconscious retention as anoetic consciousness. Unconscious retention also occurs when subjects show savings in retention without being able to recollect the experience that gave rise to the savings, as Ebbinghaus (1885/1964) first pointed out.

1.02.2.3 Voluntary and Involuntary Retention

Voluntary retention refers to deliberate, willful recollection, whereas involuntary or incidental retention refers to recollection that occurs without conscious effort. Involuntary retention, as the name implies, refers to memories that arise in consciousness unbidden, with no conscious effort to recollect. For example, in studies of autobiographical memory (memory for events in one's life), voluntary recollections may be assessed by asking individuals to remember personal events in response to queries (e.g., recall a memory from your past that is associated with an automobile). The naturalistic study of involuntary memories can be achieved by asking individuals to keep a diary and jotting down memories that seem to come out of the blue, as it were, wherever and whenever they occur (e.g., Berntsen and Rubin, 2002; Rubin and Berntsen, 2003).

It should be noted, though, that acts of voluntary or involuntary recollection may not be entirely pure, and one may influence the other. For instance, a person's attempt to remember the details of a baseball game that occurred years ago might be influenced by his inadvertently remembering details of a more recent game. Or when engaging in a test of implicit memory, such as completing word fragments, a person might become aware of the fact that some of the target words were encountered during the study phase and, therefore, might intentionally think back to the study phase to help complete the test word fragments (Jacoby, 1991). In addition, as previously mentioned, one might experience involuntary conscious recollection whereby thoughts of a past event come to mind automatically, and it might take further reflection to realize how the memory came to mind (Richardson-Klavehn et al., 1996).

1.02.2.4 Intentional and Incidental Learning and Retrieval

1.02.2.4.1 Intentional and incidental learning

Intentional and incidental learning refer to whether or not people intend to learn material to which they are exposed. Of course, as we go about the world watching TV, driving, or reading the paper, we rarely say to ourselves: I need to remember this commercial on TV. Educational systems provide the main form of relentless intentional learning, although of course we all sometimes try to remember the name of a new acquaintance or the name of a book or movie someone recommended. In the laboratory, intentional or incidental learning is manipulated by instructions to subjects. In an intentional learning situation, an individual studies certain materials with the express purpose of remembering them at some later point in time. In an incidental learning task, the same materials might be provided but with an orienting task to induce some sort of processing of the material but without any instructions concerning a later memory test. For example, in a standard levels-of-processing manipulation (e.g., Craik and Tulving, 1975), a person might be shown a list of words and asked to judge whether each word (e.g., BEAR) is presented in capital letters (graphemic or structural processing), whether it rhymes with a certain word like chair (phonemic processing), or whether it fits into a certain category such as animals (semantic processing). Subjects in incidental learning conditions would be told that the researchers are interested in studying the speed with which people can make such decisions. In the intentional learning conditions, they would be told the same rationale, but would also be told that their memory for the words will be tested later.

The natural expectation is that material studied under intentional learning conditions is better retained than under incidental learning conditions, and this outcome is sometimes obtained (Postman, 1964). However, at least when semantic orienting tasks are used, the differences between incidental and intentional learning conditions are surprisingly slight and often there is no difference at all (Craik and Tulving, 1975; Hyde and Jenkins, 1969).

1.02.2.4.2 Intentional and incidental retrieval

Just as intentionality can be manipulated during study of materials, so can it be manipulated during

testing. In fact, the distinction already drawn between explicit and implicit memory tests can be cast in this light. Explicit tests require intentional retrieval, but implicit tests reveal incidental retrieval (Jacoby, 1984). Under intentional retrieval conditions, a person is asked to engage in conscious, deliberate recollection of a past event (e.g., recalling a word from a previously studied list that completes a word stem). By contrast, incidental retrieval involves giving people the same word stem with the instruction to write the first word that comes to mind. Incidental retrieval is indexed by priming, the better performance in completing the stem with the target word relative to a control condition in which the word had not been studied.

As noted, the comparison between intentional and incidental retrieval is not necessarily a pure one, because performance on explicit memory tests may be affected by incidental retrieval just as performance on implicit memory tests can be influenced by intentional retrieval (Jacoby, 1991). Several solutions exist for attempting to gain leverage on this issue. Schacter and his colleagues (1989) proposed the retrieval intentionality criterion to test for the contamination of incidental retrieval measures by conscious recollection. The basic idea is to compare incidental and intentional recollection, holding all other study and test conditions constant. If performance differs markedly between the two tests when all conditions are held constant except for instructions just prior to the test, then one can have greater confidence that they measure intentional (conscious) and incidental (automatic or unconscious) retrieval. Roediger et al. (1992) crossed intentional and incidental study and test conditions with other variables and showed that incidental tests reflected quite different patterns of performance from the intentional tests. Jacoby (1991) proposed a different method, the process dissociation procedure, to separate conscious from unconscious influences during retrieval. Although providing the details of his ingenious method is outside the scope of this chapter, his method has proved extraordinarily useful in separating conscious from unconscious (or automatic) cognitive processes.

1.02.2.5 Declarative and Nondeclarative Memory

Declarative memory and nondeclarative memory (sometimes referred to as procedural memory) are terms that have gained prominence following their use by Squire (1982), although the original distinction was proposed by Ryle (1949). Ryle distinguished between declarative knowledge (knowing that) and procedural knowledge (knowing how). For example, we know that Washington, D.C., is the capital of the United States, but we know how to tie our shoes.

More recently, Squire has proposed declarative memory as an overarching category that includes episodic memory (remembering specific events of the past) as well as semantic memory (general knowledge). Declarative memory processes rely upon the hippocampus and related structures in the medial-temporal lobe including the perirhinal, entorhinal, and parahippocampal cortices. As it has been extended, the term declarative memory has become a bit of a misnomer, because the concept is often applied to infrahuman species that are not prone to making declarations. (Ryle tied his distinction specifically to linguistic usage so that people would know that such and such occurred.)

Procedural memory was originally intended to cover motor skills, such as tying shoes, riding a bicycle, or typing (Ryle, 1949), but it was broadened to cover mental as well physical procedures. For example, the mental processes involved in multiplying 24×16 are examples of mental procedures that can be studied. As Squire (1992) developed his theory, the term procedural memory became broader and covered such topics as priming on implicit memory tests, classical conditioning of responses, and habituation. Because of these and other uses, the broader term nondeclarative memory came into use. It refers both to traditional procedural tasks and to others such as priming and skill learning. The distinction between declarative and nondeclarative types of memory rests partly on evidence that different brain structures are involved in various forms of memory. The evidence supporting the differences between the different forms of memory has come both from studies of human amnesic patients with damage to the medial-temporal lobes and in animals where such alterations can be achieved experimentally (e.g., Squire, 1992).

As noted, the term declarative memory originally referred to memories that could be verbally stated (Ryle, 1949). This term has also been broadened so that it now includes many other kinds of memory, including spatial memory, some types of long-term visual memory, and any other form of memory subserved by the hippocampal complex. Nondeclarative memories include all other types, whether

they involve memories for physical movements and actions, priming, or skills.

Tulving (1985) has proposed a somewhat different schematic arrangement of episodic, semantic, and procedural memory systems. In Tulving's scheme, procedural memory is phylogenetically oldest and is shared among all organisms. Semantic memory grows out of (and depends upon) procedural memory. Episodic memory is evolutionarily most recent and, according to Tulving, only humans have this form of memory (see Tulving, 2005, for further elaboration). Different forms of consciousness are proposed for the three systems: anoetic (non-knowing) for procedural memory, noetic (knowing) for semantic memory, and autonoetic (self-knowing) for episodic memory. Tulving proposes that a critical function of autonoetic consciousness is planning for the future, which brings us to another critical distinction.

1.02.2.6 Retrospective and Prospective Memory

The vast majority of memory research deals with the ability to remember past events when given specific cues (as in explicit memory tests of recall or recognition) or with the effects of past experience on current behavior (priming on implicit memory tests). All tests that fall into these categories assess retrospective memory: memory for the past or effects of past experience on current behavior. In the past 2 decades, researchers have examined memory for intentions to be performed in the future, or prospective memory. Strictly speaking, prospective memory is retrospective in nature: it involves remembering a past intention. A prospective memory task differs from a retrospective memory tasks in that there is usually no explicit cue to elicit recall of the intention. Instead, a prospective memory task requires that subjects must use an environmental cue to know when to retrieve the intention, so it is a curious mix of incidental and intentional retrieval. We face prospective memory tasks all the time, whenever we need to remember to perform some act in the future. Prospective memory tasks can be classified as cue-based or event-based when some cue should remind us to perform an action (e.g., pass along a message to a friend when we see her) or time-based (e.g., remembering to take out the trash Tuesday evenings). Both cue-based and time-based prospective memory tasks have been investigated in naturalistic settings and in the laboratory. Retrieval of prospective memories may sometimes involve monitoring and may sometimes be spontaneous and effortless (Einstein and McDaniel, 2005).

We turn next to categorizations of memory based on (roughly) the time they persist, starting with varieties of short-term memory.

1.02.3 Types of Short-Term Memory

Information from the external world is believed to be represented in various storage systems that, roughly speaking, hold information for fractions of a second, seconds, or much longer. Atkinson and Shiffrin's (1969, 1971) influential theory, shown in **Figure 1**, provides one conceptualization. Our treatment here provides some amendments to their original theory.

1.02.3.1 Sensory Memories

The border between perceiving and remembering is blurred. There is no good answer to the question: When does perception end and memory begin? Even the operations in the two types of experiments are similar. When stimuli are presented rapidly to the visual or auditory system and some report or judgment is made quickly afterward, the experiment is referred to as one of perception. If the report or judgment is delayed after presentation, the study is usually called a memory experiment. Sensory memories are the brief holding systems for information presented to the various sensory systems; the information is thought to be held briefly in each system as it undergoes further processing.

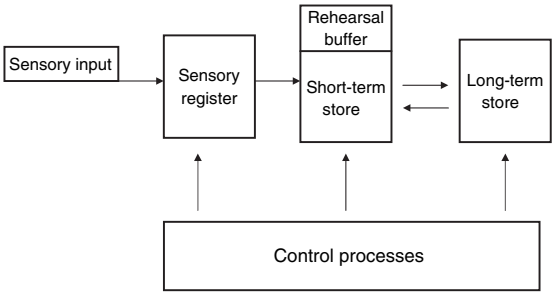

Figure 1 Simplified version of the original multi-store memory model of Shiffrin and Atkinson. Information is conceived as being transmitted through various memory stores. Adapted from Shiffrin RM and Atkinson RC (1969) Storage and retrieval processes in long-term memory. *Psychol. Rev.* 76: 179–193; used with permission of the American Psychological Association.

Sperling (1960) identified a rapidly fading store of visual information that he called precategorical visual storage. The term precategorical was in the title, because Sperling's evidence convinced him that the information was held in a relatively raw form, before linguistic categorizations had been applied. Somewhat later, other researchers proposed a system of precategorical acoustic storage, the auditory equivalent of Sperling's visual store (Crowder and Morton, 1969). These two sensory stores have been studied quite thoroughly by many researchers (*See* Chapter 2.03), but the names they are given in the literature today have been changed to iconic and echoic memory (following Neisser's (1967) suggested terminology). Iconic memory refers to the visual store, whereas echoic memory is used for auditory storage. Echoic storage seems to persist longer than iconic storage, although the decay characteristics of both systems have been debated and depend on such factors as stimulus intensity and the technique used to measure loss of information over time.

Researchers assume that similar storage systems exist for the other senses, but touch is the only sense that has been studied in this regard (and rather sporadically). The close association between smell and taste makes such studies difficult, although longer-term olfactory memory, in particular, has been well studied.

1.02.3.2 Short-Term Storage

Short-term memory (or short-term storage; the two are often used interchangeably) refers to retention of information in a system after information has been categorized and reached consciousness. In fact, contents of short-term memory are sometimes equated with the information of which a person is consciously aware. Information can be continually processed in short-term storage (e.g., via rehearsal or subvocal repetition). If a person is distracted, information is rapidly lost from this store.

Many different techniques have been developed to study aspects of short-term memory, but all have in common that subjects are given relatively brief numbers of items (often digits or words) and are asked to recall or recognize them later (often after some brief interfering task). Another term used for short-term memory is primary memory, owing to a distinction introduced by William James (1890/1950) between primary and secondary memory (reintroduced to the field much later by Waugh and Norman, 1965). Primary memory is what can be held in mind at once, whereas secondary memory referred to all other kinds of long-term memory. The terms short-term memory and long-term memory seem to have become accepted today.

1.02.3.3 Working Memory

Working memory is a term for the type of memory used to hold information for short periods of time while it is being manipulated (Baddeley, 2001). Working memory encompasses short-term memory, which in Baddeley's theory refers only to the short-term passive storage of information. Working memory also adds the concept of a central executive that functions to manipulate information in working memory and three separate storage components: the phonological loop, visuospatial sketchpad, and episodic buffer (see **Figure 2**). To test the short-term memory of humans, tasks that require short-term storage of information (such as digits in a digit span task) are used. On the other hand, working memory tests use tasks that require both short-term storage and manipulation of information (such as the operation span task, in which

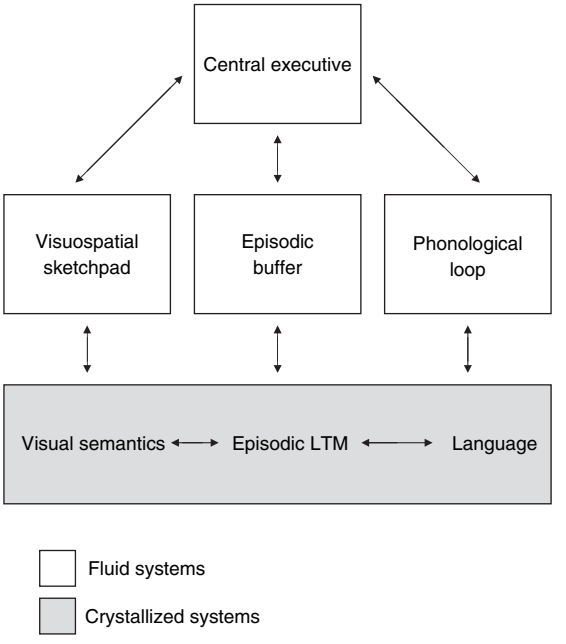

Figure 2 Baddeley's updated working memory model. Working memory is conceived as having separate storage components and a central executive process. LTM, long-term memory. Adapted from Baddeley A (2001) Is working memory still working? *Am. Psychol.* 56: 849–864; used with permission.

subjects solve simple arithmetic problems while also being given words to remember (*See* Chapter 2.04).

Three different storage systems are believed to constitute working memory. The phonological loop is involved in subvocal rehearsal and storage of auditory information (or written visual information) and is the most-studied component of working memory. The phonological loop is responsible for subvocal rehearsal and is used to account for many different empirical findings, such as the word length effect, or the finding that longer words are recalled less well than shorter words (because they take longer to rehearse).

The visuospatial sketchpad is similar to the phonological loop, except it maintains visual and spatial information, rather than acoustic information. The visual and spatial components of the sketchpad are at least partially separable, because one can observe dissociations between performance on visual working memory tasks and spatial working memory tasks (Baddeley, 2001). Most of the work on the visuospatial sketchpad up to now has focused on dissociating it from the other components of working memory.

The episodic buffer is the newest component of working memory, proposed only recently by Baddeley (2000) to explain several experimental findings. The episodic buffer is much like the phonological loop or the visuospatial sketchpad: It is a short-term store of information, although it is assumed to be able to store information of different modalities. Any information that is retrieved from long-term episodic memory (see section titled 'Episodic memory') is temporarily stored and manipulated in the episodic buffer.

The central executive component of working memory controls the subsystems. Some critics have complained that the concept is underspecified and that the concept is used to explain findings not well handled by the basic model. However, the executive component has much in common with other proposals of a central executive attention system that is used to explain how people can divide attention to different sources of information, switch attention among sources or tasks, or focus attention exclusively on one task.

1.02.3.4 Long-Term Working Memory

Long-term working memory extends the concept of working memory to account for a person's ability to readily access and utilize information stored in long-term memory. The concept of long-term working memory is particularly useful in explaining how skilled readers have the ability to easily read and comprehend texts. Indeed, the act of reading seems to require much more capacity and flexibility than the proposal for short-term or working memory can offer. A skilled reader must keep in mind words from previous sentences, paragraphs, or pages of text and readily access prior background knowledge in order to quickly and fluently process upcoming words and understand the text as a whole (e.g., Ericsson and Kintsch, 1995).

The concept of long-term working memory is also used to describe the superior mnemonic skills of experts functioning within their domain of expertise. For instance, chess masters demonstrate a remarkable ability to quickly encode and accurately remember the positions of every piece on a chess board sampled from the middle of a game, or to readily call to mind moves played in thousands of previous games in order to decide how to make the next move in a game. While researchers have attempted to explain the superior memory capacity of experts in their domain within the limits of short-term memory (Chase and Simon, 1973), evidence suggests that expert memory performance is mediated by long-term memory (e.g., Chase and Ericsson, 1982; Charness, 1991).

In contrast to the limited, fixed capacity of short-term working memory, the capacity of long-term term working memory is assumed to be flexible and may even be expanded through training. Thus, according to Ericsson and Kintsch (1995), long-term working memory is not a general cognitive ability, but rather a specialized ability that is acquired through the development of expertise for specific domains of knowledge. On the other hand, long-term working memory still depends upon the maintenance and utilization of a few retrieval cues in working memory that are, in turn, linked to retrieval structures stored in long-term memory.

1.02.4 Varieties of Long-Term Memory

Long-term memory is one of the most abused terms in psychology (and there is great competition for this honor). The reason is that the term is made to cover nearly every kind of memory not covered in the previous section. The term is used to refer to retention of words from the middle of a list presented 15 s previously to recollection of early childhood memories.

Not surprisingly, there exist various ways of carving up this huge subject. One is by type of material and mode of presentation, with the primary distinctions being among verbal memory, visual/spatial memory, and olfactory memory. Relatedly, learning of motor skills (sometimes called procedural memory, as discussed in the section 'Declarative and nondeclarative memory') is another critical and somewhat separate topic, sometimes called kinesthetic memory.

Another set of distinctions, which cut across those above, are among types of declarative (or perhaps explicit) memory: Episodic memory, autobiographical memory, semantic memory, and collective memory. We begin discussing specific codes thought to underlie long-term memory and then turn to the various types of explicit, declarative memory that have been proposed.

1.02.4.1 Code-Specific Forms of Retention

As humans possess multiple senses, there are multiple ways to sense new information and to encode that information. Raw sensory information comes in as visual, auditory, or olfactory information, as well as in other modalities. However, memories for tastes have not been much studied and because smell so greatly affects taste, separating these modalities would be difficult. Haptic memory, referring to memory for skin sensations, is also not much studied, although kinesthetic memory (for muscular movements) is a well-studied area. Studying memory for information presented in different sensory modalities has revealed both similarities and remarkable differences in how modality affects memory performance.

1.02.4.1.1 Visual–spatial memory

Memory for scenes and spatial relationships is often referred to as visual–spatial memory or just spatial memory (*See* Chapter 2.11). This type of memory is responsible for humans navigating around town in a car and for squirrels finding buried caches of acorns. Although spatial memory and episodic memory both rely on the hippocampus and surrounding areas, some theorists have argued that spatial memory is different from episodic memory and other relational (semantic) memory systems because it requires the formation of mental maps (O'Keefe and Nadel, 1978). On the other hand, Mackintosh (2002) argued that spatial learning is no different than other types of associative learning.

1.02.4.1.2 Imagery

Information presented either in events or pictures or words may be represented in the spatial system in imaginal form. One may see a butterfly and remember its appearance using this imaginal coding, or one may hear the word butterfly and be asked to form an image of the named insect. Converting verbal memories to images aids their memorability, either because the image is a deeply meaningful form (Nelson, 1979) or because coding information in verbal and imaginal codes provides additional retrieval routes to the information (Paivio, 1986).

1.02.4.1.3 Olfactory memory

Olfactory memory is more difficult to study than visual or auditory memory. Due to limitations of human olfaction, memory for odors has generally been tested with recognition tests, not with recall tests (see Herz and Engen, 1996, for a review). Olfactory memories seem to differ in some ways from other forms of memory, such as a tendency of smells to be particularly evocative of emotional memories. Indeed, the olfactory nerve is only two synapses away from the amygdala (responsible for certain types of emotions) and three synapses away from the hippocampus (which is critical for long-term memory). Olfactory memory is similar to auditory and visual memory in that performance on recognition tests decreases as the distracter set increases and as distracter similarity to targets increases. However, olfactory memory does differ from other kinds of memory in two respects. First, olfactory memory is highly resistant to forgetting: Multiple studies have shown that recognition performance for odors in a laboratory preparation is only about 5% less after 1 year than after a 30-s delay. Related to this remarkably flat forgetting curve is the finding that olfactory memory is highly resistant to retroactive interference. Proactive interference reduces olfactory memory performance greatly.

1.02.4.1.4 Skill learning

Perhaps the largest subset of different kinds of memory is the broad class of memories classified as types of kinesthetic memory or skill learning or procedural memory (the last of which was described earlier). Kinesthetic memories are those involved in motor skills: The swing of a baseball bat, how to keep a hula hoop going, and so on through hundreds of other examples (*See* Chapter 2.34). These are motor skills, the classic type of procedural memory. However, many other types of skill learning exist. There is verbal skill

learning, such as learning to read distorted or inverted text (Kolers and Roediger, 1984) – learning of grammars, both real ones and artificial ones (e.g., *See* Chapter 2.31) – and even the skillful learning of what items belong in what categories (*See* Chapter 2.47). Although a review of the various kinds of skill learning is beyond the scope of this article (see Gupta and Cohen, 2002), we can briefly point out one of the most consistent findings across the procedural learning literature: Skill learning is highly specific and transfer is often quite narrow, for example, learning to read inverted (upside down) text does not aid in learning to read backward text (Kolers and Roediger, 1984; Healy, 2007).

1.02.4.1.5 Verbal memory

Doubtless the greatest form of memory recoding and storage for human beings is based on language. People can remember events as verbal information even if they were originally presented in a different form (visual, auditory, or even olfactory or kinesthetic). Psychologists have long believed in the primacy of verbal coding, and Glanzer and Clark (1964) even proposed a verbal loop hypothesis, which theorized that all human experience is recoded into language. Subsequent research indicates that this hypothesis was a bit overstated and other forms of coding exist, but nonetheless verbal coding and verbal memories are critically important in human cognition. Verbal recoding can be impaired by instructing subjects to perform some irrelevant verbalization such as repeating nonsense words while being exposed to nonverbal information, a technique known as articulatory suppression.

1.02.4.2 Forms of Explicit Memory

We have covered these earlier in the 'Broad distinctions' section, but review them again here in more detail and provide more detailed examples of tasks used to study these forms of memory.

1.02.4.2.1 Episodic memory

Episodic memory refers to memory for particular events situated in space and time, as well as the underlying cognitive processes and neural mechanisms involved in remembering those events. A key ingredient of episodic memory that distinguishes it from other forms of memory is the retrieval of information regarding the spatial and/or temporal context in which the remembered event occurred. As previously mentioned, episodic memory is also associated with autonoetic consciousness, considered by some researchers to be an evolutionarily advanced, unique human capacity (e.g., Wheeler, 2000; Tulving, 2002, 2005).

One can point to a wide variety of examples of episodic memory, ranging from remembering what a friend wore at a party the night before to individual words studied in a list moments ago. In most contexts, episodic memory is synonymous with explicit memory, although the former term is usually used to represent a memory system and the latter term to designate types of tests that are used. Many tests have been designed to measure certain aspects of episodic memory in the lab, including free recall (recall of a set of material in any order), serial recall (recall of events in order), cued recall (recall of events given specific cues), recognition judgments (recognizing studied material intermixed with nonstudied material), source judgments (recognizing the source of presented material, such as whether it was presented auditorily or visually). Subjects may also be asked to make judgments of the recency of an event, its frequency of occurrence, or of some other quality. In addition, subjects can be asked to make metamemory judgments, or judgments about their memories. For example, a student might be asked to rate how confident he or she is in the accuracy of his/her recollections. Similarly, individuals might be asked to judge whether they can remember the moment an event occurred or the context in which it occurred or whether they only just know that they were previously encountered but cannot remember the context (Tulving, 1985). These remember/know judgments (with remember judgments reflecting episodic recollection) have been much studied (*See* Chapter 2.17).

1.02.4.2.2 Autobiographical memory

Autobiographical memory refers to memory for one's personal history (Robinson, 1976). Examples might include memories for experiences that occurred in childhood, the first time learning to drive a car, or even one's Social Security number or home address. Brewer (1986) divided autobiographical memories into categories of personal memories, autobiographical facts, and generic personal memories. Personal memories are memories for specific events in one's life that are accompanied by imagery. As such, personal autobiographical memories are thought by some to be the real-world analog to episodic memories as studied in the lab, because they are the episodes of one's life as dated in space and time. On the other hand, autobiographical facts are facts about the person that are devoid of personally experienced

temporal or spatial context information. For example, you know when and where you were born, but you cannot remember the event. Finally, generic personal memory refers to more abstract knowledge about oneself (what you are like) or to acquired procedural knowledge such as knowledge of how to ride a bicycle, ski, or play a musical instrument. Despite the conceptual overlap across classification schemes, a unique feature of autobiographical memory is that it must directly relate to oneself or one's sense of personal history.

A variety of techniques have been used to examine autobiographical memory. One approach is to simply ask people to report the most important personal events of their life (e.g., Fitzgerald, 1988; Berntsen and Rubin, 2002; Rubin and Berntsen, 2003) or to report self-defining memories (e.g., Conway et al., 2004). Another frequently used method is to ask people to describe for each of a given set of cue words the first personal memory that comes to mind, e.g., being given the word window and asked to retrieve a discrete event from your past involving a window. This task is known as the Galton-Crovitz cueing technique after its inventor (Galton, 1879) and its first modern proponent (Crovitz and Schiffman, 1974).

Many studies have plotted the temporal distribution of autobiographical memories across the life span, as described more fully by Conway (*See* Chapter 2.46). Briefly, such distributions usually exhibit three striking features (Rubin et al., 1986; Janssen et al., 2005). The first is that people tend to recall very little from the first few years of their life. This is referred to as childhood amnesia. Second, people tend to recall quite a few events from early adulthood, roughly the ages 15–25. This effect is called the reminiscence bump. Finally, most reported events are recalled from the last few years, which (like many other examples of good recall of recent information) is known as the recency effect.

Due to the personal nature of autobiographical memory, researchers have difficulty comparing what a person remembers to what actually occurred. Researchers overcome this challenge in one of several ways. One approach is to have subjects keep a diary for a length of time (e.g., days, months, years) and to record events that occurred to them at regular intervals or in response to specific cues. In addition to providing descriptions of the events that occurred, subjects might also record other accompanying details such as the exact time or location of the event and its emotional valence, salience, or distinctiveness. In turn, the diary entries are treated as the to-be-remembered stimuli in subsequent tests of memory. Moreover, as previously mentioned, the diary method is also used to capture involuntary recollections of personal events that are extremely difficult to elicit in laboratory settings. Such involuntary recollections tend to come out of the blue in response to environmental cues such as specific smells, words, or objects (e.g., Berntsen, 1996).

Another method is to assess individuals' recollections for specific historical events (e.g., the German occupation and liberation of Denmark during World War II) and then to compare the recollections with objective records of what occurred at the time, such as weather reports, newspapers, or radio broadcasts (Berntsen and Thomsen, 2005). Numerous studies of flashbulb memories (vivid recollections that surround a salient personal experience) focus on personal recollections surrounding unexpected, momentous, or emotionally charged events of public or personal significance, such as the assassination of President John F. Kennedy, the explosion of the space shuttle Challenger, or the more recent terrorist attacks on New York's World Trade Center (Brown and Kulik, 1977; Neisser and Harsh, 1993; Talarico and Rubin, 2003). However, it still remains unclear how reliable such memories are, what types of events induce flashbulb memories, and whether they really differ from memories for emotionally charged stimuli or circumstances (*See* Chapter 2.09).

1.02.4.2.3 Semantic memory

Semantic memory broadly refers to a person's general knowledge of the world. Of course, this is a vast store of information. Examples of semantic memory range from knowledge of words and their meanings, all kinds of concepts, general schemas or scripts that organize knowledge, and also specific facts about the world, such as the capital of France or famous battles in World War II.

It is reasonable to assume that when information is first learned, it is accompanied by information regarding the time and place of the learning episode. Over time and with repeated presentations of the same information, the accompanying episodic information may be lost or detached, and what remains is semantic memory. Still the distinction between episodic and semantic memory can easily blur. If someone asks about what you learned during a recent lecture, your response will likely reflect the influence of both episodic and semantic memory: Your reliance on temporal or contextual cues to remember particular points made during the lecture would reflect

episodic memory. In contrast, how you choose to reconstruct, organize, interpret, or paraphrase knowledge garnered from the lecture would reflect the influence of semantic memory.

In addition to tests of explicit and implicit memory, a variety of cognitive tests are designed to measure the contents and organization of semantic memory. These tasks might involve naming as many members of a category or words that start with a given letter that come to mind, providing word definitions, answering general knowledge questions. Other measures are designed to capture the psychological representations of word meanings by having individuals provide quantitative ratings of individual words along a variety of semantic dimensions (e.g., Osgood et al., 1957).

One of the most powerful tools for studying semantic memory is the word-priming technique in which individuals are asked to make lexical decisions (word–nonword decisions) for pairs of stimuli that might be semantically related or unrelated. For example, individuals are faster and more accurate at identifying a word (doctor) if it is was preceded by a related word (nurse) relative to an unrelated word (shoe). Indeed, comparisons in the response times for items that are semantically related versus unrelated to current or previously encountered stimuli have inspired and helped to distinguish among competing theories of how knowledge is mentally represented and accessed (e.g., Collins and Quillian, 1969; Meyer and Schvaneveldt, 1971; Collins and Loftus, 1975; Neely, 1977; *See* Chapter 2.28).

1.02.4.2.4 Collective memory

Collective memory is conceptualized in a variety of ways. In a literal sense, collective memory refers to remembering that occurs within any social context. When employees at a company meeting attempt to recall what was discussed during a previous meeting, they are engaging in a collaborative recall effort. In general, social situations can influence what individuals remember or choose to report of the past. A given social setting can dictate what sorts of recollections are most appropriate or commensurate with individual goals of communication. For instance, it is very tempting to highlight or embellish certain details of a remembered event in order tell a more entertaining story. And in turn, an individual can influence what other individuals of a group remember of the past. Studies of collaborative recall typically involve having a group of people study lists of words, pictures, or prose passages and then asking them to recall the previously studied materials either individually or in collaboration with the rest of the group (Weldon, 2000).

Work in this area has shown that collaborative recall can increase the amount of previously studied information recalled as compared to individual recall performance, but that collaborative recall tends to reduce or inhibit the amount of information recalled per individual within a group (e.g., Weldon and Bellinger, 1997). Furthermore, collaborative recall can induce recall errors, as erroneous information supplied by one member of a group is accepted and later remembered by other members of the group (e.g., Roediger et al., 2001; Meade and Roediger, 2002).

Collective memory also refers to a representation of the past that is shared by members of broader social groups defined by nationality, religion, ethnicity, or age cohort (*See* Chapter 2.48). Such a conception of collective memory is shared across the fields of psychology, anthropology, and sociology, as may be seen in the writings of Wilhelm Wundt (1910/1916), Sir Frederic Bartlett (1932), and the French sociologists Maurice Halbwachs (1950/1980) and Emile Durkheim (1915). Carl Jung (1953) used the notion of a collective unconscious in a similar sense. One commonly held assumption is that remembering is shaped by active participation within the life of a particular group. Thus, group characteristics may bias the recollections of individual group members. For instance, Russian and American high school students are likely to tell strikingly different versions of the history of World War II, with each group recalling and weaving together a different set of key events in their narratives (Wertsch, 2002). Despite the widespread use of the term collective memory, both in public discussions of how groups remember historical events such as the Vietnam War or the Holocaust and across academic disciplines, there is still little agreement as to its definition or methods of study (*See* Chapter 2.48).

In contemporary memory research, studies of collective memory bear resemblance to those of autobiographical memory in the sense that remembering one's personal history may be heavily influenced by one's cultural background. For instance, numerous studies of flashbulb memories have examined individual recollections for major historical events such as the assassinations of President John F. Kennedy, Martin Luther King, Jr., and the fall of the Berlin Wall in 1989. Some of these studies have shown striking differences in recollections across groups.

Berntsen and Thomsen (2005) examined Danes' memories for the German invasion of Denmark in 1940 and their liberation in 1945. Interestingly, they found that individuals who had ties to the Danish resistance had more vivid and accurate memories than those who did not. A key difference between autobiographical and collective memory might, therefore, lie in the impact of group identification on memory and the extent to which remembering in general is socially framed.

1.02.5 Conclusions

This chapter has surveyed some of the most common terms and distinctions among types of memory. Although we have considered only a fraction of the 256 types that Tulving (2007) identified in his (semi-serious) essay, we believe we have hit upon the great majority in contemporary use. Most of the terms used in this chapter were not used by researchers 50 years ago. We hazard the guess that someone examining the field in 50 more years might have an even greater variety of items to review, even if the serious contenders do not quite approach 256.

1.03 History of Behavioral Learning Theories

E. J. Capaldi and A. Martins, Purdue University, West Lafayette, IN, USA

1.03.1 Instrumental Learning Historically and Today

One way to better understand a subject is to approach it historically – to contrast previous ideas, discarded or not, with contemporary ones. Another way is to examine current ideas in depth. The advantage of the historical method is that by contrasting older ideas with current ones, a better understanding is available of why one idea was rejected and another accepted. A disadvantage is that it requires time and effort and so may detract from an in-depth analysis of the evidence for and against contemporary ideas, which is the strength of the in-depth approach. So in examining some contemporary ideas, we would like to know if alternatives to it were raised in the past and, if so, the extent to which such alternatives are still seen as viable. Obviously a better understanding of a subject

matter requires both approaches described earlier. Accordingly, both are used here to better understand instrumental learning.

In an attempt to provide historical perspectives, brief thumbnail examinations of selected views of significant figures who have theorized about instrumental learning are provided. This treatment by no means provides a complete discussion of the theorizing of the historical figures, nor is it meant to. Rather, we selected for examination only those views of historical figures that can help to illuminate current approaches to instrumental learning. Some of these earlier views provide illumination because they are still accepted, and some because they have been replaced by other, more adequate views. In either case, contrasting earlier views with current ones is intended to provide a broader context for a better understanding of where, theoretically speaking, we are today.

The framework that encompasses all matters treated here is provided by two major issues. The two issues are relevant to any attempt to understand acquisition processes, e.g., instrumental learning or not. One issue is: What conditions are necessary for learning to occur? For example, if Event A precedes Event B, will Event A become a signal for Event B merely because the two occur together in close temporal relation (contiguity principle), or must Event B be a motivationally significant event such as food for a hungry animal (reinforcement principle)? Or must some other condition or conditions prevail for learning to occur? The second major issue is: When learning occurs, precisely what changes occur? Consider a hungry animal that traverses a runway (a tunnel of sorts) at the end of which is food. Does the animal learn an S-R association, an S-S association, an R-O association, or some combination of these, or is learning encoded in some more cognitive propositional form? According to the S-R view, a stimulus (S, runway stimuli), elicits a response (R, in the presence of these runway stimuli, run down the runway). According to the S-S view, the animal learns that the initial runway cues (S_1) are followed by terminal runway cues (S_2). In runway situations, the hungry animal would tend to use S_1 to approach S_2 when S_2 signals the availability of food. The S-S view, unlike the S-R view, does not suggest that a specific response is learned, only that the animal may perform any number of different responses to get to the second stimulus and food. The R-O view suggests that an association is formed between the response (run down the runway) and the food reward or outcome (O). Learning, in propositional form, may be expressed as follows: If in the presence of these stimuli I traverse this runway, I will obtain a satisfying morsel of food appropriate to my state of hunger.

In any instrumental situation, a response in the presence of a discriminative stimulus produces a reinforcer. For example, a person who enters a building (response) when the sky darkens (discriminative stimulus) to avoid being rained on (reinforcer) is exhibiting a form of instrumental learning. In the laboratory, a rat might cross a barrier when a tone sounds to avoid a shock. In this form of instrumental learning, called avoidance learning, as in various other forms to be discussed, a response (entering a building, crossing a barrier) in the presence of a discriminative stimulus (dark sky, tone) produces a reinforcer (avoiding rain, avoiding shock). Clearly we engage in instrumental behavior under many conditions: when we go to the supermarket, work for a paycheck, study for a test, or do myriad other things. In a word, instrumental behavior is ubiquitous.

The three components of instrumental behavior (a discriminative stimulus, a response, and a reinforcer) will each be examined in some depth, comparing contemporary views on these topics with selected views of major figures, such as Thorndike and Hull. This approach should provide a sound introduction to some of the major findings and theoretical issues of the day (*See* Chapters 1.06 and 1.10).

Instrumental learning cannot be fully understood by focusing on instrumental behavior alone. Two related matters that cannot be completely ignored when considering instrumental behavior are biology and Pavlovian conditioning. By biology we refer to the innate capacities an animal brings to the instrumental situation. Procedurally, Pavlovian learning differs from instrumental learning in not requiring a response to obtain a reinforcer. For example, in the laboratory, food may be presented following a tone of a given duration, regardless of whether or not a rat responds. Over the years a variety of differences between instrumental and Pavlovian learning have been suggested (*See* Chapters 1.06 and 1.10). Although these are interesting for considering the relation between the two, they do not constitute the single greatest reason why some considerations must be given to Pavlovian learning when considering instrumental learning. The major reason is the wide acceptance of the proposition that instrumental learning involves, and to some extent is influenced by, Pavlovian learning. By considering what has been called misbehavior, and some of the research and

theory it spawned, we can illustrate clearly why instrumental learning cannot be examined in any depth independent of biological factors and Pavlovian conditioning. Later we shall suggest that instrumental learning may be influenced by another form of learning in addition to Pavlovian learning.

1.03.1.1 Misbehavior

Keller and Marian Breland (Breland and Breland, 1961) trained a variety of animals ranging from birds to whales to make instrumental responses that might be amusing to people at zoos and other places. A very interesting finding in a variety of species was that the instrumental behavior, performed smoothly at first, began to deteriorate with further execution. For example, hungry pigs were required to deposit four or five coins in a piggy bank before food reinforcement was provided. Pigs learned this instrumental task rather easily. But with further execution, the pigs became slower and slower in depositing the coins. A major reason for the slowdown was that the pigs, instead of taking the coin to the bank straight away, would repeatedly drop it, root it, drop it again, toss it in the air, and so on. Of course these rooting behaviors with the coin are the sorts of behavior pigs perform to food itself. To explain this unexpected behavior in pigs (unexpected because it was thought at the time that with further execution instrumental responding would improve), which was called misbehavior, the Brelands suggested that the pigs were drifting back to the sort of instinctive behaviors they innately made to food, just as other species were exhibiting their own form of instinctive drift (Breland and Breland, 1961). In this view, innate responses an animal might have to, say, food were reinforced and strengthened and so came to interfere with "arbitrary" instrumental responses such as depositing a coin in a piggy bank. The idea that signals for food can cause animals to respond to those signals as they would, more or less, to the food itself has given rise to very surprising results under laboratory conditions. In a famous example, when a light signal for food was located some distance from the food itself, pigeons developed the tendency to peck the light before running back to the food hopper. Because food was available only for a rather short specified time this sign tracking behavior, as it is called, either reduced the quantity of reinforcement the animal received or caused the bird to miss reinforcement entirely. The 'rational' thing for the bird to do, of course, would have been to simply wait near the food hopper, ingesting food when it appeared over the entire time it was available. We see that innate behaviors of the animal can interfere with the smooth performance of instrumental behavior.

Sometime later Boakes et al. (1978) produced misbehavior under controlled laboratory conditions. Rats had to press a flap to obtain a ball bearing to deposit in a chute for food reward. As training progressed, the rats became more and more reluctant to deposit the ball bearings. They developed the tendency to mouth and paw the balls before letting them go. Boakes et al. (1978) suggested a rather different view of misbehavior than did the Brelands. The instinctive drift hypothesis as indicated suggested that food reward was strengthening instinctive food-related behavior. Boakes et al. (1978) suggested that the ball bearings were conditioned stimuli (CSs) eliciting unconditioned Pavlovian responses (URs). Essentially, the ball bearing CSs were eliciting innate food-related behaviors. Further evidence that misbehavior was due to Pavlovian learning interfering with instrumental learning was supplied shortly after by Timberlake et al. (1982).

In the case of misbehavior, instrumental behavior was disrupted. A little reflection serves to show that the interaction of Pavlovian responses with instrumental ones may not always disrupt instrumental performance. To elaborate on a familiar example, the Pavlovian relation between a dark cloud signaling rain and unpleasant wetness may energize the instrumental response of entering a building. One of the oldest, broadest, and most well-developed approaches to instrumental learning assumes that Pavlovian learning interacts with instrumental learning either to facilitate it or disrupt it, an approach generally called two-factor theory. The two factors, of course, are Pavlovian learning and instrumental learning. There are many examples of two-factor theory applied to a variety of instrumental learning phenomena. For now let us examine two-factor theory in relation to two different types of instrumental learning, avoidance conditioning and the acquisition and extinction of an appetitive response.

According to Mowrer (1960), a dark cloud signaling rain is classically conditioned (i.e., is Pavlovian). It supplies motivation for entering the building (i.e., fear of getting wet). Entering the building is an instrumental response, reinforced by a reduction of the fear of getting wet.

Amsel (1958) suggested that when an instrumental response is consistently reinforced with food, stimuli

that accompany the food, e.g., the stimuli in the feeding area, are classically conditioned to the feeding response that occurs. Once this Pavlovian conditioning occurs, stimuli prior to the feeding area may elicit a conditioned form of the eating response. This conditioned response itself produces stimuli that become conditioned to the instrumental response and energize it. This conditioning to the instrumental response of stimuli produced by classically conditioned eating responses is identified with expectancy of reward in the Hullian framework favored by Amsel. We shall hear more of Hull later. Amsel suggests that after expectancy of reward is established and the animal is subsequently nonrewarded, the discrepancy between the reward expected and the reward obtained will give rise to a frustrative response. This response will produce frustrative stimuli that, if introduced for the first time, will disrupt instrumental responding.

1.03.1.2 Guthrie

It will be helpful to begin with Guthrie's theory because his views, which are simple and easy to understand, provide a context for better illuminating a variety of other issues. Guthrie (1935) views instrumental learning as S-R associations established by contiguity. He suggests that a combination of stimuli that accompany some movement will on repetition tend to again produce that movement. A stimulus combination gains its full associative strength on its initial pairing with the response. One reason why repetition may be necessary to produce effective performance is that other stimuli may intervene between the movement made and a particular combination of stimuli. The effective association occurs only between simultaneous events.

In a famous experiment intended to demonstrate that behavior tends to repeat itself under highly similar conditions, Guthrie and Horton (1946) provided instead a good reason (like misbehavior much later) for being aware of an animal's natural behavior. In the Guthrie and Horton experiments, cats were photographed as they learned to escape from a small box. To escape, the cat had to make some response to a rod near the box. In responding to the rod, the cat's behavior was described as highly stereotyped behavior interpreted as providing evidence for S-R associations. The reader has probably had experience with hungry housecats brushing against his or her leg in a particular manner. If so, you have a pretty good idea of the response the cats made to the pole. They are instinctive greeting reactions made by a variety of cats, wild and domestic, known as flank rubbing. In a series of experiments Moore and Stuttard (1979) demonstrated that domestic cats would make the responses observed by Guthrie and Horton even when they are not hungry and are not rewarded for responding. They are greeting responses elicited by the sight of human observers. In the Guthrie and Horton study, the cats were aware of being observed by people. Keep this behavior in mind for later, when the behavior systems approach to instrumental learning is considered.

1.03.1.3 Estes Stimulus Sampling Theory

Stimulus sampling theory began as an attempt to formalize certain of Guthrie's ideas. Various versions of stimulus sample theory are in vogue today, as will be briefly considered later, so in this sense Guthrie lives today. In the Estes (1950) version of stimulus sampling theory, the stimulus is represented as a population of elements. On a trial, only a sample of elements from the entire population is effective (i.e., sampled). Two sources affecting which elements are sampled are random events (noises, etc.) and changes in the participant (variable behavior over trials, etc.). One view of stimulus sampling suggests that each element has a particular probability of being sampled. Another is that a number of elements is drawn without replacement from the population elements. Still another view suggests other possibilities. Estes assumed that each element is connected to one response. In this manner different S-R associations would be formed.

1.03.1.4 Thorndike

Thorndike's (1898) experiments in which hungry cats had to make some response to escape from a puzzle box to obtain food essentially introduced a new way to study learning and, for that reason alone, were justly famous. Learning was seen by Thorndike as forming connections. According to Thorndike, most learning could be explained in terms of animals making responses to situations as they were perceived. In an earlier formulation Thorndike identified three laws of learning: readiness, exercise, and effect. For learning to occur (i.e., for connections to be made), an animal had to be ready to learn (e.g., ready to read), practice or exercise was required, and the consequences of an act would determine whether

the connection would be strengthened or weakened, with satisfying consequences strengthening connections and annoying consequences weakening them.

Later on, the law of exercise was practically rejected, and the law of effect was modified. The famous finding that a blindfolded subject showed no improvement in drawing a line of a given length was among those that led to rejection of the law of exercise. The results of several experiments led Thorndike to believe that reward had a more powerful effect than punishment. For example, in certain choice experiments, Thorndike (1898) found that performance was much more affected by correct choice and reward than by incorrect choice and punishment. Punishment, according to Thorndike, caused animals to make other than the punished response. Something new introduced by Thorndike (1898) was the principle of belongingness. According to this principle, some stimuli are more easily associated with some responses than others. For example, taste cues are more easily associated with sickness than visual cues.

1.03.1.5 Hull

On considering Hull, we focus on his best-known single work, the *Principles of Behavior* (Hull, 1943). According to Hull, if in the presence of some stimuli a response was made, and the response was followed by a reinforcer, learning would occur in the form of strengthening a stimulus–response connection called a habit and symbolized as ${}_{S}H_{R}$. Reinforcement occurred when a need was reduced, as when a hungry animal obtained food. The bigger the need reduction, the greater the reinforcement. Greater reinforcement leads to stronger habits and more vigorous performance. But the expression of a habit in performance depends on several other factors, the most important for our purposes being drive (D), hunger drive produced by food deprivation, thirst drive being produced by water deprivation, and so on. Habit and drive interacted in multiplicative manner (i.e., ${}_{S}H_{R} \times D$). If D were zero, or near zero, as in the case of hunger drive in a recently fed animal, the product ${}_{S}H_{R} \times D$ would be near zero, and the animal would not respond, press a lever, run down a runway, and so on. Of course, if D and ${}_{S}H_{R}$ had high values, the product ${}_{S}H_{R} \times D$ would be large, and the animal would respond vigorously.

Responding produced inhibition, which opposed responding. The conditioned form of inhibition was symbolized as ${}_{S}I_{R}$. Reinforcement in this case was produced by the fading or diminution of inhibition with rest or not responding. Because in Hull's 1943 system ${}_{S}I_{R}$ was subtracted from ${}_{S}H_{R}$ (i.e., ${}_{S}H_{R} - {}_{S}I_{R}$), it may be seen that if the tendency to perform a response (${}_{S}H_{R}$) was opposed by an equally strong tendency not to perform the response (${}_{S}I_{R}$), responding would not occur. The failure of an acquired response to occur because of nonreinforcement is called extinction. It's important to note that extinction in Hull's 1943 system was due to competition between the tendency to respond (${}_{S}H_{R}$) and the tendency not to respond (${}_{S}I_{R}$). Although competing responses may play a role in extinction, as will become clear later, other mechanisms may play larger roles.

1.03.1.6 Skinner

Although few on the contemporary scene would claim to be, say, Hullians, many, it seems, would be happy to describe themselves as Skinnerians. Skinner's system may be classified as a descriptive one. Two examples may make clear what is meant by a descriptive system. A reinforcer is defined by its effects: Any stimulus that increases the probability of a response is a reinforcer. By drive Skinner (1938) means to point to a set of operations (say the number of hours since feeding) that have an effect on responding. Reinforcement does not arise from need reduction or a satisfying state of affairs. Drive does not arise from a state of need.

Thus Skinner is interested in functional relations between variables. He and his followers are not interested in explaining, for example, bar pressing as a habit arising from that response being followed by food that reduced a need, as Hull did. Sometimes Skinner's approach is classified as radical behaviorism. In our view it can be more correctly identified as a form of radical empiricism.

In Skinner's system the causes of behavior are not in the organism (its habits, drive, cognition, and so on) but are in the environment (reinforced behaviors are strengthened). This approach, among other things, has led Skinner to place much emphasis on schedules of reward – how, for example, ratio schedules (only some responses are reinforced), time schedules (reinforcement is available following a certain elapsed time), and other schedules influence behavior. So Skinner had little use for systems postulating hypothetic entities. He placed heavy emphasis on the practical implications of his system. In his book *Walden Two* (Skinner, 1948), he

essentially designed a society in terms of reinforcement principles. In other ways, too, Skinner went beyond the laboratory. For example, he applied reinforcement principles to verbal behavior.

It is important to note that Skinner did not necessarily deny the existence of nonobservable concepts such as cognitions. What he did deny is that such unobservable concepts, if they exist, cause behavior.

1.03.1.7 Tolman

Tolman (1932) suggested that behavior is molar and purposeful. Molar behavior, Tolman suggested, has properties all its own and cannot be identified with muscular movement, glandular secretion, or neural processes. By purpose, Tolman suggested, behavior occurs with some end in mind. Mailing a letter, buying a car, or going to a movie are purposeful behaviors executed with an end in mind. Signal learning is a distinctive feature of Tolman's system. For example, in traversing a complex maze, the learner is guided by internal and external stimuli rather than by executing a series of muscular movements. Put slightly differently, the participant follows signs to a goal, learns, in effect, a route rather than movements without meaning. This may be illustrated by an early experiment from Tolman's laboratory: Rats that learned to run through a complex maze still performed correctly when later the maze was flooded and entirely different movement patterns were required (swimming rather than running). This sort of reasoning led to what is without doubt Tolman's best-known idea on the contemporary scene, cognitive maps. Although there is some disagreement as to the definition of a cognitive map, Tolman (1948) suggested that it is a representation of the environment that includes paths, routes, and environmental relationships that a participant may use in deciding where to move.

Experiments by Blodgett (1929) and later Tolman and Honzik (1930) indicated that hungry animals could learn their way through a maze even when not given food reward. Animals performing more or less at chance prior to being given food immediately reduced errors substantially when given food reward. Acquired learning in the absence of appropriate performance was called latent learning. In order for learning that is latent to manifest itself in performance, appropriate conditions of motivation and reinforcement must be present.

1.03.2 Types of Instrumental Behavior

Various types of instrumental learning that have been used are briefly described next.

1. *Appetitive.* In an appetitive situation a response produces an appetitive stimulus such as food. Example: Pressing a bar produces food. In secondary reward training, pressing a bar might produce a stimulus, called a secondary or learned reinforcer, that was initially paired with a primary reinforcer such as food. Secondary reinforcers may be effective in increasing performance.
2. *Punishment training.* In punishment training a response produces an aversive effect such as shock. Animals make punished responses because some appetitive stimulus is provided, such as food. Evidence suggests that when nonreinforced trials are given along with reinforced ones, called partial reward, the nonreinforced trials are aversive (Brown and Wagner, 1964). Partial reward then may be a variety of punishment training.
3. *Extinction.* Following acquisition training, all trials may be nonreinforced. This is called extinction. Typically, behavior declines in extinction.
4. *Discrimination training.* Responses may receive appetitive training in the presence of one stimulus and nonreinforcement in the presence of another stimulus. Such discrimination training has many variations. For example, both stimuli may receive appetitive training, but appetitive outcomes may occur more frequently in one alternative than in the other.
5. *Escape training.* In escape training, a response terminates an aversive stimulus – usually shock. For example, an animal that is shocked may learn to run to a place in which shock does not occur.
6. *Avoidance training.* In a signaled avoidance situation, if an animal makes some response when some stimulus occurs, it can avoid an aversive event, usually shock; otherwise it is shocked. In a popular version of avoidance training, running or jumping to the other side of a box when a tone sounds can avoid shock. In Sidman or operant avoidance, the animal can avoid shock for a certain time (the response–shock interval) by making a response. Shock occurs at a shorter interval if a response is not made (the shock–shock interval). For example, the response–shock interval may be 20 s and the shock–shock interval 10 s. Thus, it pays the animal to respond.

7. *Passive avoidance.* In the passive avoidance situation, the animal is shocked for making a response. It differs from punishment training in that only the aversive shock event occurs, and not the appetitive event. As might be expected, behavior is quickly modified in the laboratory by passive avoidance training.

Sometimes the instrumental procedures just described are explicitly combined with Pavlovian ones. A popular example is as follows: After learning to press a bar for food, a rat may be shocked when a tone sounds. The tendency of the tone to reduce bar pressing is used to index fear of the tone.

1.03.3 What Makes a Stimulus a Reinforcer?

The three elements of an instrumental response are a discriminative stimulus, a response, and a reinforcer. In this section we consider various theoretical positions on reinforcers.

1.03.3.1 Contiguity

According to Guthrie (1935), reinforcement is not necessary for learning, temporal contiguity between stimulus and response being sufficient. Or one may assume, along with Skinner, that explaining why a reinforcer is a reinforcer is not necessary. All that is required is the description of a functional relationship between some response and some stimulus. The latent learning studies of Blodgett (1929) and Tolman and Honzik (1930) suggest that the effect of reinforcement is not on learning but on the motivation to engage in behavior learned by other means. Hull, who changed his position on reinforcement between his 1943 book and his 1952 book, suggested an important role for incentive motivation in determining behavior. He added to ${}_{S}H_{R} \times D$ a role for incentive motivation (V), so that in his later statement, we have ${}_{S}H_{R} \times D \times V$. Like D, if V is zero, behavior will not occur.

1.03.3.2 Satisfying Needs

As to the various explanations of what makes a reinforcer a reinforcer, Thorndike's idea that satisfaction and discomfort were key to understanding the effectiveness of reinforcers has several drawbacks: It is subjective, and like Skinner's view, it suggests that one can determine what is or is not a reinforcer only after the fact, after observing its effects on responding.

1.03.3.3 Need Reduction

Hull's idea of need reduction provides a means for determining whether a stimulus is or is not a reinforcer that is independent of its effects on the behavior it follows. For example, food deprivation will increase the need for food, and thus eating food will reduce the need and become reinforcing. Two problems with this formulation are that learning has been shown to occur when rats are given sucrose, which has no calories and thus does not reduce a need or drive (Sheffield and Roby, 1950), and when drive is increased rather than decreased, as with learning responses that increase sex drive (Sheffield, 1966). Hull's 1943 position was that greater need reduction increased the limit of asymptote to which learning could occur, a popular position today, as we shall see. In 1952, Hull assumed that reinforcement was necessary for learning but did not affect the asymptote of learning. More vigorous performance for larger reinforcers was now suggested to be due to V or incentive motivation, as indicated earlier. A major reason Hull modified his position was a set of findings provided by Crespi (1942). Crespi reported that after rats had been trained to respond, shifting reinforcement from large to small or vice versa produced a rapid change in behavior – too rapid, Hull thought, to be explained in terms of changes in learning or ${}_{S}H_{R}$. Rapid behavior change was due to a change in incentive motivation, or V.

Hull's 1952 position suggested that reinforcers can exert an effect on responding that is independent of its effects on the S-R association itself. More recent theories accept this view, as we will see in greater depth when we take up the issue of what is learned (i.e., what changes occur when learning occurs). For now it is enough to say the following: If a response is followed by a reinforcer, the execution of the response can be affected by devaluing the reinforcer in the absence of the response itself. That is, if the reinforcer is associated with lithium chloride, a poison that makes the animal sick, the animal will avoid that reinforcer, and its tendency to make the response that produced the reinforcer will be reduced (Rescorla, 2001). Along similar lines is the finding that merely placing the animal in an empty goal box, in effect showing the animal that food may no longer be available, reduces the vigor of responding,

an effect called latent extinction or nonresponse extinction (Young et al., 1960).

1.03.3.4 Premack Principle

Monkeys placed in a box by Butler and Harlow (1954) learned a response for the opportunity to look into a room. Rats will learn a maze simply by exploring it (Montgomery, 1951). These and other findings suggest that stimuli not necessary for physical survival can function as reinforcers. This view was forcefully put forward by David Premack (1965). According to Premack, activities are reinforcing to the extent that they are probable. For example, depriving a rat of food makes eating more probable, and thus reinforcing. Higher-probability responses reinforce lower-probability responses. Thus, higher-probability eating will reinforce lower-probability bar pressing. As another example, a teenager may be induced to clean his or her room, a low-probability behavior, for the opportunity to watch TV, a higher-probability behavior. This view, unlike the views of Skinner and Thorndike, allows us to determine, in advance of learning, the reinforcing capacity of particular behaviors. That is, before putting an animal in a learning situation, we can determine how probable it is that an animal would perform various behaviors under particular conditions. If the Premack principle is correct, it is possible to predict in advance which behavior will reinforce which.

1.03.3.5 The Response Deprivation Hypothesis

There is evidence that, contrary to the Premack principle, low-probability responses can reinforce higher-probability responses. It is a matter of depriving the animal of the less-probable response. For example, if ingesting X is less probable than ingesting Y, the tendency to ingest Y can be increased above its baseline by depriving the animal of X and making the availability of X contingent on ingesting Y (e.g., Timberlake and Allison, 1974; Allison, 1989). There are many interesting applications of the response deprivation hypothesis. For example, 3-year-old children who loved to run around and scream were induced in a fairly short time to sit still, a not highly probable activity for 3 year olds. Essentially, after the children sat quietly for a specified time period, they were allowed to run and scream for a few minutes (Homme et al., 1963).

The response deprivation hypothesis allows us, like the Premack principle, to determine in advance how reinforcing some activity might be. It also allows us to adjust reinforcers to particular animals or people. For example, a person who enjoys TV will perform other behaviors if those behaviors allow TV viewing, which is otherwise reduced. But if a person enjoys reading more than TV watching, let reading be contingent on TV watching.

A more subtle implication of the response deprivation hypothesis bears mention. Normally we think of instrumental behavior such as bar pressing as different from consummatory behavior such as eating. This distinction is violated by the response deprivation hypothesis. That is, any behavior can serve as a reinforcer if it is made to occur below its normal baseline. Animals deprived of food will run in order to eat, and an animal deprived of activity will eat in order to run.

1.03.3.6 Reinforcer Relativity

A popular view of reinforcement and its effects today is that it is determined by some state of the organism. For example, in Amsel's 1958 formulation of frustration theory, a given reward magnitude would tend to increase responding if it were larger than expected but would be frustrating and would tend to decrease responding it if were smaller than expected. The most recognizable form of this 'relativity' of reinforcement is contained perhaps in the Rescorla-Wagner model (Rescorla and Wagner, 1972). On a given trial, the learning actually accomplished might be lower or higher than that supported by the reinforcer employed. If it were lower, excitatory learning would occur, the change in excitation being greater the greater the difference between the learning accomplished and the learning supported by the reinforcer. However, if learning accomplished on a trial is greater than that supported by the reinforcer, inhibitory learning would occur, the inhibitory change being greater the greater the discrepancy between learning accomplished and learning supported by the reinforcer. It is probably the case that most learning psychologists accept some form of reinforcer relativity.

1.03.4 Discriminative Stimuli

Identifying the stimuli that give rise to instrumental responding is one of the most controversial types of

learning at present. We treat the topic under seven headings.

1.03.4.1 Common Understanding

In many theories, particularly earlier ones such as those of Thorndike, Hull, and Guthrie, the stimuli that controlled instrumental responding were described in commonsense terms. For example, if the animal ran down a black runway to obtain food, the situation might be described as the black runway elicits the instrumental response (I) of running. Symbolically this may be expressed as $S_B \rightarrow I$. In Hull's 1943 formulation, for example, this S-R formulation was considered adequate to explain instrumental responding. Both earlier in his journal publications (see Amsel, 1958, for Hull's collected journal papers) and later in his 1952 book, Hull would consider other important stimuli in controlling responding, as will be considered in due course. But in his 1943 statement, Hull considered instrumental responding to be controlled by exteroceptive stimuli such as "black runway" and certain interoceptive cues such as drive stimuli (stimuli produced by, e.g., hunger) and proprioceptive cues such as feedback stimuli from overt responses such as turning left or right.

1.03.4.2 Contextual Cues

Both in Pavlovian and instrumental learning, the idea arose that various contextual cues controlled responding in ways other than merely eliciting them as the S-R formulation considered earlier suggests. An important thing to note about contextual cues is that they could arise from any source: from the apparatus, from the passage of time, to just name a few. In one manifestation of this approach, the contextual cues affect responding by competing with or supporting the cues of interest to the experimenters. In the Pavlovian situation, for example, contextual apparatus cues occur along with the CS when the US is presented. To the extent that the contextual cues signal the US, they would, for one reason or another, weaken responding to the CS (see, e.g., Miller and Matzel, 1989; Rescorla and Wagner, 1972). In the instrumental situation, the contextual cues might also reduce instrumental responding. For example, animals that learned a discrimination under a so-called irrelevant cue (degree of floor tilt) had that discrimination disrupted when the floor was titled differently (Thomas, 1985). So one effect of considering context was to bring to our attention to the fact that the animal was responding to a greater range of stimuli than was previously recognized.

Another way of thinking about context is that it may function as a superordinate stimuli, informing the animal as to the specific relations that prevail under a given set of conditions. For example, in a wide variety of both instrumental and Pavlovian situations, it has been found that the extinction of responding in one context (e.g., white box) after acquisition in another context (e.g., black box) is 'renewed' when the animal is returned to the original black context. That is, responding extinguished in the black box reappears to some extent when the animal is returned to the original context, or even some novel context (see, e.g., Bouton, 1993, 2004).

Precisely how context regulates responding is a matter of some interest, which will be considered when reward produced memories are considered.

1.03.4.3 Configural Cues

When two or more cues are presented, they may be fused, so to speak, into a single representation that is perceived differently than the individual cues that comprise it. Such fused stimuli are called configural cues. In both the instrumental (e.g., Spence, 1952) and Pavlovian areas (e.g., Pearce, 1987), there are phenomena that, in the opinion of some, call for a configurational approach. We consider three examples of such phenomena. In a feature negative discrimination, the stimuli A and B are reinforced, while the combination of stimuli AB is nonreinforced (A+, B+, AB−). Animals will come to respond more strongly to the stimuli A and B than to the combination AB. It is perhaps clear that if the stimuli in a feature negative discrimination are conceptualized, as is commonly understood, then the feature negative discrimination could not be solved. That is, if the stimuli A and B are excitatory, then the compound AB must be even more excitatory. Other examples also difficult to understand are feature positive discriminations (A−, B−, AB+) and biconditional discriminations (e.g., AB+, CD+, AC−, BD−).

One way to deal with the learning of these complex discrimination problems is to assume that stimuli are configured. For example, in the negative patterning case, it may be assumed that the stimuli A and B differ from AB in that AB is a configuration. In this view, AB may be conceptualized as giving rise to a distinct stimulus X. In this way, excitation that generalizes from A and B will have less of an effect

on X than on AB. One configural approach is to assume that stimuli such as AB are configured under some circumstances but not others (e.g., Rescorla and Wagner, 1972). Another (Pearce, 1987) is to assume that all stimuli are configured whether presented alone (A, B) or in compound (AB). The former view suggests that in, say, the negative patterning case, generalization and discrimination occur between A and X and B and X. In the Pearce view, generalization and discrimination occur between the configurations A, B, and AB. Still another view, considered in the next section, rejects configuration, attempting to solve problems like negative patterning by considering stimuli to be composed of a number of discrete elements that interact.

1.03.4.4 Stimulus Sampling Theory Revisited

As we saw, Estes's version of stimulus sampling theory was derived from Guthrie's theory. Several different, newer versions of stimulus sampling theory are designed to explain phenomena such as negative pattern. One such that eschews any type of configural cue, proposing to postulate stimulus elements only, is that of McLaren and Mackintosh (2002). Prominent assumptions of this view are as follows: Some elements of a stimulus may be more weakly activated than others; however, elements weakly activated in individual stimuli may be strongly activated when two stimuli are presented in compound. This view explains a conditional discrimination such as the negative patterning problem, suggesting that certain elements weakly activated in stimulus A and in stimulus B are strongly activated in the AB compound. In this way the AB compound is made discriminative from A and from B using an element model and not a configural model. Thus, the animal can learn to respond strongly to the reinforced A and B stimuli and weakly to the nonreinforced AB compound.

1.03.4.5 Behavior Systems

According to the behavior systems approach (Timberlake et al., 1982), animals possess instinctive behavior systems such as feeding, predation, defense, mating, and so on. Certain stimuli are effective in activating a particular behavior system (see Timberlake, 2001). Stimuli employed in the laboratory are effective in activating a behavior system according to their similarity with natural stimuli. For example, a moving object will activate predator responses in a rat, which results in the responses such as chasing and biting.

1.03.4.6 Reinforcement-Produced Stimuli (Pavlovian Version)

Outcomes such as food reward, shock, nonreward, and so on, it is generally agreed, produce stimuli that may come to control instrumental responding. What mechanisms produce these stimuli? One approach, the Pavlovian one, is considered in this section. The other approach, the memory view, is considered later.

One version of the Pavlovian approach is associated with Hull and Spence and, in its most popular form perhaps, by Amsel (1958). Consider a rat that, having completed an instrumental response, is fed in the goalbox of the runway. Events in the goalbox can be seen as analogous to Pavlovian conditioning. Thus the goalbox cues (S_C) may be seen as the CS, the food as the US, and eating as the unconditioned response (R_G). The goalbox cues can be seen to elicit a conditioned eating response. This conditioned response is referred to as r_g, the conditioned form of the unconditioned eating response R_G. So we have $S_C \rightarrow r_g$. Runway cues prior to the goalbox (approach cues S_A) will elicit r_g to the extent that they are similar to S_C. Response in this formulation produces stimuli (i.e., $r_g \rightarrow s_g$). In the early portions of the runway, runway stimulus (S_A) elicits r_g, which produces s_g, and so s_g becomes conditioned to the instrumental response (I_R). This may be expressed as is shown in **Figure 1**.

This is a very powerful formulation. Earlier we indicated that merely placing the animal in the goalbox could lead to extinction. Such nonresponsive extinction is easily explained by the r_g mechanism. In the goalbox without food, the S_C-r_g association is extinguished as would any Pavlovian association. Thus, after goal placement, we would have $S_A \rightarrow I_R$. In the absence of the s_g-I_R association, instrumental responding would decline.

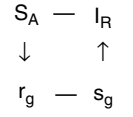

Figure 1 How stimuli produced by anticipatory responses come to control instrumental responses according to Hull, Spence, and Amsel.

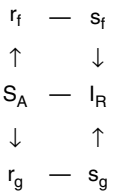

Figure 2 Amsel's formulation slowing how stimuli produced by anticipatory consumatory responses and anticipatory frustration responses come to control instrumental responses.

A powerful assumption introduced by Amsel is that if obtained reward was smaller than expected reward (r_g), the animal would be frustrated (R_F). As with R_g, a conditioned form of R_F will be elicited by goalbox cues (r_f). By the same means used in connection with r_g, r_f will become conditioned to runway cues and would produce s_g, which will become conditioned to I_R. We would have what is shown in Figure 2.

Among the many phenomena this view explains, the most prominent is the partial reinforcement extinction effect or PREE. The PREE consists of greater resistance to extinction when responses are both nonreinforced and reinforced (partial reinforcement or PRF) than when all responses are reinforced (consistent reinforcement or CRF). The PREE was a problem for all the major earlier theories (Thorndike, Hull, Guthrie, Skinner, and so on). Amsel's frustration view explains the PREE as follows. Extinction following CRF results in the introduction of considerable unconditioned frustration (R_F), which produces stimuli that elicit responses incompatible with the instrumental responses or I_R. Following PRF, frustration is conditioned to I_R, and so the animal is able to respond over a considerable number of nonrewarded trials.

What is sometimes called modern two-process theory, like the Hull-Spence-Amsel traditional version of two-process theory, assumes that classical conditioning is important in guiding and motivating instrumental behavior (Rescorla and Solomon, 1967). Modern two-process theory, unlike the traditional version, does not assume that some particular response is learned. What classical conditioning does, according to modern two-process theory, is to elicit a particular type of motivation, called a central emotional state. The emotional state elicited by the CS corresponds to that produced by the US. The emotional states do not result in a particular response. A frown may produce fear, anger, or indifference, for example – fear if the frowner is a stronger competitor, anger if the frowner is a weaker competitor, and indifference if the frowner is a stranger we likely will not encounter again. Instrumental behavior may be disrupted when, for example, a CS that is followed by shock elicits fear that disrupts bar pressing for food. A CS followed by food may, however, increase bar pressing for food by increasing hope. Traditional two-process theory with its emphasis on specific responses producing specific stimuli and modern two-process theory with its emphasis on motivational state affecting responding are not necessarily at odds with each other. For example, Rescorla, one of the authors of modern two-process theory, has recently found some of Amsel's assumptions useful for explaining extinction (Rescorla, 2001).

1.03.4.7 Stimulus Process Models

Earlier theories, on the whole, tended to assume a rather passive organism. For example, Spence (1936, 1937) suggested that all stimuli falling on the animal's receptors become associated with the instrumental response. Lashley (1951) put forward an attention view suggesting that animals actively and selectively attend to stimulus dimensions. Lashley's view did not gain general acceptance. At present a variety of proposals have been put forward suggesting that some stimuli may be more successful than others in gaining control over responding.

One suggestion, generally accepted, is that some stimuli are more salient than others and therefore will tend to be more successful in gaining control over responding. For example, brighter lights or louder tones may be more salient than less bright lights or less loud tones.

Another general type of suggestion is that over trials the organism may become more or less receptive to some stimuli than others. For example, Mackintosh (1975) assumed that stimuli will be attended to depending on the extent to which they predict reinforcement. Pearce and Hall (1980) made the rather different assumption that stimuli that predict reinforcement will not be attended to. Wagner (1978) assumed that stimuli will be processed to the extent that they are surprising. Each of these views can explain an important phenomenon that has been investigated in both instrumental and Pavlovian situations: blocking. In blocking, a given stimulus A is reinforced. Following this, stimulus A is presented along with stimulus B, and the compound is

reinforced. A typical finding is that responding to B is weak when B is presented in isolation. Mackintosh (1975) suggested that the animal is attending to A and not B, and thus blocking occurs. Pearce and Hall (1980) assumed that the compound AB predicts reward, and thus B is not attended to. Wagner (1978) assumed that the compound is not surprising and thus is not processed, and so blocking occurs.

1.03.4.8 Reward-Produced Memories

The stimuli produced by reinforcement events may be conceptualized as memories rather than the feedback stimuli of Pavlovian responses. In some cases (e.g., the PREE), the memory view and the r_g view successfully explain the same phenomena. In other cases some phenomena are better explained by one view than the other. For example, faster running sometimes occurs under PRF relative to CRF, an effect that the frustration model explains well. In another example, the sequence in which larger and smaller reinforcement occur may have profound effects on responding. The sequential model is better equipped to explain such findings (see, e.g., Capaldi, 1967, 1994).

The sequential model assumes that discriminable stimuli (memories) are associated with a large and small magnitude of reinforcement, with nonreinforcement, with different numbers of these events (e.g., the memory of two nonrewards in succession differs from that of a single nonreward), and with different combinations of reinforcement (e.g., the memory associated with nonreinforcement following reinforcement differs from that associated with the successive nonreinforcement or a single nonreinforcement).

The sequential model has been applied to a variety of phenomena. To best understand the implications of the view with a minimal amount of data, it is well to recognize that two PRF schedules equated along many dimensions (e.g., percentage of reinforcement, number of trials, magnitude of reinforcement) but differing in terms of the sequence in which the reinforced and nonreinforced trials are presented may produce quite different responses in acquisition and extinction, both when the interval between trials is short and when it is long (e.g., Capaldi, 1994). This is explained in terms of different sequences of reinforcement giving rise to different stimuli (memories) that then exercise control over responding. The details of this approach are too complex to be fully elaborated here, but some idea of the process may be gleaned from the following example: If a reinforced trial follows a nonreinforced trial, the memory of nonreward will tend to become a signal for reward. But if the nonreinforced trial follows the reinforced trials, then the memory of reward will tend to become a signal for nonreinforcement. In this example, quite different things are learned when the same number and percentage of rewarded and nonrewarded trials are presented in different sequences.

Perhaps the best intuitive understanding of how memories control instrumental responding is provided by a schedule in which reinforced and nonreinforced trials are given in single alternation fashion (SA schedule). Under the SA schedule, rats will come to show pattern responding and faster running on reinforced than on nonreinforced trials even at intervals between trials of 20 min and 24 h (Capaldi and Stanley, 1963).

1.03.5 Response

Two somewhat different but related issues are considered in this section. One is concerned with how to characterize the instrumental response. The other is concerned with the role the response might exercise in relation to reinforcement outcome (R-O association).

1.03.5.1 Characterizing the Response

In the simple T maze shown in **Figure 3**, the animal starts at S and can gain food by making the correct response. One of the most divisive issues of early theories was with how to characterize the correct response. Is the rat learning a movement pattern associated with left turning, as Guthrie would say, or is the animal learning something more general, such as going to a place? In an attempt to resolve this issue, a variety of procedures have been employed.

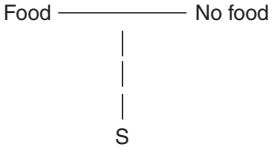

Figure 3 A simple T maze. The animal is placed in the maze at S and can respond by turning to the left or the right – a right turn produces food reward, a left turn no reward.

1.03.5.1.1 Extensive training

One procedure is to train the animal for a considerable number of trials to see whether the response becomes progressively more stereotyped with training. The idea here is that if the response is best characterized in terms of movements, it should show less and less variability as training progresses. But if the animal is learning something more general, such as obtaining food by approaching the windowed wall on the left, behavior could show considerable variability over trials. Muenzinger (1928) trained guinea pigs to approach a bar and to press it to obtain food. The animals were trained for 1000 trials; considerably more training was required for performance to improve. Muenzinger classified the animal's behavior into nine classes: press with left foot, press with right food, press with both feet, press with head, and so on. Behavior varied over trials, with one behavior rising and another falling. Tolman (1932) used results of this sort to support his idea that animals obtain goals and do not necessarily engage in movement patterns. For an alternative interpretation of these findings, see MacCorquodale and Meehl (1954).

1.03.5.1.2 Shift responses

Another approach is to allow an animal to obtain reinforcement by performing one response, then requiring another response to obtain the same reinforcement. For example, an animal might obtain reinforcement by running through a maze. Then after learning, as indicated, the maze might be flooded so that now a different series of movements (swimming) must be made to obtain food (Tolman, 1932). Lashley (1951) operated on animals so that a new response, rolling through the maze, rather than running, was required to obtain food. In both cases, considerable transfer was obtained from running to swimming and from running to rolling.

1.03.5.1.3 Blocked routes

A third way was to have animals obtain reinforcement by going to some particular place for food by a given route. After learning, the original path would be blocked and a variety of new alternative paths provided. The question was: Would the animal select an optimal path to the goal such as the shortest one? In a famous experiment of this sort, Tolman et al. (1946) obtained positive findings.

1.03.5.1.4 Cross maze

A related method involved the use of a cross maze of the sort shown in **Figure 4**. A trial would start by placing the animal at S1 or at S2. One group, the place group, was required to go to G1 to obtain food, both when started from S1 and when started from S2. The other group, the response group, was required to turn in a given direction, say left, for food. This means that when started from S1, the animal was required to go to G1, and when started from S2, the animal was required to go to G2. Better performance by the place group than by the response group would suggest that a more cognitive characterization of what was learned would be in order, according to Tolman et al. (1946). Better performance by the response group would indicate that more stereotyped responses were learned according to Tolman et al.

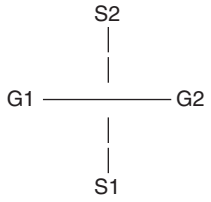

Figure 4 A cross maze. The animal may be placed at either S_1 or S_2. It may respond by turning either to G1 or to G2.

Considerable research was reported using the cross maze. The outcome of this research was that better place than response learning occurred under some conditions, the opposite being the case under other conditions (see Restle, 1957).

Restle suggested that animals may learn either stereotyped responses or broader responses, a conclusion that is not surprising, considering earlier research. For example, it was shown early on that rats that learned to run a certain distance for food would turn into an empty wall when the runway was lengthened, and they would fly out into empty space when the runway was shortened (Munn, 1950).

On the other hand, it is clear that animals can also obtain a reinforcer using other than the original response, such as swimming instead of running.

1.03.5.2 R-O Association

Classically, two sorts of associations have been posited by theorists such as Thorndike and Hull in instrumental learning, S-R associations and S-S associations (stimulus–outcome associations). In an S-S association, some stimulus (window on the right) elicits some response (turn left or approach the window). Recently several theorists have suggested that the reward outcome (O) may be anticipated on the

basis of the response, an R-O association. This makes common sense: A person might say "I am pressing the bar (R) in order to obtain food (O)."

A major procedure for investigation of R-O association involves reinforcer devaluation. We will now describe in general terms how this is done. The animal might be trained to make two different responses such as bar pressing (R1) or chain pulling (R2) to obtain two different reinforcers, say plain pellets (O1) and sucrose pellets (O2) (e.g., R1-O1, R2-O2). Following this training, one of the outcomes may be devalued by poisoning it following its ingestion. Without further training, the animal is given access to both R1 and R2. A critical finding is that the response followed by the poisoned reinforcer is reduced relative to the other (see, e.g., Colwill and Rescorla, 1985). This indicates that the animal is able to anticipate which O follows which R.

1.03.6 Extinction

Every theory of learning has to deal not only with acquisition of responding but with its extinction as well. The theories of extinction embraced by Thorndike, Hull, Spence, Estes, and others have not fared well. For example, Hull (1943) suggested a theory of extinction in which the tendency to respond and the tendency to not respond at the end of extinction would be in balance. Essentially, according to the Hullian position, at the end of extinction, reacquisition of responding would be impossible. At the other extreme, the Rescorla-Wagner view of extinction (Rescorla and Wagner, 1972) suggests that original learning would be erased by extinction, and reacquisition would have to start from scratch and be no different from original acquisition.

Numerous phenomena indicate that whatever was learned in the acquisition phase survives in extinction to a considerable extent. One is so-called spontaneous recovery, in which responding recovers following the elapse of time since extinction. Rapid reacquisition following extinction is another example. In rapid reacquisition, three phases may occur: CRF, extinction, and CRF again. In the third phase, responding that was lost in extinction quickly recovers.

Over the years three views of extinction have been suggested. One is the sort of competing response view suggested by Hull (1943) – that the tendency to respond in extinction is opposed by the growth in extinction of the tendency not to respond. Another is the unlearning view suggested, for example, by Rescorla and Wagner (1972) that whatever was learned in acquisition is unlearned in extinction. The third is that extinction is a variety of discrimination learning in which stimuli that are excitatory in acquisition are replaced in extinction by stimuli that are not excitatory (e.g., Capaldi, 1967, 1994). Some theories, Amsel (1958) for example, assumed all three. According to Amsel, in extinction r_g is extinguished, unconditioned frustration elicits responses incompatible with the instrumental reaction, and frustration may introduce entirely new nonexcitatory stimuli in extinction, particularly following CRF acquisition. Extinction, a highly popular area of investigation in the 1960s to about 1980, has recently become a fertile area of investigation again (see, e.g., Rescorla, 2001; Bouton, 2004).

1.04 Multiple Memory Systems: A New View

L. Nadel, University of Arizona, Tuscon, AZ, USA

1.04.1 Introduction

> It has been already stated that those who have a good memory are not identical with those who are quick at recollecting. But the act of recollecting differs from that of remembering, not only chronologically, but also in this, that many also of the other animals (as well as man) have memory, but, of all that we are acquainted with, none, we venture to say, except man, shares in the faculty of recollection. (Aristotle, *Ars Memoria*)

While Aristotle clearly recognized that memory comes in different forms, and pointed out that remembering and recollecting seem different, he left many questions open. Is there a single memory that can be accessed in different ways – by remembering or recollecting? Are there multiple memories, one of which supports remembering, the other recollecting? If so, how do these relate to one another, if at all? Questions like these, asked in a variety of ways, have dominated the memory literature in recent years. While it is beyond the scope of this chapter to represent all these approaches (see Schacter and Tulving, 1994; and a collection of papers in a special recent issue of *Neurobiology of Learning and Memory* (Vol. 82) for a sampling of views; *See* Chapters 1.02, 1.05), I hope to illuminate some recent history and provide a new perspective on how one might think about memory and its various forms.

Memory is best conceived as a set of functions that serve specific adaptive purposes (cf., Klein et al., 2002). These functions all share the common property of enabling organisms to benefit from prior experience. Since these experiences are many and varied, and the needs of complex organisms are similarly diverse, it is hardly surprising that there would be many kinds of memory. This chapter considers the different types of memory and ask how they differ, how they are instantiated in the brain, and how they interact. It also speculates about the separate functions they serve and discusses implications of the fact that memory comes in multiple forms.

Before diving into this thicket, we need to clear some brush and ask what we mean by each of the terms in the phrase 'memory system'. What exactly is memory? What do we mean by a system? We'll start by briefly discussing what is meant by the term system and then address the nature of memory systems at some length. This will lead to the surprising proposal that we change the way we think about memory altogether.

1.04.2 What Is a System?

A standard definition of system goes something like this: A system is a group of interacting, interrelated, or interdependent elements forming a complex whole. There seem to be two critical parts to this definition. First, a system is composed of parts, and second, these parts interact in some way to form a whole whose properties are more than just the sum of the separate parts. As important as what the definition includes is what it does not. A system need not make up a coherent physical entity, and it need not always act in an interrelated fashion. The parts of a system can be distant from one another (an extended family for example), and they can sometimes act together and sometimes not. What is more, the parts of a system can be made up of similar things or of quite different things.

Complex biological systems come in a variety of forms, but one thing we can assume they all share is that they have achieved their present form through a process of selection, shaped by phylogeny, epigenetic needs, and their environmental niche. The brain is among the most complex of biological systems and is not one but many systems that must interact effectively to sustain life and maximize the potential for procreation. Memory, in this context, is but one of many neurobiological systems, the one that allows organisms to benefit from knowledge obtained during their individual lifetimes. Organisms also benefit from knowledge acquired in the course of phylogeny by virtue of the fact that fundamental aspects of the world we inhabit are built into the structure of the nervous system. Although this knowledge about the world may emerge over the course of individual development, it is in no sense learned or remembered: It is simply known. Basic facts about the physical world, such as the laws pertaining to gravity, space, time, and causality, are examples of this kind of knowledge. The associative rules that govern our understanding of how the things we experience relate to each other are another example (*See* Chapters 1.03, 1.06).

1.04.3 What Is a Memory, and a Memory System?

Memory is, by definition, a record created by an individual as a result of its past experience. But what is the nature of this record, and how long does it last? How is it accessed? It has long been understood that some memories are evanescent while others last a long time. A distinction between short-term and long-term memory has been part of the scholarly discussion of memory for more than a century, even though the boundaries between these two are not clearly worked out. In recent years, the notion of working memory has emerged to complicate matters. For some, short-term memory and working memory (which may or may not be the same thing) are memory systems, and given the generic definition of systems offered above, this seems indisputably true. However, these are not the systems of which memory researchers typically speak when they speak of multiple memory systems. The notion of multiple memory systems emerged well after the idea that memory could exist in different temporal forms was entrenched in the field.

For much of the past century, most memory researchers have adopted a particular framework that viewed memory as reflecting the presence of a coherent trace in the brain, an engram that could be identified if only we knew just what we were looking for. The difficulty inherent in this pursuit was forcefully expressed by Lashley, whose failed search for the engram led to the contrarian thought that:

> I sometimes feel, in reviewing the evidence on the localization of the memory trace, that the necessary conclusion is that learning just is not possible. It is difficult to conceive of a mechanism which can satisfy the conditions set for it. (Lashley, 1950: 501)

A possible solution to the problem raised by Lashley's work was provided by Hebb (1949) in his connectionist theory of synaptic change, cell assembly formation, and phase sequence activity. These postulated mechanisms presumed to show how an engram could be distributed within the brain and how the full pattern of the memory trace could be activated by many different paths, or cell assemblies (*See* Chapters 1.33, 1.34, 1.35). His theory showed how a memory trace could exist, could avoid total disruption when damage occurred, and could permit what we now call pattern completion. It seemed, in other words, that Lashley searched in vain because he was looking for the wrong thing, and that it still made sense to talk about a fixed memory trace.

In order to understand this debate, it is important to recognize that the term memory was at that time reserved for what we now call episodic memory (*See* Chapters 1.22, 1.23). The term was used to refer to the recollection, in Aristotle's terms, of specific

events in one's past, such as what happened yesterday, or the week/month/year before. This usage persisted at least until the 1960s. Other forms of knowledge that reflected prior experience were not labeled as memory *per se*. Instead, terms such as habit were used. One result of this usage was the long-standing resistance to attributing memories to non-human animals (again reflecting Aristotle).

A major shift in terminology resulted from the emergence of neuroscience and attempts to understand the neural bases of learning and memory. Since the relevant studies were being done in rodents and various invertebrates, the notion of what constituted a memory had to be broadened. The term memory came to be applied to just about any change in the nervous system that resulted from prior experience, becoming interchangeable with the notion of plasticity. Given this much broader definition of memory, it was only a matter of time before the idea that there were qualitatively different kinds of memory emerged. I have sketched out my understanding of some of the historical forces at play here in earlier papers (Nadel, 1992, 1994), so I will be relatively brief here.

When the patient HM was first described (Scoville and Milner, 1957), memory was thought of in the univocal way described above. Milner (1966) described the deficit created by medial temporal excision in HM and several other patients as follows:

> The pattern of amnesia which emerges from the clinical observations of the patients with bilateral hippocampal damage is one in which long-term memories survive, as does the ability to attend normally to on-going events. The essential difficulty appears to be in adding any new information to the long-term store. (Milner, 1966: 124)

HM could show some learning of motor skills (cf. Corkin, 1968), suggesting to Milner that "the pattern of amnesia demonstrated by these patients is incompatible with a unitary-process theory of memory" (Milner, 1966: 131). However, this did not lead immediately to the notion that there were multiple memory systems, since such motor learning, after all, did not actually involve memory by the definitions of the time. Instead, the data from amnesia were taken to support then current models of memory involving separate short-term and long-term systems, with a memory consolidation process responsible for the transition from one system to another. Milner suggested "It is possible that in normal learning, the hippocampal region acts to prime activity in cortical areas where storage is taking place" (Milner, 1966: 130). From this notion the idea that the hippocampus was critical for what is now called systems consolidation emerged, and it has played a central role in thinking about the hippocampal role in memory ever since (see Nadel, 2007, for a brief history and update of this idea). Although the concept of multiple memory systems is implicit in this notion, it remained implicit for some years.

Research attention turned instead to the issue of which brain areas were critical to the amnesic deficit, and the attempt to establish an animal model of the syndrome observed in HM. The initial failure to replicate HM's memory deficit with what were assumed to be comparable lesions in primates (Orbach et al., 1960) left researchers confused. Had significant changes in the function of the relevant structures emerged during evolution? Did the medial temporal lobe do something very different in primates and humans, not to mention rats? These kinds of questions were very much in the air in the 1960s.

In a seminal series of papers in the late 1960s, Warrington and Weiskrantz (1968, 1970) showed that amnesic patients could indeed benefit from some forms of prior experience in addition to showing motor learning. Their early demonstrations included the use of fragmented pictures and words – amnesic patients exposed to such materials took less and less time to identify the materials with repetition. They noted that there are "two types of task, motor learning and retention by partial information, which are relatively well preserved in amnesic subjects," and they wondered "Is there a common factor linking performance on these apparently dissimilar tasks?" (Warrington and Weiskrantz, 1970: 630). They pointed out that the presence of spared memory capacity might allow one to explain the apparent discrepancy in the data from the clinic and from animal studies, but this would necessitate dropping the idea that the defect caused by hippocampal damage was one of impaired memory consolidation.

From a historical perspective, it is intriguing that both research programs, in Canada and the United Kingdom, had uncovered the fact that in the amnesic syndrome some forms of learning and memory were spared while others were impaired, but neither jumped to the idea that there were multiple memory systems.

This advance came instead from the domain of animal research, in particular several programs focused on the functions of the rat and monkey

hippocampus. Three publications in 1974 proposed, in rather different ways, that there were multiple forms of memory and that the hippocampus was only responsible for one of them. Gaffan (1974) suggested that there were two forms of memory, one involving recognition, the other association, and that the hippocampal system was only critical for recognition. Hirsh (1974) suggested that memory could be either context bound or context free, and that the hippocampus was critical only for context-bound memory. Nadel and O'Keefe (1974), building on the discovery of place cells in the hippocampus of the rat (O'Keefe and Dostrovsky, 1971), suggested that the hippocampus was critical only for acquiring cognitive maps and that the place learning and episodic memories that depend upon them, whereas other forms of learning and memory depended on other brain circuits.

O'Keefe and Nadel (1978, 1979) laid out a comprehensive theory that rested squarely on the notion that there are multiple forms of memory.

> there are different types of memory . . . localized in many, possibly most, neural systems. . ..
>
> there is no such thing as the memory area . . . there are memory areas, each responsible for a different form of information storage. The hippocampus . . . both constructs and stores cognitive maps (O'Keefe and Nadel, 1978: 373–374).

The authors argued that the hippocampal system was concerned with knowing that, while other memory circuits were concerned with knowing how. This idea was taken up by Cohen and Squire (1980), who showed that amnesics could learn how to mirror read but could not remember that they had done so. Within a matter of a few years, the notion of multiple forms of memory was accepted in both the animal and human domains, and though there have been occasional attempts to argue against this view, the idea seems firmly rooted.

The answer to the question – what memory is – seems only to complicate matters, because memory is many things, not one. But how are these many things, these multiple forms of memory, to be distinguished from one another? Do they reflect the operation of different systems, in the sense described above? In order to answer this one question we need to ask, and answer, several others. Do the different forms of memory reflect different kinds of information? Do they differ in terms of the processes they instantiate? Do they differ in terms of the brain mechanisms and structures they involve? Do these separate learning and memory systems obey different rules of operation? Most researchers would agree that there are different memory systems only if the answer to most of these questions is yes.

Because of the central role played by the hippocampal system in thinking about memory, the early tendency was to talk about two kinds of memory, one dependent upon hippocampal circuits and the other not. Thus, O'Keefe and Nadel (1978, 1979) talked about locale and taxon memory, Cohen (1984) and Squire (1987) talked about declarative and procedural systems, and others talked about explicit and implicit systems, to name but a few. There are many commonalities among these various ways of handling the multiplicity of memory, but they all share the fate that they are too simplistic. Current approaches suggest as many as 5 to 10 kinds of memory. As the number of putatively separable memory systems increases, it becomes important to step back and ask the fundamental questions again. What exactly do we mean by memory? How is prior experience incorporated into current behavior?

1.04.4 What Is Memory, Redux

Given the expanded view of memory forced upon us by neuroscientific exploration of memory's biological bases, it seems time to rethink the notion of memory itself. If there are 5, 6, or 10 different kinds of memory, does it make sense to call them all memory? My answer is that it does not. Instead, I propose to go back to using the term as it had been used before recent developments widened its application. That is, I believe we should use the term memory solely to refer to what happens when an organism recollects the past. All else would best be called knowledge (Nadel and Wexler, 1984). As a function of experience we acquire knowledge, which is represented in various brain systems. Knowledge is used to generate both memories and behaviors. What we call a memory is constructed from this knowledge as required. The hippocampal system, serving as a contextual binding device, a creator of cognitive maps, plays a critical role in this construction process.

This way of thinking has its roots in debates more than 60 years ago between adherents of different views of learning and behavior. Following Tolman (1932), we assumed that organisms always act with purpose, trying out one or another strategy or hypothesis to deal with their current situation

(cf. O'Keefe and Nadel, 1978: chapter 2). We focused our attention on spatial behavior and spelled out a number of different hypotheses an animal could use to get around in the world, including place, guidance (or cue), and orientation (or response) hypotheses. Typically, hypotheses require complex interactions among different knowledge systems, only some of which reflect learning. That is, some of the knowledge an animal uses to act in the world comes from prewired circuits. For example, animals do not have to learn *de novo* that stimuli in close temporal contiguity are more likely to be causally linked to one another than stimuli widely separated in time.

By this analysis, we have multiple knowledge systems, which we use to generate various forms of behavior and to construct memories. Much the same set of questions applies to these multiple knowledge systems as applies to what have been called multiple memory systems. How do they differ, how do they interact, what rules of operation do they obey, how are they instantiated in the brain? If the reader prefers, she or he can continue to think about multiple memory systems as they read the words multiple knowledge systems.

One consequence of this proposed shift in terminology is that the idea of a brain system devoted purely to long-term memory no longer makes sense. This idea, stated perhaps most forcefully by Squire and his colleagues with reference to the medial temporal lobe (e.g., Squire, 1994), depended on the idea that damage to this part of the brain affected only memory but not short-term processing or perception. This idea has been criticized both in the past (Horel, 1978, 1994) and in recent writings (cf. Ranganath and Blumenfeld, 2005; Hannula et al., 2006), and in my view it should now be retired. It makes more sense to think about all neural systems as both processing and storing knowledge, with the differences between systems reflecting the nature of the knowledge being processed and stored, and the timescale of that storage.

1.04.5 Multiple Knowledge Systems

What kinds of knowledge does an organism need to acquire about its world in order to survive and even prosper? Bear in mind we are assuming that fundamental facts about how the world works are built into the organism's system by phylogeny and do not have to be relearned by each generation. What does have to be learned are those things that cannot have been acquired in the course of phylogeny. What are they?

Quite a lot it turns out: who your mother, father, sister, or brother are; who, what, and where you should approach or avoid; what you should eat and drink, and when; who you should try to copulate with, and when (and where); how to do various things such as explore, play, fight, hunt, escape predation, find your way home again, and more. A special form of acquired knowledge concerns those accidental conjunctions that we call events, when actors, actions, and worldly objects come together in combinations that could never have been predicted in advance. What sorts of knowledge/memory systems would provide the best way of learning all this and solving all the problems life confronts us with?

As a first cut, it is useful to note that organisms appear to need knowledge systems concerned with two very different kinds of information – first is the need for knowledge accumulated over many similar events, and second is the need for knowledge about unique occurrences, and the limits these might put on the application of cumulative knowledge (cf., Klein et al., 2002). Tulving's (1972) discussion of semantic and episodic memory captured this distinction. I have tried to make the case that the term memory should be reserved for recollections of unique episodes, but there has lately been considerable interest in cumulative knowledge, which has been viewed as allowing organisms to extract reliable information about the statistical structure of the environment. A significant complication in thinking about knowledge systems is that the systems engaged in processing these two types of information are in constant interaction. Indeed, how to think about the relations between episodic and semantic knowledge, and the brain systems underlying these forms of information, constitutes one of the major challenges for the future. We return to this issue later, after addressing in more detail the question of what kinds of knowledge systems the brain must contain.

Before turning to a discussion of types of knowledge systems, it is worth pointing out that thinking in terms of knowledge rather than memory forces us to put the function of knowledge acquisition front and center. What propels an organism to gather knowledge in the first place? This is a question that bedeviled early psychologists focused on biological categories and drives. The existence of curiosity and exploration were an embarrassment since the mere acquisition of knowledge could not be simply related to any particular biological drive. Within a

framework that emphasizes knowledge, curiosity and exploration become critical. Instead of being relegated to sidebar status, these behaviors deserve careful study in their own right. It remains a remarkable fact about modern cognitive neuroscience that so little attention has been paid to these core functions (cf. Avni et al., 2006; Whishaw et al., 2006; for two recent exceptions to this neglect).

1.04.5.1 Types of Knowledge Systems

One way to think about knowledge systems is in the following simplistic fashion – an organism needs knowledge about what it experiences, where and when things happened, who was involved, the value of the things experienced, and how to act in the future when confronted with similar experiences (*See* Chapters 1.21, 1.22, 1.23). One might imagine that organisms extract and store knowledge about each of these aspects of experience in separate systems, combining this knowledge when required to do so by the demands of a given situation, or an experimenter-defined laboratory task. As we consider each of these separately, it becomes clear that things are not as simple as they might seem. To start, these categories are not absolutely clear-cut – there is overlap between them in some instances, as we see later. Further, some kinds of knowledge are inferred rather than experienced. Perhaps the best example concerns why things happen. Organisms make inferences about causality, even though these are rarely backed up by direct experience, and these inferences become an important part of their knowledge base. Notwithstanding these problems, it still seems worthwhile thinking about knowledge systems along these lines. In what follows, I briefly discuss each of these kinds of knowledge. A serious analysis of this approach would require a substantial expansion of this discussion, one that is beyond the scope of this chapter.

1.04.5.1.1 Knowing what

It is best to start with the kind of knowledge that informs an organism about the stuff of which existence is made. All else is subservient to this kind of knowledge, since in the absence of what there is no where, when, why, or how. Or, as Kant put it, form in the absence of content is meaningless. What knowledge provides this content, the semantics of existence one might say.

The category of what knowledge is complex, comprising several different kinds of knowledge, including:

- What happened
- What entities were involved
- What properties these entities have

These three forms of knowledge are quite different in kind, and one might imagine that they are subserved by quite separate underlying neural and cognitive systems themselves.

Processing and storing information about what happened is central to memory for events, or episodes, and hence must incorporate the ability to capture sequence information. Every such sequence would consist of entities interacting in space and/or time. The entities themselves must be represented in a fashion that captures their properties, both structural and functional. The ventral visual stream (Ungerleider and Mishkin, 1982) is a well-known example of what I am here calling a what system, and indeed this is the name given to it by Ungerleider and Mishkin. It is reasonable to assume that similar what systems exist within each of the sensory/perceptual processing streams. These systems contain representations of entities in the world and their properties, representations that have been shaped by the experiences an organism has had with these entities in multiple event contexts. Each time an entity is encountered in the world, its "what" representation is activated, and as a function of this new experience, the representation altered. These representations are activated and hence mobilized in the act of memory retrieval.

1.04.5.1.2 Knowing where

This category is also complex, because animals need to know several things that could be referred to as where knowledge. They need to know where they are at any given moment. They need to know where important things, such as food, water, safety, and conspecifics, are located, both with respect to an environmental framework and with respect to where they are themselves located at any given moment. They need to know where events happened. They also need to know how to get from one place to another (*See* Chapters 1.20, 1.21, 1.25).

It seems clear that significant neural resources are devoted to processing and storing where knowledge. Extensive systems seem devoted to representing where things are relative to the current location of the organism. What is more, this information seems to be multiply represented, in that it is captured with respect to several frames of reference. That is, organisms simultaneously know where an object is with

respect to the head, the eyes, the hands, and the body. This is important because action depends upon such knowledge. In addition to these various ego-centered spatial systems, there is a system, centered on the hippocampal formation, that represents an organism's location in absolute, or allocentric, space. This system makes use of inputs from multiple sources, and includes elements such as place cells in the hippocampus (e.g., O'Keefe, 1976), head-direction cells in the thalamus and postsubiculum (e.g., Taube et al., 1990), and the recently discovered grid-cells in the entorhinal cortex (Hafting et al., 2005).

In addition to providing specific information about an animal's location in space, this system is also central to knowledge about context, that is, the spatial setting within which events happen (cf., Nadel and Willner, 1980; Nadel et al., 1985). It is this role, we have argued, that makes the hippocampal cognitive mapping system central to episodic memory, which by definition incorporates information about where an event transpired. It is certainly one of the main challenges for the future to discover why and how spatial mapping and episodic memory utilize the same circuits (*See* Chapter 1.33).

1.04.5.1.3 Knowing when

There are at least two kinds of when knowledge that organisms might need. First, they might need to know when, over a long span of time, an event occurred. Was it yesterday, last week, last year? This kind of knowledge is integral to episodic memory, and there remain debates about whether animals other than humans actually represent it. Second, organisms need to know when within a particular event the various parts of that event occurred. This might seem a trivial matter, but if one argues, as we are arguing, that the various parts of an event are processed and represented in separable brain regions, then being able to assemble them in appropriate temporal order, to know when each of them occurred with respect to the others, is critical. The simplest example will suffice to make this point: it makes all the difference whether A comes before or after B, because the attribution of causality depends upon knowing which of these two entities or events came first. An organism that gets temporal order wrong is going to make the wrong attributions and is not going to survive very long.

1.04.5.1.4 Knowing who

This is a somewhat simpler category, and one that might be of importance only in species with the capacity to recognize individuals, itself a function of the sophistication of its what systems. In humans, it plays a critical role, of course. George is smarter than Dick leads to a very different conclusion than Dick is smarter than George, although both statements employ the same words.

1.04.5.1.5 Knowing how

This is a big category, comprising all the knowledge referred to as procedural by many authors. There are some important distinctions to be drawn, however, between some of these forms of how knowledge. For example, knowledge of how to carry out some kind of motor act, such as brushing your teeth or driving your car or playing squash, is rather different than knowledge about how to get from one place to another (e.g., which route to take, not how to move). It is not within the scope of this chapter to go into much detail on this category of knowledge, but current work on the functions of the caudate nucleus in particular, and the basal ganglia in general, are shedding light on how we know about how.

1.04.5.1.6 Knowing valence

In addition to storing knowledge about the kinds of entities they confront in the world, organisms represent the value of these entities, whether they are good or bad, exciting or frightening, and so on. This kind of knowledge plays a critical role in determining not only how an organism deals with such entities in the future but also how strongly the knowledge itself is committed to storage. In general, the greater the valence, the more robust the storage, at least within most of the brain's knowledge systems. As with all kinds of knowledge, the use of value information is highly dependent upon the context within which an organism is acting, including its internal motivational context. Knowing that something tastes good is much more useful when one is hungry than when sated, for example. Considerable evidence in recent decades suggests that the amygdala plays a central role in representing value knowledge, but it is by no means the only structure so engaged. Extensive midbrain circuits are devoted to assessing and presumably storing information about the reinforcing value of various stimuli an organism comes into contact with. Portions of the cingulate cortex and frontal cortex also contribute to this system.

1.04.5.1.7 Implications of the existence of multiple systems

There are many implications of assuming that the brain is organized into multiple knowledge systems. Consider the fact that the knowledge about an episode in one's life is dispersed within the brain, across multiple systems. What happened, who was involved, where and when it happened – these various aspects of a memory are widely distributed, which means that retrieving and reporting an episode memory must be a constructive act, much as Bartlett (1932) and others have argued. And being constructed, memory for episodes must be open to error in a way that engrams were not supposed to be.

Different knowledge systems, utilizing separable neural substrates, could operate by distinct rules. O'Keefe and Nadel (1978), for example, proposed that there were two quite different brain systems engaged in learning and remembering, which they called the locale and taxon systems. The locale system was associated with the hippocampal formation, and the various taxon systems were associated with neocortical and subcortical structures. It was suggested that learning within these two kinds of systems reflected different operating principles. The taxon systems obeyed standard laws of reinforcement and followed associative principles. Learning within the locale system, by contrast, was assumed to proceed independent of reinforcements such as food, water, safety, or access to a mate – animals formed cognitive maps whether rewarded or not. Further, O'Keefe and Nadel asserted that learning within the locale system did not follow associative rules. Consistent with these speculations, Hardt and Nadel have shown that learning within the locale system differs from learning within taxon systems in that the latter reflect the operation of standard associative phenomena such as overshadowing and blocking, whereas the former does not. Instead, knowledge acquisition in the locale system is automatic, such that new information updates previous representations, whether or not reward contingencies have changed. Behind the assertion that these two learning systems obey different rules is the assumption that the underlying neural architectures in the systems subserving these two forms of knowledge differ in critical ways that allow different learning rules to be implemented in each.

In addition to these system-level implications, there are a number of others that reflect the fact that by being separate, knowledge systems can be affected differentially by all that life has to offer. In what follows, I discuss several examples, including development, aging, and the reaction of different systems to stress. In each case it will be seen that knowledge systems vary in how they are affected, and that these variations help us to understand a number of phenomena of considerable importance.

1.04.6 The Development of Knowledge Systems

It is reasonable to assume that each neural system develops at its own rate, and that there are differences among neural systems in this regard. To the extent to which a particular form of knowledge depends upon a specific neural substrate, it is then likely that the various knowledge systems have different developmental trajectories. The very capacity to know certain things depends upon the development of the underlying neural system that processes and represents that kind of knowledge. Until that happens, such knowing should be impossible. It is a reasonable further assumption that still-developing systems are susceptible to alteration, induced either by experience or the unfolding of some genetic program. Such factors are less likely to act on already-developed systems. This means that ways of knowing can be more or less influenced by early life experience as a function of when they develop.

Neural systems responsible for processing knowledge about objects in the world seem largely functional early in life, as must be the case if organisms are to respond appropriately to those entities and events that are of critical survival value. However, large differences are seen within this category. Systems responsible for knowing about the smell or taste of things seem in general to develop before systems responsible for knowing about the sight or sound of things. The generalization here might be that systems concerned with knowledge about internal states, and stimuli related to those states, develop before systems concerned with external states.

In most mammals, several neural systems, and the knowledge systems that depend upon them, show prolonged maturation, much of it postnatal. This has significant implications for understanding how both our memory and performance capabilities change during early life. A prominent example is the hippocampal formation, portions of which undergo substantial postnatal maturation (cf. Nadel and Hupbach, in press). Evidence about the development of the hippocampus

comes from studies of both structure and function. At present, the best evidence comes from studies with rodents, but we now know enough about primates and humans to state a general case. Across a wide range of species, it appears that the hippocampus first becomes functional at about the natural time of weaning. Unfortunately, we do not know when this is for humans, hence we must make guesses based on anatomical, physiological, and behavioral data to determine just when the hippocampus becomes functional in humans. Note that it is unlikely that this, or any other, brain structure suddenly becomes functional, as if by the flipping of a switch. It is more likely that hippocampal function emerges piecemeal, taking a considerable time to reach the adult state.

It has been known for several decades that the dentate gyrus of the rat is particularly subject to postnatal development (see Frotscher and Seress, 2006, for a recent review). Large numbers of dentate granule cells are created after birth in the rat in a special proliferative zone within the hippocampus itself. Initially it was thought that rodents were unique, and that postnatal maturation of hippocampus was either absent or less prominent in primates and humans. This, however, turns out not to be the case. Even in these species, the hippocampal system emerges into function after birth. Hippocampal pyramidal cells, unlike dentate granule cells, proliferate in the prenatal stage. But, two other critical components of any developed brain system – the integration of inhibitory neurons and the myelination of fibers – lag behind in hippocampus. Seress and his colleagues conclude that while cells are generally born early, further steps critical to normal function are quite prolonged.

In rodents, we can use the appearance of exploration and place learning as markers of the emergence of hippocampal function. Data from such studies in general support what was deduced from studies of structure – namely, that hippocampal function begins at about 3 weeks of life in the rat. Since the two major cognitive functions in humans that depend upon the hippocampus are episodic memory and memory for allocentric spatial location, delayed maturation should be reflected in the late emergence of these capacities.

Infants at quite a young age can learn about space as it relates to their body or its parts (eyes, hand, head). They can learn to crawl or walk to objects in space and readily solve simple spatial tasks such as 'go right' or 'go to the door and turn left.' These kinds of spatial learning do not, however, depend upon a functioning hippocampus. Instead they depend upon knowledge systems subserved by other, earlier-developing, neural systems. The capacity to know, and use, allocentric space, on the other hand, does depend upon the hippocampus, and data from a variety of studies suggest that this capacity emerges only between 18 and 24 months of age in humans (cf. Newcombe et al., 1998).

There are several major implications of the postnatal maturation of the hippocampus. The first concerns behavior. We assume adult behavior reflects the presence of both hippocampal and nonhippocampal systems, what they do and how they interact. Prior to hippocampal emergence, however, behavior reflects functions and behaviors dependent on brain systems operational at birth. The second major implication concerns development. A developing system is more susceptible to influence than an already developed one. This is presumably why environmental influences exert a particularly strong impact on the developing hippocampus.

1.04.6.1 The Delayed Emergence of Episodic Memory

In general, little evidence of episodic memory, as measured in standard recall and recognition tests, is observed until the age of 3 or 4 years. The absence of episode memories from the first 2 years of life resulting from the late maturation of the hippocampus can help us understand at least part of the syndrome of infantile amnesia (Nadel and Zola-Morgan, 1984; *See* Chapters 1.15, 2.37). It is a well-established fact that for most individuals, few if any early episode memories survive into adulthood. It is only after 2–3 years of age that significant numbers of episode memories appear to be formed and retained. Over the years, there has been considerable debate as to whether this syndrome, first discussed at length by Freud, reflects biological maturation or some other factors, such as the mismatch between the nonverbal coding of early memories and the verbal means used later in life to retrieve and report memories or the emergence of a sense of self at around 2–3 years of age. Arguments against the biological case depend on assertions that the hippocampus develops early in life, as noted above. These assertions, as we have seen, rested either on the use of inappropriate tasks or on incorrect interpretations of the nature of contextual coding and the hippocampal role in it. Now that a consensus has emerged to the effect that hippocampus is most likely to become functional

between 18 and 24 months of age in children (Newcombe et al., 2007; Nadel and Hupbach, in press), we can conclude that a significant part of infantile amnesia reflects biological maturation.

Further support for this view comes from the study of the unique population of developmental amnesics, individuals with damage to the hippocampus caused, typically, by an early anoxic or ischemic event (cf. Vargha-Khadem et al., 1997). These individuals, mentioned earlier, went unrecognized for quite a while because they did reasonably well in educational settings. Only careful testing brought out the fact that they suffered from quite severe losses in the domain of episodic and spatial memory. Developmental amnesics have general difficulties orienting in space and time, remembering events, finding their way through any but the most familiar environments, and remembering where they placed objects. However, they are usually not impaired in their social and language development and score low to average on standard tests of intelligence. They have a relative preservation of semantic memory and often show normal scores on immediate or short-term episodic memory tests, but they are unable to retain episodic information over longer periods of time. Studies using structural magnetic resonance imaging suggest that the described symptoms of developmental amnesia are caused by bilateral hippocampal volume reduction of at least 20%–30%.

The increased susceptibility to influence following from postnatal development of the hippocampus manifests itself in two rather different ways. First, the hippocampus seems to be very sensitive to environmental perturbations. Careful studies of the neuropsychological impact of early exposure to lead, for example, suggest that impairment of hippocampal function contributes to the resulting cognitive deficit (e.g., Finkelstein et al., 1998). Second, genetic conditions that influence development in a general way seem to have their greatest impact on late-developing parts of the nervous system (and other organ systems as well). There is a kind of selection bias inherent here: Genetic conditions that affect structures formed early in development might have such devastating effects that they are inevitably lethal. Influences on late-developing structures might be prevalent simply because they are the only ones that can be survived.

Down syndrome presents such a case. This condition, resulting from an error in very early embryonic life, almost always reflects the existence of an extra copy of chromosome 21 (cf. Nadel, 2003). As a consequence, extra gene product results, and this in turn leads to a variety of problems in a host of biological systems. In almost all cases, these problems seem to impact the later-developing parts of the relevant system. Thus, in the nervous system, the hippocampus, cerebellum, and prefrontal cortex, all of which mature late, are disproportionately affected. How these effects translate into the mental retardation observed in Down syndrome remains to be determined, and the creation of appropriate mouse models is moving toward that goal. Williams syndrome might present another such case, as it has recently been shown that children with this syndrome, caused by deletion of a subset of the genes on chromosome 7, have significant abnormalities in hippocampal structure and function (Meyer-Lindenberg et al., 2005).

It seems clear from these various examples that some knowledge systems, and in particular those critical for what we are here calling memory, develop later than other knowledge systems critical for such things as what and how much knowledge. It is worth pointing out that at the other end of the age scale, aging also has an uneven impact on knowledge systems. Evidence suggests that as in development, it is the hippocampal system, central to episodic memory, that is most at risk (cf. Burke and Barnes, 2006).

1.04.6.2 The Impact of Stress

Another way in which the existence of multiple knowledge systems matters is that these systems can be differentially affected by experience. One very important example is offered by how knowledge systems are affected by arousal and stress. The literature in this area has been confusing, since evidence existed that arousal facilitates memory formation (Reisberg and Heuer, 2004), while at the same time acute stress, which is undoubtedly arousing, has been shown to impair memory in several studies (Jackson et al. 2006; Payne et al., 2006). The best way to understand this discrepancy is in terms of multiple knowledge systems and how they are differentially affected by stress. Payne et al., for example, showed that memory for neutral information is impaired by stress at the same time that memory for emotional information is facilitated. This result is best understood by assuming that emotional information (value knowledge) is handled by one system in the brain, the amygdala, while neutral detail, typically of the background context (where knowledge), is handled by another brain system, the hippocampus. It has been established that within much of the range of physiological stress, amygdala function is enhanced while

hippocampal function is impaired. Thus, the same stress manipulation can simultaneously increase acquisition of one kind of knowledge while decreasing acquisition of another. The implications of this simple fact for various legal issues, such as the viability of eyewitness testimony, and the veracity of recovered memories, are immense (see Jacobs and Nadel, 1998; Payne et al., 2003, for some discussion of these matters; *See* Chapters 2.14, 2.44).

1.04.7 Conclusions

That there are multiple systems engaged in acquiring and deploying knowledge gained from experience seems clear. I have argued that it is better to think about these as knowledge systems rather than as memory systems. This difference is not a mere semantic quibble, since a number of consequences flow from this change in terminology. However one does refer to these systems, the fact that they exist as separable entities has a variety of implications that I have tried to briefly explore in this chapter.

One final implication that I have not explored concerns the fact that the existence of multiple, separate, systems opens up the possibility of competition between systems for control of behavioral output. Within the domain of spatial behavior there is strong evidence that such competition exists between, for example, strategies that depend upon the egocentric information subserved by caudate and other structures and the allocentric information subserved by hippocampus and related structures (cf. Nadel and Hardt, 2004). Similar findings have been reported recently for a nonspatial task involving probabilistic classification (Foerde et al., 2006). It remains for future research to explicate these competitive relations in greater detail, as they will ultimately turn out to be extremely important in understanding how organisms deploy optimal knowledge in various circumstances. Looked at in this way, all forms of behavior involve decision-making at some level, creating linkages between previously disconnected literatures on memory and choice.

1.05 Retrieval from Memory

G. P. Urcelay and R. R. Miller, State University of New York at Binghamton, Binghamton, NY, USA

1.05.1 Retrieval from Memory

The field of learning and memory has traditionally emphasized acquisition and storage as the critical determinants of learned behavior (*See* Chapters 1.02, 1.04). In the field of associative learning, this orientation is clearly evident in Pavlov's work, which suggested that spreading activation between nodes was necessary for memory formation (Pavlov, 1927). Similarly, Hebb (1949) proposed that experiencing a learning event temporarily activates certain neural circuits that, while active, strengthen the synaptic connections that constitute the basis for that experience becoming permanently stored in memory. This emphasis on acquisition and storage can be seen at many different levels of analysis. For instance, in the human memory literature, Craik and Lockhart (1972) proposed that the acquisition and storage of new information would create a more durable memory trace if processing during the acquisition (i.e., study) phase occurred at a relatively deep level (i.e., more integrative semantic than superficial phonetic). As another example, the Rescorla–Wagner rule for the formation of associations assumes that competition between stimuli trained together in a Pavlovian conditioning preparation occurs exclusively during the training phase (Rescorla and Wagner, 1972). All these views share the common assumption that any disruptive manipulation that occurs during training will inevitably result in that learned information being permanently lost and unavailable in future encounters within a similar situations. The influence of this view is so pervasive that the term *learning* itself for some researchers represents the totality of information processing underlying stimulus-specific changes in behavior resulting from prior experience. This use of the term discourages consideration of any of the post-acquisition processing that may also be necessary to see learned behavior. By definition, learning is the process by which experience is encoded and results in stimulus-specific changes in behavior that can be observed later. By memory, we are referring to any stimulus-specific permanent change in the brain (structural and chemical) resulting from past experience that allows usage of that previous experience on future occasions. Finally, retrieval is the process of reactivating an established memory so it can influence ongoing behavior, and thus we will argue that retrieval is a key component of memory performance.

In the early 1960s, however, a number of studies showed that information thought to be lost or not encoded was still available, provided that the appropriate retrieval cues were presented at the time of testing (see Tulving and Thomson, 1973, for a review). In other words, these studies suggested that memory deficits typically thought to result from processing limitations during training could be recovered at the time of testing. These experiments, conducted primarily with human subjects, provided a strong rationale for investigating a critical stage in

the information processing stream: retrieval from memory. In most of these experiments, subjects were presented with material to be learned (encoding) and subsequently evaluated to determine the conditions under which that information could be retrieved and brought to bear on response generation. As a result of this research, the emphasis on encoding that dominated the early stages of human memory research shifted to also encompass retrieval mechanisms. Interestingly, these observations with human subjects promoted changes in the study of animal memory. A vast amount of data concerning retrieval processes has been gathered from nonhumans since the late 1960s, and ever since, the notion of retrieval has proven to be a useful heuristic for the study of memory phenomena.

This chapter will focus on memory research with nonhuman animals. In the first section, we will review the empirical evidence suggesting that deficits in memory tasks do not necessarily reflect a deficit in acquisition or storage. Specifically, we will summarize representative experiments in which memory deficits are observed after changes in the internal state of the organism, or the administration of amnesic treatments such as electroconvulsive shock or protein synthesis inhibition. Moreover, we will review recent evidence suggesting that already consolidated memories, when reactivated, undergo a new period of vulnerability, so-called reconsolidation. Importantly, memory deficits can also be obtained by manipulating the amount of information presented either during training of the target memory (cue competition) or by presenting additional information at other points in the study (interference). Cue competition and memory interference experiments have also contributed evidence concerning the role of encoding and retrieval of memory and therefore will also be analyzed in this section. In the second part, we will summarize how these observations led to the development of memory models that account for a wide range of phenomena. As is the case in most scientific disciplines, there is no single approach that accounts for all the empirical evidence available. Therefore we will review three models that address the phenomena described in the first section. The first general framework is that proposed by Spear in the late 1970s that explains memory deficits induced by changes in the context or insufficient retrieval cues at the time of test. The second retrieval framework we will review is focused on associative phenomena originally thought to reflect learning deficits. As we will see, these deficits are easily anticipated in a framework that emphasizes retrieval mechanisms. The third framework is that proposed by Bouton to explain several characteristics of extinction that are important to understand some anxiety disorders in human populations (*See* Chapter 1.09). Lastly, we will briefly review neurobehavioral studies in which the physiological substrates of memory retrieval have been investigated. The importance of these studies lies in the fact that inquiries into the neurobiological basis of memory are inspired by behavioral models, such as the ones we describe in the section titled 'Theories of memory retrieval.'

1.05.2 Empirical Evidence

Several key empirical observations suggest that numerous deficits in acquired behavior result from information processing that occurs when subjects are tested rather than when they acquire or store information. Critical here is the fact that, theoretically speaking, if information is inadequately acquired or is not retained, then that information will not be available to influence the animal's behavior in any test situation. In contrast, the following observations suggest that the target information has often been sufficiently encoded and stored, but a processing deficit occurs when the information is evoked, which translates into decreased performance at the time of testing. We will review decrements in retrieval that arise from natural changes in the organism's internal state and from changes in the state of the external environment between training and testing, as well as those that arise in the laboratory as a result of programmed invasive manipulations (i.e., experimentally induced amnesia). Moreover, we will review recent evidence suggesting that memories that are retrieved from an inactive state could be subject to new consolidation processes, so-called reconsolidation (*See* Chapter 1.24, 1.27). Finally, we will review demonstrations of recovery from performance deficits arising in situations in which multiple cues are simultaneously present during training (cue competition) and from exposing subjects to select nontarget information removed from target training (stimulus interference).

1.05.2.1 Changes in the Organism's Internal State

One of the earlier observations that suggested a deficit in retrieval was state-dependent learning. State-dependent learning refers to the observation that

when the internal state of the organism is different at testing than it was at training, acquired performance is impaired (Overton, 1964). Operationally, state-dependent learning is observed when subjects experience training under one of two internal states (a state induced by the presence or absence of a drug in Overton's case) and tested under the opposite internal state. The common finding is that when subjects are trained in a nondrug state and tested in a nondrug state, behavior consistent with training is observed. Conversely, if subjects are trained while in a drug-induced state (e.g., amphetamine) and tested while not in a drug state, a decrement in performance is typically observed. This decrement could easily be accounted for by a deficit in learning, perhaps due to the drug-altering perceptual processes or the encoding of information. Similar decrements in performance are observed when subjects are trained while undrugged and tested while drugged. These decrements can be accounted for by perceptual processes at the time of testing. However, subjects trained under a drugged state and tested under the same drugged state do not always show a decrement in memory performance. This suggests that the observed performance decrements often result from retrieval deficits due to a change in the internal state of the organism (Spear, 1978). If the internal state of the subject during testing is the same as during training, regardless of whether it is a state induced by administration of a drug, performance consistent with training is observed. State-dependent learning has been observed in a wide range of memory tasks and with states induced by several different drugs, such as amphetamine, alcohol, and morphine (Overton, 1972, 1985), and also emotional states induced by various manipulations (for a review, see Overton, 1985). Obviously *state-dependent learning* is a misnomer; the phenomenon would more accurately be called *state-dependent retrieval*.

Another example of state-dependent learning that can be understood as a retrieval failure is the Kamin effect (Kamin, 1957, 1963). This effect typically has been observed in avoidance tasks in which subjects show poor retention of avoidance training when they are tested at intervals ranging from 1 to 6 h after training. The interesting observation is that such poor retention is not observed if subjects are tested a half hour after training or more than 24 h after training. In other words, subjects show a U-shaped retention function, with retention being good immediately after training and at later intervals, but not between 1 and 6 h after training. This U-shaped function has been viewed as the result of memory retrieval being dependent on the internal state of the organism. A more specific hypothesis was based on the fact that most of these demonstrations of the Kamin effect used aversively motivated tasks, which are known for their capacity to induce a stressful internal state. Moreover, the release of a hormone closely correlated with stress, adrenocorticotropic hormone (ACTH), is inhibited relatively soon after a stressful experience (McEwen and Weiss, 1970). Researchers reasoned that, because of ACTH inhibition, the internal state of the subjects from 1 to 6 h after training was different from the internal state during training, leading to a failure to retrieve the appropriate information required to perform in the task. Consistent with this interpretation, exposing subjects to foot shocks immediately before testing overcame the deficient retention observed at intermediate test intervals (Klein and Spear, 1970). Moreover, exposure to other stressors, such as immersion in cold water for 2 min, also alleviated the intermediate interval deficit in retention (Klein, 1972). Note that this stressor was unrelated to the training situation in terms of external, sensory attributes of the memory (other than being stressful), but it apparently restored the internal state that was temporarily inhibited after the original stressful experience. Importantly, the cold water bath had no effect at other retention intervals, suggesting that the effects are not related to overall activation or motivational effects of the stressor (Klein, 1972). Presumably, exposure to either foot shock or cold water provided subjects with an internal state (ACTH release) that corresponded to that of training and consequently alleviated the deficit observed at intermediate intervals. Moreover, this deficit in retention was also alleviated if subjects were infused with ACTH into the lateral anterior hypothalamus or if the same structure was electrically stimulated (Klein, 1972). More recently, Gisquet-Verrier and colleagues observed an alleviation of the Kamin effect when they exposed subjects simultaneously to the conditioned stimulus (CS) and the training context in a brightness-discrimination avoidance task 7.5 min before an intermediate interval test (Gisquet-Verrier et al., 1989; Gisquet-Verrier and Alexinsky, 1990). Overall, all of these demonstrations suggest that the Kamin effect can be alleviated if (a) the subject's internal state is restored (either by administration of ACTH or exposure to a stressor), or (b) the appropriate retrieval cues (such as the CS and the training context) are presented before testing.

Similar recovery effects have been found when retention deficits were induced with hypothermia. Specifically, subjects showed impaired retention if they were immersed in cold water immediately after training (Vardaris et al., 1973). However, if they were recooled before testing, no impaired retention was observed (Hinderliter et al., 1976; Mactutus and Riccio, 1978). These results have been interpreted as arising from a retrieval failure if there is a mismatch between training and testing in the subject's internal state. Consistent with this explanation, administering the recooling treatment immediately before testing presumably alleviates the effects of the hypothermic treatment by providing contextual cues that were present close to the time of training.

1.05.2.2 Experimentally Induced Amnesias

The notion that deficits in acquired behavior result from a processing deficit at the time of retrieval has received additional support from experimental manipulations known to induce amnesia (*See* Chapter 1.14). It is important to note that the three examples from the previous section resulted from changes in the internal state of the subject. In contrast to state-dependent learning and the Kamin effect, in the studies reviewed later, a performance deficit was induced by the administration of an amnestic agent. For example, if soon after training subjects are administered an electroconvulsive shock (hereafter ECS; Duncan, 1949), hypothermia (described earlier; Vardaris et al., 1973), or protein synthesis inhibitors (e.g., Barraco and Stettner, 1976), little behavior indicative of retention is observed. These observations have been taken by many as evidence that amnestic treatments work by disrupting memory consolidation (Gold and King, 1974; McGaugh, 1966, 2000). Memory consolidation is defined as a time-dependent process by which recent learned experiences are transformed into long-term memory, presumably by structural and chemical changes in the nervous system (e.g., the strengthening of synaptic connections between neurons). Support for this explanation comes from the fact that the effects of amnestic treatments are retrograde in nature, with recent memories being more vulnerable than earlier memories to the amnestic treatment (e.g., Duncan, 1949). The temporally graded nature of amnesia is explained by the consolidation view in the following way: After a given learning experience, memories undergo a consolidation process that leaves the memory trace more stable as time passes. Following this logic, the shorter the interval between training and the administration of the amnestic treatment, the larger the impact of the amnestic agent on the formation of the memory trace.

Since the discovery of these amnestic treatments, however, a number of observations have suggested that, instead of disrupting the consolidation process, these treatments might alter the memory's retrievability, thereby rendering it inaccessible at the time of retrieval (*See* Chapter 1.14). Evidence supporting this notion comes from studies that reminded subjects of the original episode. For example, Lewis et al. (1968) trained rats in a passive avoidance task and immediately administered amnesia-inducing ECS. They tested their subjects 20 h later and observed that subjects that received the amnestic treatment showed no behavior indicative of the passive avoidance event; that is, the amnestic treatment was effective in inducing amnesia. However, 4 h after training, they placed other rats given the amnesic treatment immediately following training in a separate compartment (different from that of training) and administered a foot shock (unconditioned stimulus – US), similar to the reinforcer used in training. When these subjects were tested 20 h later in the training compartment, they showed recovery from the amnestic treatment, as evidenced by longer avoidance latencies. In other words, when they exposed rats to a reminder of the initial training experience, subjects' performance indicated that the memory trace was not altered by the amnestic treatment. Subjects lacking original training showed no effect of such reminder shocks. Because this recovery effect could have been specific to the avoidance tasks involving stressful situations, Miller et al. (1974) conducted a similar study, but instead of using an aversive preparation, they used an appetitively motivated task with sucrose as a reinforcer. Interestingly, they reported that, after the amnestic treatment, a foot shock did not affect a recovery of memory. Moreover, they showed that exposure to the sucrose solution following the amnestic treatment reversed the retention deficit induced by the amnestic treatment. Further experiments demonstrated that exposure to the training apparatus also recovered the memory rendered silent by the amnestic treatment. Thus, exposure to any of several elements from the training task restored access to the target memory, whereas exposure to task-irrelevant stimuli, even if they were of strong affective value, did not restore memory.

1.05.2.3 Reconsolidation

As part of the effort to understand and contrast approaches to memory, studies of experimentally induced amnesias gained popularity during the late 1960s and 1970s. This popularity was recently reinvigorated when new findings suggested that old memories when reactivated need new (*de novo*) protein synthesis to become once again stable and permanently stored in the brain (Przybyslawski and Sara, 1997; Nader et al., 2000; *See* Chapter 1.24). This phenomenon has been called reconsolidation. For example, a day after Nader et al. exposed their rats to simple CS → US pairings, they presented the CS alone (which presumably reactivated the memory trace for that association) and immediately infused anisomycin (a protein synthesis inhibitor) into the lateral and basal amygdala. When they tested subjects 1 day later, they observed decreased conditioned freezing to the CS relative to anisomycin-treated rats lacking the CS exposure on day 2, suggesting that the memory trace that was activated needed new protein synthesis to become stable again. These findings brought back the question extensively debated in the 1970s: Are memories destroyed or simply made inaccessible after a retrieval manipulation followed by an amnestic agent (e.g., Gold and King, 1974; Miller and Springer, 1973, 1974)? Several recent reports suggest an answer to this question. For example, Lattal and Abel (2004) observed that after reactivating a memory of contextual fear and administrating systemic anisomycin, subjects showed decreased conditioned freezing when tested 1 day later in the training context. However, if the test was delayed by 21 days (a standard retention interval used for spontaneous recovery from extinction of fear memories), no effect of protein synthesis inhibition was observed. In fact, Lattal and Abel observed that 21 days after anisomycin treatment, response to the context was larger than that observed during immediate retrieval (1 day after training). Other recent studies also cast doubt on the generality of the reconsolidation account because similar recovery from retrieval-induced reconsolidation has been observed (Anokhin et al., 2002; Fisher et al., 2004; Power et al., 2006; but see Debiec et al., 2002; Duvarci and Nader, 2004). Moreover, some studies did not observe any immediate effect of anisomycin after retrieval-induced reconsolidation (Lattal and Abel, 2001; Vianna et al., 2001; Biedenkapp and Rudy, 2004; Cammarota et al., 2004; Hernandez and Kelley, 2004). Overall, these contradictory findings, together with demonstrations of recovery from retrieval-induced amnesia after inhibition of protein synthesis, show that further research is needed to determine whether anisomycin erases the reactivated memory or simply constrains future retrieval of the memory. More generally, it is still unclear if amnestic agents following initial training impair consolidation (storage) or subsequent retrieval (e.g., Gold and King, 1974; Miller and Matzel, 2006).

Two points deserve further discussion here. First, as recently pointed out by Rudy et al. (2006), anisomycin also has other effects beyond inhibition of protein synthesis, such as genetically programmed cell death (apoptosis). Moreover, the apoptotic cascade occurs at lower doses than those that are necessary for the inhibition of protein synthesis. Whether this is the main cause of the observed amnesia remains to be determined, but it is noteworthy that tests have not yet been conducted to determine the role of apoptosis in experimental amnesia. Second, a recent report from the same laboratory that sparked early interest in reconsolidation showed that memories activated indirectly by an associate of the target cue do not undergo reconsolidation (Debiec et al., 2006). They trained rats in a second-order conditioning preparation in which one cue was paired with the US in a first phase ($CS_1 \rightarrow US$), and in a second phase another cue was paired with the cue trained in phase 1 ($CS_2 \rightarrow CS_1$). This procedure ordinarily results in conditioned responding to CS_2, presumably because when presented at test it retrieves a neural representation of the US through an associative chain mediated by CS_1 (or a direct $CS_2 \rightarrow UR$ link; see Rescorla, 1980, for a discussion). Notably, Debiec et al. found that responding to CS_1 was not impaired after retrieval through presentation of CS_2 and subsequent administration of anisomycin. This suggests that the reactivation treatment, at most, leaves only part of the memory in a labile state, but alternatively the entire content of the memory might not be substantially altered.

In contrast to reconsolidation accounts of the reconsolidation phenomenon, there are retrieval-focused accounts of reconsolidation such as that proposed by Millin et al. (2001). In line with Spear's (1973, 1978; see following discussion) views concerning retrieval, Riccio and his collaborators have proposed that when previously stored memories are reactivated, reprocessing of the attributes of these memories will take place for some time after the reactivation episode. As a result, the internal

context provided by an amnestic treatment becomes associated with the target memory. At test, the context provided by the amnestic treatment is not ordinarily present, and thus retrieval failure occurs. Consistent with this account, amnesia induced by the administration of anisomycin has been observed to be alleviated if subjects are administered anisomycin just prior to testing (Bradley and Galal, 1988). Another explanation of this phenomenon has been advanced by Miller and Matzel (2000; also see Nadel and Land, 2000), who proposed that the amnestic treatment produces a change in the memory representation that interferes with retrieval itself, leaving the memory trace silent after the administration of the amnestic treatment. Regardless of the specific version of the retrieval explanation for the reconsolidation phenomenon put forth, these alternative views can be contrasted with reconsolidation accounts by determining the extent to which amnestic treatments really erase the memory trace or simply render it inaccessible for future use. Based on the recovery data presented earlier, the latter alternative seems to be the more plausible at this time (Prado-Alcalá et al., 2006).

Four points are important to keep in mind. (1) Recovery from amnestic treatment is often observed when subjects are exposed to a portion of the event that had been presented during training. Such reminder treatments are most effective soon before testing, but sometimes have enduring effects even when presented 24 h before testing. (2) Control groups have demonstrated that the recovery is not purely the result of altering stress levels in the subject. (3) Recovery can be obtained by reminding subjects about the training situation not only with the US, but also with other cues (such as contextual cues or sometimes even the CS) that are part of the target memory. (4) The effect of the reminder does not result from new learning concerning the cue-outcome relationship, as long as learning is defined as receiving relevant new information from events in the environment. Subjects exposed to the reminder without any prior learning experience did not show any evidence of relevant learning after the reminder experience.

So far, we have argued that most impairments in memory retention result at least in part from a retrieval failure rather than an acquisition or storage failure. We have based our assertion on studies involving changes in the state of the organism (state-dependent learning and the Kamin effect), experimentally induced amnesia (ECS, hypothermia, and antimetabolites), or reconsolidation phenomena. Next, we review evidence suggesting that decrements in learning and memory that are thought to result from processing limitations (competition) at the time of training, or from deleterious effects on learning or retention due to learning additional information (interference), could instead result from a retrieval deficit at the time of testing.

1.05.2.4 Cue Competition and Outcome Competition

Cue competition refers to a decrement in behavioral control by a target CS (X), which results from the addition of a nontarget stimulus to a simple CS–US learning situation (*See* Chapters 1.03, 1.07, 1.08). This can be observed in a number of different circumstances. For example, one can add a second CS to training and train a compound of the target cue and the added CS instead of the target cue alone (i.e., AX → US as opposed to X → US) and see less behavioral control to the target cue X (overshadowing; Pavlov, 1927). Alternatively, one can train a nontarget cue in a first phase and in a second phase train a compound of cues that contains the target cue as well as the previously trained nontarget cue (A → US in phase 1; AX → US in phase 2). This results in less behavioral control by X, the target cue, than in subjects lacking phase 1 (blocking; Kamin, 1969). A second rather different form of stimulus competition can be seen when, instead of adding a second CS, a second outcome is added. For example, one can train a cue followed by an outcome in a first phase and that same cue followed by the same outcome plus a new outcome in a second phase, and then later assess performance governed by the association between the cue and the second outcome ($X \rightarrow O_1$ in phase 1, $X \rightarrow O_1O_2$ in phase 2, test $X \rightarrow O_2$; Rescorla 1980; Esmoris-Arranz et al., 1997). This is called blocking between outcomes. Taking these examples together, one can see that the addition of nontarget stimuli (a cue or an outcome) attenuates behavioral control by the target cue X.

Phenomena like blocking between cues gave rise to a family of models of Pavlovian conditioning that emphasized critical differences in information processing during acquisition. These models assumed that limitations in processing (e.g., attention to the CS or US) during training impeded the normal establishment of associations and consequently resulted in the observed decrements in behavioral control (e.g., Rescorla and Wagner, 1972; Mackintosh, 1975;

Pearce and Hall, 1980). Similar to consolidation theory (e.g., McGaugh, 1966, 2000), these behavioral models predict that what has not been stored due to processing constraints during learning will not be reflected in behavior simply because the information was not initially acquired.

As previously mentioned, overshadowing is observed as a response decrement that results from training a target cue (X) in the presence of another, usually more salient, cue (A). Interestingly, Kauffman and Bolles (1981; see also Matzel et al., 1985) conducted overshadowing training ($AX \rightarrow US$) and subsequently extinguished the overshadowing cue (A) by presenting it in the absence of reinforcement. After extinguishing the overshadowing cue, they observed a recovery from overshadowing, that is, strong behavioral control by the overshadowed cue X at test. Similarly, after blocking treatment ($A \rightarrow US$ followed by $AX \rightarrow US$), extinguishing the blocking cue (A alone presentations) can result in recovery from blocking (Blaisdell et al., 1999). However, extinction of the competing cue is not the only manipulation known to affect overshadowing and blocking. Kraemer et al. (1988) found a recovery from overshadowing training when they interposed a long retention interval between overshadowing treatment and testing, which suggests that the association between the overshadowed cue and the outcome had been established during training but was not reflected in behavior soon after training. A similar recovery from blocking has been observed after interposing a long retention interval between training and testing (Batsell, 1997; Piñeno et al., 2005).

In the same way that recovery from experimentally induced amnesia has been observed after exposing subjects to some portions of the events presented during training (CS, US, or the training context), stimulus competition phenomena have been observed to be attenuated as a result of these manipulations. For example, Kasprow et al. (1982) observed a recovery from overshadowing after they exposed subjects to two brief presentations of the overshadowed cue (the target CS). In another series of experiments, a similar recovery from blocking was observed (Balaz et al., 1982). Specifically, Balaz et al. observed a recovery from blocking after reminding subjects of the training experience either by presenting the blocked CS, the US, or the context in which subjects were trained. Additional control groups demonstrated that this recovery was specific to the blocked association and was not due to nonspecific increases in responding. All these demonstrations of recovery from cue competition are problematic for models that emphasize impaired acquisition (see earlier discussion) because, if the association between the overshadowed or blocked cue and the outcome was not learned during training, any manipulation that does not involve further training with that cue should not alter behavioral control by that cue.

Although little attention has been given to competition between outcomes, some recent studies have not only observed similar competition phenomena as those observed between cues (e.g., blocking between outcomes; Emoris-Arranz et al., 1998), but also observed that these deficits in behavioral control can be alleviated with the appropriate manipulations. For example, Wheeler and Miller (2005) observed reliable blocking between outcomes ($X \rightarrow O_1$ during phase 1; $X \rightarrow O_1O_2$ during phase 2), similar to the blocking between cues trained together originally observed by Kamin (1969). That is, responding based on the $X \rightarrow O_2$ association was weaker than in subjects that had received $X \rightarrow O_3$ in phase 1. Wheeler and Miller went on to extinguish the blocking outcome (O_1) and observed recovery from blocking between outcomes (i.e., behavioral consistent with the $X \rightarrow O_2$ association). Moreover, they observed a similar recovery when they interposed a retention interval between training and testing, and when they briefly presented the blocked outcome before testing (i.e., a reminder treatment). Overall, the results of these experiments demonstrated that blocking between outcomes can be attenuated by several manipulations similar to those that often yield recovery from blocking between cues.

1.05.2.5 Interference between Cues and Outcomes Trained Apart

Earlier we distinguished between impairments in acquired behavior that arise from training stimuli together (competition) and from experiencing additional training apart from training of the target stimuli (provided that the additional training includes one of the target associates). The latter deficit is called interference. We have already described how impaired performance that arises from stimulus competition can be recovered, thus suggesting that retrieval mechanisms play a fundamental role in behavioral control influenced by stimulus competition. Next we will review the basic conditions under which interference is observed and the different manipulations that often result in

recovery from interference. Interference in Pavlovian conditioning is evidenced as impaired behavioral control by a target cue when it is paired with a given outcome in one phase of training and paired with another outcome in an earlier or later phase of training (e.g., $X \rightarrow O_1$ in phase 1 and $X \rightarrow O_2$ in phase 2). But this is not the only situation in which interference is observed. Interference is also observed when a target cue (X) is trained with an outcome in one phase of training and in a separate phase of training another cue is trained with the same outcome (e.g., $X \rightarrow O$ in phase 1 and $Y \rightarrow O$ in phase 2). A common characteristic of these two forms of interference is that there is always a common element between the two phases of training (the cue X in the case of interference between outcomes (*See* Chapter 1.09), and the outcome O in the case of interference between cues). The critical feature of these decrements in otherwise anticipated behavioral control by X is that the interfering cues (or outcomes) are not trained together with the target cue (or outcome).

Extinction, latent inhibition, and counterconditioning (Pavlov, 1927; Lubow, 1973; Bouton and Peck, 1992; Brooks and Bouton, 1993) are three treatments that can be viewed as forms of interference between outcomes. In simple extinction, a cue is first paired with an outcome ($X \rightarrow US$), and in a second phase it is trained in the absence of the outcome (X-alone presentations; i.e., $X \rightarrow$ No US). As a result of these nonreinforced presentations, the cue loses behavioral control, which used to be taken as evidence of unlearning the original $X \rightarrow US$ association (e.g., Rescorla and Wagner, 1972). However, overwhelming evidence has shown that the original $X \rightarrow US$ association is not destroyed during the second phase, but rather, new learning during phase 2 interferes with the expression of the phase 1 learning. Pavlov (1927) was the first to find a [partial] recovery effect from extinction. His observation (widely replicated since then; e.g., Brooks and Bouton, 1993; Rescorla and Cunningham, 1978) was that conditioned responding soon after extinction was minimal, but if a retention interval was interposed between extinction and the test, a recovery (which Pavlov termed *spontaneous recovery*) from extinction was observed. In other words, behavior after a retention interval was relatively similar in subjects who received extinction training and those who did not receive extinction training. What was puzzling at that time (and might have encouraged Pavlov to name the effect 'spontaneous recovery') was the fact that the extinguished response was recovered despite the fact that the subjects did not undergo any treatment other than interpolation of a long retention interval. Another manipulation that also leads to recovery from extinction is a shift in context between extinction and testing. This phenomenon is called renewal. For example, one might train subjects in a distinctive context A and conduct extinction training in a different context (B). The critical determinant of renewal is that testing be conducted outside the extinction context. If subjects are tested in a different context from the one used during extinction (ABC or ABA, where the first letter denotes the training context, the second the extinction context, and the third the test context), recovery from extinction is observed (Bouton and Bolles, 1979; Bouton and King, 1983; Bouton and Swartzentruber, 1989). If subjects are tested in the same context in which extinction took place (AAA or ABB), no such recovery is observed. A similar finding is observed when the context is defined to include the internal state of the organism, which can typically be altered by administering a drug that would change the internal state. For example, renewal has been observed when the extinction context is characterized by alcohol intoxication, and subjects are tested in a sober state, which creates a different internal context (Cunningham, 1979).

Latent inhibition is observed as a retarded emergence of behavioral control due to nonreinforced presentations of the target CS prior to conditioning (X-alone presentations in phase 1; $X \rightarrow US$ in phase 2), in comparison with subjects that experience the same phase 2 training without phase 1 treatment (Lubow, 1973). Similar to extinction, in a latent inhibition treatment subjects experience the target CS alone, but before the reinforced trials rather than after. One characteristic of latent inhibition that is suggestive of the response deficit being a retrieval effect is its context specificity. Specifically, it has been observed that if subjects experience phase 1 and phase 2 training in different contexts, latent inhibition is abolished (Channell and Hall, 1983). Presumably, during phase 1 nonreinforced presentations, the CS becomes associated with the context in which it is being presented, and these associations interfere with subsequent behavioral control after reinforcement in the same context. Thus, a context switch or massive extinction of the context (Grahame et al., 1993) between phases 1 and 2 attenuates the latent inhibition effect. A recent observation that has captured researchers' attention is the super latent inhibition effect (De la Casa and Lubow, 2000,

2002; Wheeler et al., 2004). This effect is typically observed when a retention interval is interposed between phase 2 reinforced training and testing. One critical condition necessary for this effect to be observed is that subjects have to spend the retention interval in a context different from that of conditioning. Thus, the superlatent inhibition effect might be seen as a shift from behavior based on recency (phase 2 training) to behavior based on primacy (phase 1 training) after interposing a long retention interval between phase 2 training and testing.

Counterconditioning is a phenomenon similar to extinction, but during the second phase of training, the target cue is associated with a qualitatively different outcome instead of being associated with the absence of an outcome, as is the case with extinction. The phase 2 treatment radically attenuates conditioned responding based on phase 1 training (Pavlov, 1927). What distinguishes extinction from counterconditioning is the motivational nature of the outcomes, in that in counterconditioning, the outcomes of phases 1 and 2 engage different motivational systems. For example, in a counterconditioning experiment, subjects might experience a CS followed by food in the first phase (X → food) and the same CS followed by foot shock in the second phase (X → shock; this is called appetitive-aversive transfer, but counterconditioning is also observed when the two phases are reversed, which is called aversive-appetitive transfer). After this training, the CS → shock association is thought to retroactively interfere with the CS → food associations. The question of interest is whether phase 2 learning destroys the memory of phase 1 training or if it simply interferes with the expression of that association. To address this question, Peck and Bouton (1990) trained phases 1 and 2 in two physically distinct contexts and tested subjects in the phase 1 context. Consistent with an explanation in terms of retrieval disruption rather than impaired retention, subjects tested in the phase 1 context showed responding appropriate to phase 1 training, indicating that the information had not been erased (or unlearned) but rather that behavior appropriate to each phase could be observed depending on the contextual cues present at the time of testing. Similarly, Brooks et al. (1995) trained rats with X → shock pairings in phase 1 and X → food pairings in phase 2. Before testing, they exposed the critical group to six unsignaled shocks and at test (relative to appropriate control groups) found that subjects froze to the CS, consistent with the shock US, rather than approached the food hopper, which demonstrated reinstatement of original training after counterconditioning. Moreover, this reinstatement effect was dependent on the shocks being presented in the context in which testing would occur, because no reinstatement was observed when the shocks were presented in a context other than the test context.

As we mentioned earlier, interference is observed not only when a cue is associated with two outcomes (extinction and counterconditioning), but also when two cues are associated with the same outcome. For example, Escobar et al. (2001) paired a cue with an outcome (X → O) in a first phase and subsequently paired a second cue with the same outcome (A → O) and observed impaired responding to X (relative to subjects that received A and O explicitly unpaired in phase 2), thereby providing a demonstration of retroactive interference. In subsequent experiments, they showed that the retroactive interference effect could be alleviated if subjects experienced phase 1 (X → O) and phase 2 (A → O) training in different contexts and subsequently were tested in the context in which the X → O association was trained. That is, interference was affected by the context in which testing took place. Similarly, in another experiment, they presented priming stimuli (stimuli presented during phase 1 or during phase 2 sessions but far removed from presentations of the target cue or interfering cue) that distinctively signaled phase 1 or 2 of their procedure and observed retroactive interference to be dependent on which priming cue was presented immediately before the critical test. When they primed phase 2, robust retroactive interference was observed, but when they primed phase 1, an alleviation of retroactive interference was observed, relative to subjects that did not receive any priming treatment at the time of test. Similar findings were reported by Amundson et al. (2003) but in a proactive interference preparation (i.e., A → US training followed by X → US training). Specifically, they observed an attenuation of proactive interference with responding to X when they primed the second phase of their training procedure, presumably because this impaired retrieval of the competing (phase 1) association and facilitated retrieval of the second association. Moreover, they observed recovery from proactive interference when they extinguished the phase 1 association. In summary, based on these and similar findings, it is reasonable to conclude that interference is highly dependent on the cues provided at the time of testing, thus suggesting a strong role for retrieval mechanisms. Moreover, there

are now several demonstrations of parallels in interference between cues and between outcomes in that both of these effects can be alleviated if the appropriate conditions prevail at the time of testing.

1.05.3 Theories of Memory Retrieval

There are several approaches to memory retrieval, each having been designed to explain different phenomena. However, the frameworks that we describe next point to several shared principles that have proven to be important and reliable tools for the study of retrieval from memory following learning. No single approach accounts for all the deficits in retention we have reviewed earlier. But each framework has provided an explanation of a number of observations and therefore deserves discussion.

1.05.3.1 Matching of Information as Critical for the Retrieval from Memory

Tulving and Thomson (1973) proposed the encoding specificity principle of retrieval that at the time accounted for many of the retrieval effects that were found with human participants. The principle states that subjects form a representation of events that encompasses not only the target events themselves but also many of the events surrounding the target event. Additionally, these episodic memories encode not only which events occurred, but where and when each event occurred relative to neighboring events. Moreover, the encoding specificity principle asserts that items (words, in the framework of the proposal) presented to aid retrieval will be effective only if they (or very similar items) were presented during training, consistent with the view that subjects encode a global representation of an item, its semantic meaning, and its content during training. Critical to this proposal is the notion that what enters into a memory representation (what it is encoded) is determined by the perceived functional meaning of an item, and this in turn determines which retrieval cues will be effective for memory retrieval.

Along similar lines, Spear (1973, 1978) has emphasized that similarity between retrieval cues and cues presented during training is critical for memory expression. He proposed the following principles as a conceptual framework for effective memory processing.

1. Attributes of memory function independently. In other words, an animal encodes a collection of separate but associated attributes that correspond to the events that form a memory episode. A constellation of attributes will be activated every time the subject experiences an event that has some similarity in attributes to the target memory. Moreover, an associated attribute might be activated when an event memory is activated. That is, some attributes might activate an event memory that in turn will activate attributes that need not have been presented but rather are associatively linked to retrieval cues presented. Additionally, attributes might activate memories of other attributes, regardless of whether they activate the full event memory representation.
2. The process of retrieval is determined by the number of retrieval cues that correspond to attributes of that memory. A memory failure is observed when an insufficient number of retrieval cues correspond at test to the memory of a given event, other things being equal. Moreover, events that are presented during testing but were not presented during training will lead to retrieval of nontarget memories that will interfere with retrieval of target memories (similar to the phenomenon of external inhibition that Pavlov, 1927, described).
3. A contextual cue is any event noticed by the organism, with the exclusion of the target stimuli that form the learning experience (e.g., the CS and US in a Pavlovian conditioning situation). Forgetting is caused in large part by a change between the context of acquisition and the context of retrieval. Context changes can result from different sources, and the differences in contextual information are more likely to increase as time passes (i.e., as the retention interval is increased; Bouton, 1993, views this as resulting from time actually being part of the context). Thus, in this framework sensory contexts from training will dissipate rapidly (soon after the stimuli are terminated), and neurochemical and hormonal states will dissipate somewhat more slowly. Importantly, contextual information here can be composed of internal stimuli (or states) and external stimuli, such as the physical attributes of the context where training or testing takes place. The internal context can also change due to preprogrammed factors such as aging or cyclical changes

in hormonal states (e.g., estrus). Contextual attributes learned during new experiences also might interfere with retrieval of the target memory if they share attributes in common.

This general framework has been one of the foundations for studying retrieval mechanisms in memory retention. For example, it easily explains state-dependent learning and the Kamin effect by assuming that the conditions at test are different than those during training. Consistent with this framework, several manipulations that recreate the training conditions at the time of testing have proven effective in restoring the deficient behavior observed due to changes in the organism's internal states or changes in the environment.

1.05.3.2 The Comparator Hypothesis: A Retrieval-Focused View of Cue Competition

As was mentioned in the introduction, models that emphasize processing during encoding and storage have been prevalent in the study of learned behavior in animals. One such example is the well-known Rescorla and Wagner (1972; also see Wagner and Rescorla, 1972) model. This model asserts that error correction at the time of training governs what information is acquired; that is, acquisition should be greatest when the discrepancy between the US that occurs and the US that is expected based on all cues present is largest. The model has been widely applied to Pavlovian conditioning situations in which one or more cues are concurrently paired with a given outcome. After repeated pairings, subjects emit a conditioned response when one (or more) of these cues are presented. One of the strengths of the model is that it elegantly anticipates the occurrence of cue competition (overshadowing, blocking, etc). In fact, the model was conceived in part to account for such phenomena after Kamin's (1969) demonstration of blocking. However, one of the weaknesses of the model is that it only emphasizes processing during training, with the additional vague assumption that associative strengths map monotonically onto behavior. Given all the aforementioned examples of recovery from cue competition (see prior section on empirical evidence), it is attractive to detail here a model that also explains cue-competition phenomena but appeals centrally to a retrieval mechanism.

One such model is the comparator hypothesis of conditioned responding (Miller and Matzel, 1988). The model assumes that all pairs of stimuli, including cues, that are presented together gain associative strength with each of the other stimuli present, independent of the associative status of other cues present during training. In other words, in this model there is no competition between cues for associative strength during training – all information is stored. Associative strength between stimuli A and B depends only on their spatiotemporal contiguity and saliencies. The training context also gains associative strength, although at a much slower rate due to its lower salience than punctate stimuli. Thus, following Bush and Mosteller's (1951) error correction rule, the comparator hypothesis assumes noncompetitive learning of associations between cues and outcomes, of within-compound associations between cues trained together, and of associations between cues and the training context. What is critical in the comparator hypothesis is the process of retrieval of memories. According to this framework, responding to the presentation of a CS will be determined by a comparison between the representation of the US that is directly activated by the target CS → US association and the representation of the US that is indirectly activated conjointly by the associations between the target CS and any other cues presented during training (punctate cues or the training context) and the association between those cues and the US. In **Figure 1**, a depiction of the comparator hypothesis is provided. The

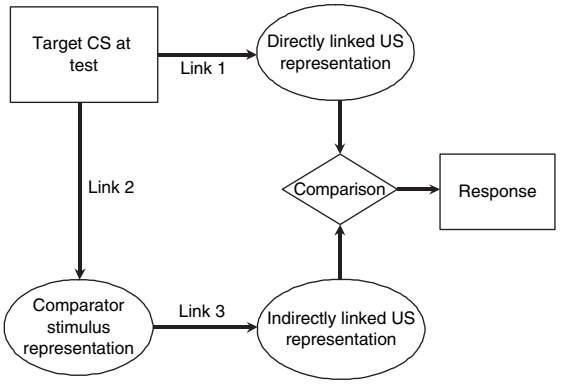

Figure 1 The original comparator hypothesis (after Miller RR and Matzel LD (1988) The comparator hypothesis: A response rule for the expression of associations. In: Bower GH (ed.) *The Psychology of Learning and Motivation, Vol. 22*, pp. 51–92. San Diego, CA: Academic Press). Rectangles represent physical events, and ovals correspond to internal representations of events that were previously associated with those physical events. The diamond represents the comparator process. Responding is directly related to the strength of link 1 and negatively related to the product of links 2 and 3.

boxes represent the external events observable in the test situation, that is, the target stimulus and the conditioned response. Ovals represent internal representations of events that were presented during training, and the diamond represents the comparator process (also internal). Direct activation of a US representation due to presentation of the target cue at test depends on the strength of the association between the target cue and the outcome, represented by link 1. Importantly, the target cue also activates a US representation mediated through other cues that were presented in the training situation, and this is represented by links 2 and 3. Responding is determined by a comparison between the directly activated representation of the US (the strength of which is determined by the target CS-US association, i.e., link 1) and the indirectly activated representation of the US (the strength of which is determined by the product of links 2 and 3). This comparison process is represented by the diamond. In an overshadowing situation (AX → US; with X being the target cue to be tested), the comparator hypothesis states that during training, subjects associate the target cue with the US (link 1 in **Figure 1**), the target cue with the overshadowing cue A (which is X's comparator cue; link 2), and A with the US (link 3). These associations are acquired independently of each other (i.e., cues do not compete during training for associative strength with the US). Critical for the comparator hypothesis is what happens when the target cue X is presented during testing. When X is presented, it directly activates a representation of the US, but it also indirectly activates a representation of the US, mediated by the overshadowing cue (which was associated during training with both the target cue and the US). This indirectly activated (competing) US representation is said to decrease (downmodulate) responding to the target cue, and thus overshadowing is observed relative to a group that experienced elemental training (X → US alone).

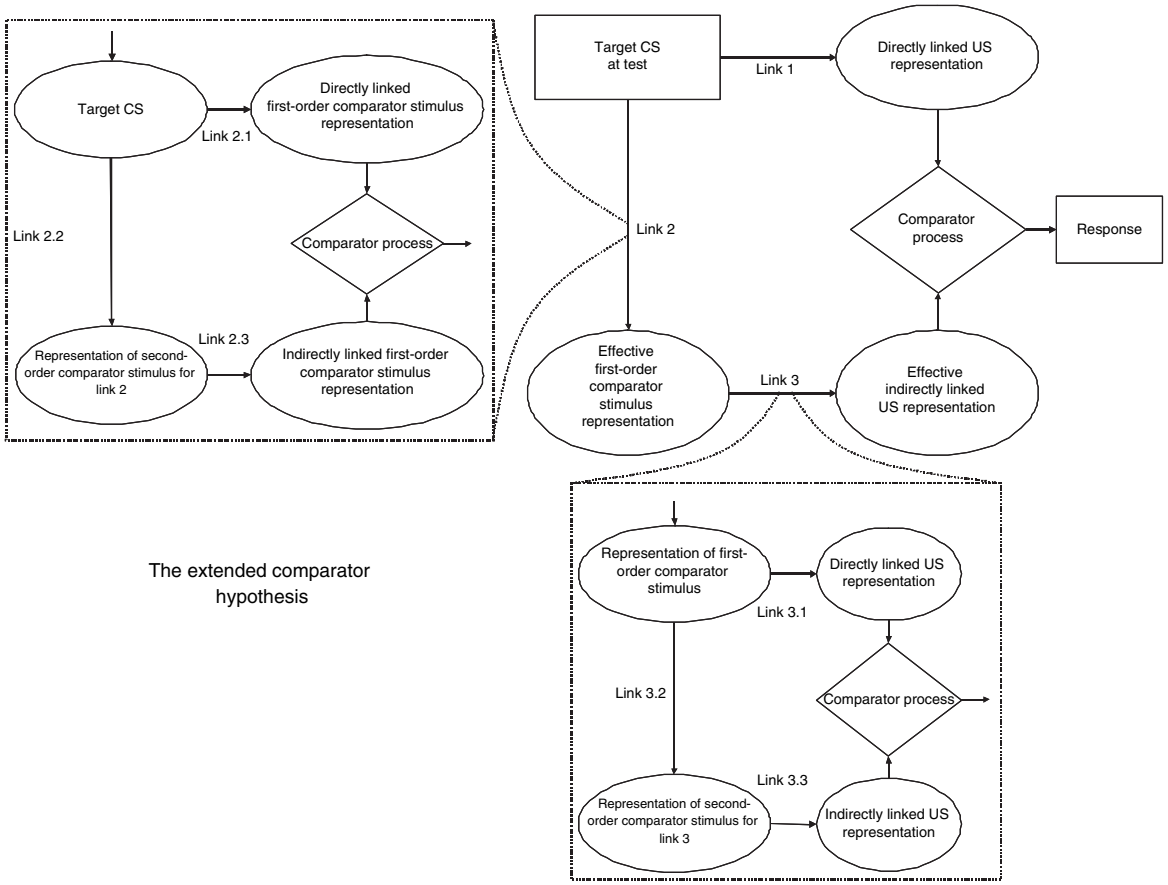
What differentiates the comparator hypothesis from acquisition-focused models (i.e., those that focus on limitations in processing during training) is not only the mechanism through which it explains cue competition phenomena, but also several novel predictions that have received empirical support in recent years. One such prediction is that after overshadowing training, extinguishing the overshadowing cue (that is, presenting A alone after training) should result in recovery from overshadowing. Specifically, by presenting A alone after overshadowing training, the links that mediate the indirectly activated representation of the US decrease in associative strength, and consequently the overshadowing cue should no longer interfere with the representation of the US that is directly activated by X. Importantly, here we have an example of a change in behavioral control by X as a result of conducting a posttraining manipulation that does not involve further training of X (that is, subjects have no additional experience with X after the overshadowing treatment), and still a recovery from cue competition is observed. Most models that emphasize processing during acquisition (e.g., Rescorla and Wagner, 1972; Wagner 1981) cannot account for these results for two reasons: (1) they do not have a mechanism that allows learning about absent cues, and (2) these models state that overshadowing results from a deficit in the establishment of the X → US association during overshadowing training, so any manipulation that does not involve the presentation of X should not affect its behavioral control. In fact, recovery from overshadowing after extinguishing the overshadowing cue has been observed repeatedly (e.g., Kaufman and Bolles, 1981; Matzel et al., 1985; Urcelay and Miller, 2006), thereby lending support to a retrieval-failure account of cue competition.

A related example is recovery from blocking. After blocking treatment (A → US followed by AX → US), responding to X is usually diminished relative to a group that experienced an irrelevant cue during training of phase 1 (B → US; AX → US). According to the comparator hypothesis, acquisition of the X → US association proceeds without any competition between A and X. At the time of testing, the blocking cue is thought to decrease responding to the blocked cue through its associations with X and the US (links 2 and 3). Similar to overshadowing, the comparator hypothesis predicts that extinguishing the blocking cue should result in recovery from blocking, as has been empirically observed (e.g., Blaisdell et al., 1999).

For several years, the comparator hypothesis was unique in predicting these recovery effects that could not be explained by traditional models that emphasized acquisition processes (e.g., Rescorla and Wagner, 1972; Wagner, 1981). However, recent revision of the Rescorla–Wagner (1972) model by Van Hamme and Wasserman (1994) and of Wagner's (1981) SOP model by Dickinson and Burke (1996) introduced mechanisms that allow for learning about an absent cue provided an associate of the absent cue is present. Posttraining extinction of a companion cue (i.e., an overshadowing or blocking cue) constitutes a

situation in which these models anticipate new learning about a target cue. Consequently, these two models are able to account for phenomena such as recovery from overshadowing and blocking as a result of extinction of an overshadowing or blocking cue. This prompted a revision of the comparator hypothesis, in part to differentiate this model from the revised versions of acquisition-focused models and also to account for data that were problematic for the original comparator hypothesis (Williams, 1996; Rauhut et al., 1999).

The extended comparator hypothesis (Denniston et al., 2001; also see Stout and Miller, in press, for a mathematical implementation of this model) carries the same assumptions as the original comparator hypothesis, but it further assumes that the links mediating the indirectly activated representation of the US (links 2 and 3) are also subject to a comparator process in which nontarget cues present during training can compete for roles as comparator stimuli for the target cue (see **Figure 2**). In other words, the extended version of the model is similar to the original version but allows more than one cue (comparator) to modulate conditioned responding to the target cue. If there's more than one comparator stimulus for the target, these comparator stimuli can in select situations cancel each other with respect to their capacity to modulate responding to the target cue. Thus, the extended comparator hypothesis makes a number of new predictions that allow for differentiating this retrieval-based account from models that emphasize processing during acquisition. For example, it makes the counterintuitive prediction that combining select pairs of treatments that



The extended comparator hypothesis

Figure 2 The extended comparator hypothesis (after Denniston JC, Savastano HI, and Miller RR (2001) The extended comparator hypothesis: Learning by contiguity, responding by relative strength. In: Mowrer RR and Klein SB (eds.) *Handbook of Contemporary Learning Theories*, pp. 65–117. Hillsdale, NJ: Erlbaum). Note principles similar to the original comparator hypothesis but with the inclusion of second-order comparator processes that operate over links 2 and 3. The magnitude of second-order comparator processes directly affects conditioned responding to the target CS, by decreasing the effectiveness of first-order comparator stimuli.

alone lead to a decrement in conditioned responding (e.g., overshadowing and the deficit seen in responding when trials are massed; see Barela, 1999, for a review of the trial massing effect) under certain circumstances can result in less (rather than more) of a decrement in behavioral control. In other words, the model predicts that the two response-degrading treatments can counteract each other, and thus less of a decrement in behavioral control should be observed during testing than with either treatment alone. How does the model anticipate this result? Because the extended comparator hypothesis allows for cues (other than the target cue) to compete with each other for comparator status provided they share a within-compound association, any treatment that establishes two comparator stimuli as potential competitors for comparator status with respect to the target cue can lead to a mutual reduction in the comparator roles of each of these stimuli and thus a reduced decrement in conditioned responding to the target cue.

As a test of this prediction, Stout et al. (2003) manipulated overshadowing and trial spacing, so that one group received elemental training with spaced trials (X → US spaced), one group received overshadowing training with spaced trials (AX → US spaced), and two more groups received identical training but with massed trials (X → US and AX → US massed). In this last group, presumably both the overshadowing cue (because of the compound training) and the training context (because of massed trials) should have been effective comparators for the target cue X, and they also should have served as comparators for each other (because A and the context should have been strongly associated). Interestingly, Stout et al. observed strong behavioral control by X in the group that experienced elemental training with spaced trials, less responding in the groups that experienced only one of the response-degrading treatments (either overshadowing or massed trials), and a recovery from these treatments (more responding) in the group that experienced both overshadowing treatment and massed trials. Similar counteractive effects have been observed when combining overshadowing with several other treatments that presumably establish the training context as a strong comparator for the target cue. These treatments include pretraining exposure to the CS alone (i.e., latent inhibition, Blaisdell et al., 1998), long CS duration during conditioning (Urushihara et al., 2004), unsignaled outcomes interspersed among the CS-outcome trials (i.e., degraded contingency, Urcelay and Miller, 2006), and unsignaled outcome alone before or after the CS → US trials (Urushihara and Miller, 2006).

In summary, the comparator hypothesis (Miller and Matzel, 1988) and its extension (Denniston et al., 2001) have proven to be powerful alternatives to associative models that emphasize acquisition processes, as evidenced by their explanatory and predictive power. However, as we shall see next, there are several effects for which the comparator model cannot account. In the next section, we detail a model that accounts for interference effects outside the domain of models of associative learning designed to explain cue competition phenomena.

1.05.3.3 Bouton's Retrieval Model of Outcome Interference

Perhaps one of the most intriguing findings that Pavlov (1927) documented was the occurrence of a recovery in conditioned responding after a retention interval is interposed between extinction treatment and testing. Since Pavlov's time, there have been many theoretical frameworks proposed to explain extinction and its recovery under different circumstances. One old view of extinction is that nonreinforced presentations of an already trained CS will result in a loss of the CS's associative strength with the US, leading to an irreversible loss of behavioral control. For example, the Rescorla and Wagner (1972) model explains extinction in this manner. However, as we have mentioned before, if the associative strength of an extinguished CS is reduced, there is no reason to expect that responding to the CS will ever recover without further training with the CS, which is opposite to the spontaneous recovery effect observed when a long retention interval is interposed between extinction and testing.

After conducting extensive work on extinction, Bouton (1993) proposed an alternative to the models that view extinction as unlearning of the original association between the CS and US (*See* Chapter 1.09). This model emphasizes retrieval mechanisms that apply to a wide range of phenomena. Bouton's model has four principles.

1. Contextual stimuli influence memory retrieval. That is, analogous to Tulving and Thomson's (1973), Spear's (1978), and Riccio's (Riccio et al., 2002; Riccio et al., 2003) emphasis on the importance of similarity between the conditions of training and testing, Bouton proposed that

retrieval of a representation depends on the similarity between the conditions present at the time of testing with those that were present during training. Thus, as changes between the context of training and the context of testing are introduced, retrieval failure (i.e., forgetting) is more prone to occur. Furthermore, and perhaps in disagreement with Spear's elemental view, Bouton has proposed that CSs and contextual information are stored as interactive units containing information about the cues, the context, and the US. These interactive units function as an AND gate that requires activation of both the cue and the context for the activation of the representation of the US.

2. Time is part of the training context. As time elapses following training, the temporal component of the test context that is provided by external and internal cues is likely to change. In other words, the passage of time by itself will progressively result in a context change. Therefore, forgetting as a result of the passage of time is an instance of retrieval failure due to a change in the temporal context between training and testing.
3. Different memories depend differentially on the contextual information. In his 1993 seminal article, Bouton proposed that excitatory memories are relatively stable over time and do not depend on contextual information as much as do inhibitory memories (including those that represent extinction experience). Additionally he stated that a memory's sensitivity to contextual information depended on whether the training procedures promote subjects to encode and integrate contextual information with other features of the memory representation. One such procedure is when a CS takes a new meaning different from that of earlier training, as is the case when a CS is consistently followed by the US in one phase and it is no longer followed by the US (operationally, extinction) in a second phase. In this case, the second phase makes the CS an ambiguous signal for the US, and thus the model anticipates that the second-learned association will depend more on contextual information. In fact, Bouton (1997) later clarified this issue by stating that regardless of whether a memory is excitatory or inhibitory, each instance in which there is ambiguity with regard to the content of a memory (i.e., training in two sequential phases with opposing outcomes in the different phases), the second-learned meaning will be more context dependent. This later assertion has received empirical support from Nelson (2002; also see De la Casa and Lubow, 2000, 2002).
4. Interference occurs at the time of testing rather than at the time of training. This principle captures all of the previously mentioned principles by stating that interference occurs at retrieval rather than during learning. With ambiguity in the meaning of the CS, the activation of an outcome representation occurs in direct relationship to the similarity between the context at test and those during the different phases of training. Additionally, information that is similar to, but incompatible with, the target memory will compete for a limited available space in working memory (i.e., currently active memory). That is, activation of a conflicting memory could reduce activation of the target memory. Thus, forgetting can result from two sources: retrieval failure (because of a change in context) and interference due to activation of conflicting information.

Bouton's model explains spontaneous recovery from extinction by assuming that the second-learned meaning of the CS (that is, CS → no outcome or an inhibitory association between the CS and the outcome) is context dependent, based on the principle of context dependency of the second-learned meaning of a cue. Moreover, the model states that a change in temporal context is analogous to a change in spatial context. As a result, when the temporal context of the second meaning of a cue is changed between phase 2 of treatment and testing (i.e., interposing a long retention interval after extinction), the memory representation of extinction treatment cannot be as readily retrieved. Thus, a recovery from extinction is observed with a long retention interval. A similar explanation is put forth by this model to explain all forms of renewal, spatial as well as temporal. In renewal, the second-learned meaning of the CS (CS → no US) should be context dependent, so any change in the spatial attributes of the context between extinction treatment and testing will result in interference in retrieving that memory. As a result of such a context shift, a recovery from extinction should be observed.

Another finding that is problematic for models that emphasize processing during acquisition is reinstatement, which is a recovery from extinction observed when subjects experience outcome-alone

presentations in the test context prior to testing. In this case, Bouton's model assumes that the test context becomes associated with the outcome so that at test it biases retrieval in favor of the memory of reinforcement. Thus, a recovery from extinction is observed. Another way by which this model has been tested is by associating a neutral cue (a priming stimulus) with the phase of treatment in which extinction occurs. If the test is conducted in a context different from that of extinction treatment, renewal typically occurs. However, if during testing subjects are presented with this neutral cue from the extinction phase soon before being tested with the target cue, renewal is attenuated, presumably because this cue retrieves the memory of extinction treatment (Brooks and Bouton, 1994). A parallel attenuation of spontaneous recovery from extinction has been observed when the temporal context, as opposed to the spatial context, is altered between extinction training and testing (i.e., interpolation of a long retention interval). That is, reduced spontaneous recovery has been observed when a retrieval cue for the memory of extinction treatment is presented before testing following a long retention interval (Brooks and Bouton, 1993).

As we previously discussed, counterconditioning is another example of the context dependency of memory. If counterconditioning training is conducted with an appetitive reinforcer given in one context and an aversive reinforcer given in a different context, conditioned responding to the CS is guided by the context in which subjects are tested (Peck and Bouton, 1990). The retrieval model outlined earlier simply states that whichever memory representation is facilitated by contextual cues will be more prone to guide behavior.

In summary, we have reviewed general models of memory that emphasize retrieval mechanisms as critical for behavioral control. In general, Spear's (1978) model emphasizes the similarity between the total information presented during training and that presented at test and by this simple principle explains memory phenomena such as state-dependent learning and the Kamin effect. The comparator hypothesis (Miller and Matzel, 1988) is an associative model that emphasizes competition between representations and explains cue-competition phenomena and recovery from cue competition that does not involve further training with the target cue. Bouton's model (1993, 1997) emphasizes the role of retrieval cues in situations in which one cue has more than one meaning, as in the cases of extinction, latent inhibition, and counterconditioning. One obvious conclusion is that each model has been designed to account for a family of phenomena at the expense of explaining other phenomena. For example, the comparator hypothesis (Miller and Matzel, 1988) accounts for cue competition phenomena and several other effects in classical conditioning, but it does not explain the recovery from extinction or counterconditioning effects that are consistently observed. Moreover, this model does not explain state-dependent learning. In contrast, Bouton's retrieval model (Bouton, 1993, 1997) accounts elegantly for interference effects, but it does not incorporate any mechanism that accounts for cue competition phenomena. Perhaps the biggest challenge these models face is to explain phenomena outside their current domain without necessarily increasing their complexity and thus losing predictive power. As we shall see in the next section, a few efforts have been made to integrate these behavioral models with the neurobiological evidence concerning the role of retrieval in memory performance.

1.05.4 Neurobiology of Retrieval

Recent technological advances have widened the possibilities of understanding learning and memory phenomena by studying their underlying neurophysiological basis. Interestingly, the focus on acquisition processes (e.g., Waelti et al., 2001) and memory consolidation (e.g., McGaugh, 2000) has dominated the field, perhaps because of the discovery of potential molecular mechanisms underlying long-term potentiation (Bliss and Lomo, 1973) that are thought to be the basis for the formation of memories (but see Shors and Matzel, 1997, for an alternative view). However, the neurobiological basis of retrieval mechanisms has also received some attention. But before we review some experiments that studied the role of different brain regions in retrieval, it is important that we clarify the general strategy underlying these studies. In any memory experiment, there are at least three identifiable phases amenable to study, namely acquisition, consolidation, and retrieval. As pointed out by Abel and Lattal (2001), one of the problems associated with different manipulations (pharmacological, genetic, and lesions) is that, with the exception of recently developed inactivation techniques that allow researchers to temporarily inactivate a specific anatomical area, they can affect more than one of the three stages. For example, a lesion soon after acquisition might impair not only consolidation but also

retrieval. A lesion before any training might alter training, consolidation, and/or retrieval. Moreover, pharmacological manipulations might be temporary, but the effects of the mere exposure to the drug are not always completely known, as reflected earlier when we discussed the apoptotic effects of anisomycin (Rudy et al., 2006). Clearly all these considerations have to be taken into account to obtain valid information regarding the neurobiological underpinnings of memory.

Next, we briefly summarize the main findings regarding contextual determinants of memory retrieval. Notably, because of space limitations, we will only summarize a few studies that have the merit of integrating behavioral theories with neurobiological data. Studies such as these are few in number (but see, for example, Fanselow, 1999; Waelti et al., 2001; McNally and Westbrook, 2006; for notable exceptions focused on acquisition).

The hippocampus is one of the most extensively studied brain regions with regard to retrieval mechanisms (as well as acquisition processes). In general, the hippocampus has been implicated in both the coding and retrieval of spatial information and also in relations between events in the environment (e.g., Maren, 2001; but see Wiltgen et al., 2006). In fear conditioning, the hippocampus is thought to assemble contextual representations before they reach the amygdala, which is the site in which fear-motivated information is mainly processed. As we previously mentioned, contextual information is critical for the retrieval of associations. One of the questions researchers have recently asked concerns the role of the hippocampus in the retrieval as opposed to acquisition of contextual information. For example, behavior indicative of extinction is observed when contextual cues facilitate the retrieval of the extinction memory as opposed to the acquisition memory. Based on this finding, Wilson et al. (1995) investigated the effect on context-dependent extinction of fornix (one of the two primary inputs into the dorsal hippocampus) lesions made prior to training. It is important to recall that two of these context-dependent effects are renewal and reinstatement, and in terms of Bouton's theory of retrieval, they are mediated by different mechanisms. In the case of renewal, the context seems to disambiguate the two meanings a CS has after acquisition and extinction training. In the case of reinstatement, the test context-US association facilitates retrieval of the original CS → US association. Wilson et al. (1995) observed that fornix lesions attenuated reinstatement, which depends on context-US associations, but not renewal nor spontaneous recovery which depend more on the properties of the context to disambiguate information. This outcome is surprising because it leaves no role for the hippocampus on the retrieval of ambiguous information. However, other studies using temporary reversible lesions have found that the hippocampus does in fact participate in the retrieval of information needed to disambiguate the meaning of an extinguished CS. Specifically, Corcoran and Maren (2001) used muscimol (a gamma-aminobutyric acid$_A$ (GABA$_A$) receptor agonist) infusions into the dorsal hippocampus just prior to testing (i.e., retrieval) to investigate the effect of the hippocampus on the retrieval of ambiguous memories (renewal). They found that the renewal effect was attenuated when they deactivated the dorsal hippocampus. Similar findings have been observed by Corcoran and Maren (2004; although the effect was not seen in ABA renewal). Overall, these findings raise several interesting points: (1) These results show that the hippocampus, a brain region known for its role in the encoding and retrieval of contextual information, is critical for the expression of extinction memories, which are context dependent. (2) Reversible lesions have the advantage of allowing dissection of the different processes (such as retrieval) involved in memory performance. (3) Behavioral theories (e.g., Bouton, 1993) can provide fertile grounds for research in the neurobiology of learning and memory and vice versa. Clearly, the key is to combine information from both approaches as a starting point for conducting further research.

Another recent study exemplifies context-dependent memories and the role of the hippocampus in such learning. As previously stated, latent inhibition refers to retarded emergence of behavioral control that results from CS-alone exposures prior to CS → US pairings (Lubow, 1973). A retrieval-based account such as the comparator hypothesis (Miller and Matzel, 1988) explains latent inhibition by positing that, during CS preexposure, subjects associate the CS with the context, which interferes during testing with the retrieval of the CS → US association. Consistent with this explanation, extinction of the training context abolished the latent inhibition effect (e.g., Grahame et al., 1994; Westbrook et al., 2000). Moreover, if CS preexposure is conducted in one context and reinforced training in a second context, latent inhibition is not observed (Channell and Hall, 1993). Consistent with these predictions, Talk et al. (2005) found that context extinction following the

CS-US pairings increased neural firing to the preexposed CS in the posterior cingulate cortex, a structure hypothesized to have a role in retrieval of learned behavior. Presumably, the hippocampal formation sends (through the fornix) contextual information to the posterior cingulate cortex. When the contextual information is decreased as a result of the context extinction treatment, an increase in neural responses to the CS is observed, and this is reflected in the diminished latent inhibition.

These examples have the merit of integrating retrieval-focused behavioral theories of memory and neurobiological evidence concerning the underlying mechanisms of retrieval. We believe that further understanding of the neurophysiology of learning and memory will be most fruitful when it has some relationship to behavioral models. As these examples demonstrate, research guided by knowledge obtained in behavioral experiments (and the theoretical developments that follow those results) seems to be a reliable foundation for investigation of the neural foundations of retrieval.

1.05.5 Concluding Remarks

In this review, we started with the premise that a vast majority of the research concerning mechanisms of learning and memory has been guided by the notion that memory depends uniquely on mechanisms of acquisition and storage. Although we should not underestimate the contribution of these processes, we pointed out numerous phenomena suggesting that retrieval mechanisms also play an important role in determining stimulus control of behavior. We reviewed various examples, ranging from forgetting due to natural changes in the environment or in the organism's internal state, through amnesia experimentally induced in the laboratory, to situations in which additional (sometimes conflicting) information decreases target behavior. In all of these examples, there was evidence that the information was not lost, but rather was present but not expressed at the time of testing. Providing conditions during testing similar to those during training strongly facilitates retrieval and, as a consequence, stimulus control of behavior. In a similar vein, facilitating retrieval by the aid of reminder cues has also proven effective for memory performance. These demonstrations imply that information was stored but not expressed at the time of testing, which suggests a strong role of retrieval mechanisms.

In the second section, we described several models that emphasize processing at the time of retrieval as being critical for memory expression. Perhaps the unsatisfying conclusion from this section is that there is not a single approach that accounts for all of the data available. Some models seem to fare well in accounting for some phenomena, but fail to explain fundamental aspects of other phenomena. As an example, we pointed out how well the comparator model accounts for cue competition phenomena, but also recognized its failure in addressing important aspects of extinction and competition between cues trained apart. Obviously, the ultimate goal of any science of behavior is not only to explain behavior but also to predict it. At least the models we reviewed provide strong foundations for future theoretical developments, and in some ways each proposal has proven its heuristic value as a tool to guide new research. Current behavioral models have stimulated research into the neurobiological underpinnings of memory. We see this avenue as perhaps the most fruitful in the future because bridging the gap that exists between behavior and its underlying neurobiological basis is an important step toward societal application.

Retrieval, the act of making stored information available for use, is as important as acquisition in terms of adaptive value. Consider, for example, what would happen if an organism faces a dangerous situation and is able to survive. If the animal does not retain that information by virtue of either acquisition failure or storage failure, memory of that experience will not be available for future use. On the contrary, if the animal stores the information, it will be available for later encounters with the dangerous situation. This brings us to the question: why does retrieval failure occur? Perhaps retrieval failures, as we have seen, arise from processing limitations. But more important, it seems plausible that retrieval failures arise from a strategy for organizing information based on how relevant this information is in the test situation. That is, leaving some information less accessible enables organisms to have access to other information that could be more important, depending on the demands imposed by the immediate environment.

1.06 Operant Behavior

J. Jozefowiez and J. E. R. Staddon, Duke University, Durham, NC, USA

1.06.1 Introduction

1.06.1.1 Behavior as a Function of Its Consequences

In a famous experiment, Edward Thorndike (1898) trained cats to escape from puzzle boxes by activating various mechanisms. The time taken by the animals to escape the box on successive trials tended to decrease. During early trials, the cat tried various ineffective behaviors (pawing at the door, scratching the wall of the box, etc.) until by accident, it triggered the mechanism unlocking the latch. Starting from this point, trial times improved because ineffective acts gradually dropped out. This led Thorndike to formulate his famous law of effect according to which behaviors followed by positive consequences are strengthened, while behaviors followed by negative consequences are weakened. Later, the American psychologist B. F. Skinner (1938) coined the term operant behavior for activities that follow the law of effect.

Operant behaviors are behaviors guided by their consequences. In most cases, this requires that the animal first solve an assignment-of-credit problem by deciding which events are a consequence of a specific behavior. This is operant learning. Once this is done, the behavior and its consequence are linked in a feedback loop, and depending on the motivational properties of the consequence, the emission of operant behavior will be regulated by it.

In this chapter, we will first deal with operant learning and the question of how animals are able to detect the connection between a behavior and its consequences. Then we will deal with the maintenance and regulation of operant behavior by consequences. But first, we must say a word about the procedures used to study operant behavior in psychology.

1.06.1.2 Operant Conditioning

The main procedure for the study of operant behavior in psychology is operant conditioning, a term proposed by Skinner in the early 1930s (Skinner, 1938; *See* Chapters 1.03, 1.10). In operant conditioning, delivery of a biologically significant stimulus or a neutral stimulus signaling such a stimulus is made contingent on an easily repeatable response with low energy cost. The main dependent

variable is the response rate (number of responses emitted per unit of time). The standard version uses either hungry rats or pigeons in an experimental cage called a Skinner box (**Figure 1**), which allows for automated delivery of stimuli and recording of responses without any intervention by the experimenter. Rats are usually trained to press a lever for food pellets, whereas pigeons peck at illuminated response keys to gain access to grain. Electric shocks are used if negatively valued consequences are required by the experiment.

Operant conditioning procedures are classified according to their effect on responding and whether the consequence is the presentation or removal of a stimulus. If the procedure leads to an increase in the response rate, it is a reinforcement procedure and the consequence a reinforcer; otherwise, if it leads to a decrease in responding, it is a punishment procedure, and the consequence is a punisher. A reinforcer can be either the delivery of an appetitive stimulus (positive reinforcement, such as a hungry rat pressing a lever for food) or the withdrawal of an aversive one (negative reinforcement, for example, a rat pressing a lever to stop electric shock). Similarly, a punisher can either be the delivery of an aversive stimulus (positive punishment, such as a rat pressing a lever that produces electric shock) or the withdrawal of an appetitive stimulus (negative punishment, for example, food withdrawn from a cage if a hungry rat presses a lever). As a practical matter, research has focused on positive-reinforcement procedures (to the point that the word positive is usually omitted).

Figure 1 Pigeon in a Skinner box. By pecking on the illuminated disks (response keys), the pigeon occasionally gains access to food delivered in the feeder (opening below the response keys).

The rule that describes how reinforcement depends on responding, whether number-based, time-based, or according to some other rule, is called the schedule of reinforcement (Ferster and Skinner, 1957). Simple schedules arrange reinforcement for only one response, whereas concurrent schedules arrange reinforcement for two or more simultaneously.

The basic schedules of reinforcement are ratio and interval schedules. In ratio schedules, a certain number of responses (the ratio of the schedule) must be emitted for reinforcement to occur. The ratio is fixed in fixed-ratio (FR) schedules while it varies after each reinforcement around a mean in variable-ratio (VR) schedules. The ideal case of a VR is a random-ratio (RR) schedule where each response has a constant probability of reinforcement equal to the inverse of the ratio. In interval schedules, a certain amount of time (the interval of the schedule) must have elapsed before a reinforcement is made available. The interval is fixed in fixed-interval (FI) schedule but varies randomly around a mean after each reinforcement in variable-interval (VI) schedules. The ideal case of a VI is a random-interval (RI) schedule where the probability of a reinforcer being scheduled each time step is equal to the inverse of the interval. VI schedules usually generate a steady rate of responding, whereas in FI schedules, animals typically pause after trial onset (reinforcement) before starting to respond (Ferster and Skinner, 1957).

Traditionally, when describing an operant procedure using schedules of reinforcement, the acronym of the schedule (i.e., FR, VI) is given followed by its relevant parameter (i.e., its ratio for a ratio schedule or its interval for an interval schedule). So, instead of saying that a rat had to press a lever 50 times before a reinforcer was delivered, we would say that lever pressing was reinforced according to an FR 50. In the same way, instead of saying that a peck on a response key was reinforced only if 15 s have elapsed since the last reinforcement, we would say that key pecking was reinforced according to an FI 15 s. Instead of saying that a rat had the choice between two levers (a concurrent schedule), one delivering reinforcement according to a VI 15 s, the other according to a VI 30 s, we would say that the rat was exposed to a concurrent VI 15 s VI 30 s.

Finally, schedules of reinforcement can deliver either primary reinforcers – stimuli having biological significance for the organism (e.g., food for an hungry animal) – or conditioned reinforcers – stimuli that are correlated with the delivery of a primary

reinforcer. For instance, pecking on a red key for a pigeon could be reinforced according to a VI 15 s, but when reinforcement occurs, instead of food being delivered, the key turns green, and pecking it is reinforced with food according to an FR 15. The green key is considered a conditioned reinforcer because it signals the future delivery of food. Such a procedure is also an example of a chain schedule (a chain VI 15 s FR 15 in this case) where reinforcement for one schedule is access to another schedule, and the transition from one to the other is signaled by a change in some stimulus. Tandem schedules resemble chain schedules, except that the transition from one schedule to the other is unsignaled.

Concurrent chain schedules (**Figure 2**) combine chain schedules with concurrent schedules. They comprise two phases: the initial link and the terminal link. During the initial link, the animal has a choice between two schedules, usually VI or RI with the same interval. When a response is reinforced on one of the two schedules, this leads to the terminal link: The two schedules used during the initial link are deactivated, and the animal is left with only one response opportunity, reinforced with food according to its own schedule of reinforcement. Each initial link leads to a different terminal link schedule: for instance, one VI initial link could lead to an FI 15 s terminal link, whereas the other leads to an FI 30 s terminal link. The allocation of behavior on the two schedules during the initial link is used as a measure of the relative preference of the animal for the two terminal-link schedules. In this example, the animal would respond more often on the (initial-link) VI leading to the FI 15 s than on the one leading to the FI 30 s.

1.06.2 Operant Learning

1.06.2.1 Nonoperant Effects in Operant Conditioning

Before trying to understand the condition in which operant learning takes place, it is important to realize that not all the effects observed in operant conditioning are due to the operant aspect (i.e., to the response-reinforcer contingency *per se*). Reinforcers are highly motivating stimuli, and their mere delivery has an effect on the organism: It arouses it, increasing its general level of activity. Killeen et al. (1978) showed that the arousing effect of a single reinforcer delivery (measured as general activity) decreases exponentially with the time elapsed since the reinforcer delivery; when reinforcements are repeated, arousal builds up to an asymptotic level. According to Killeen (1998), this model implies that response rate should be proportional to reinforcement rate.

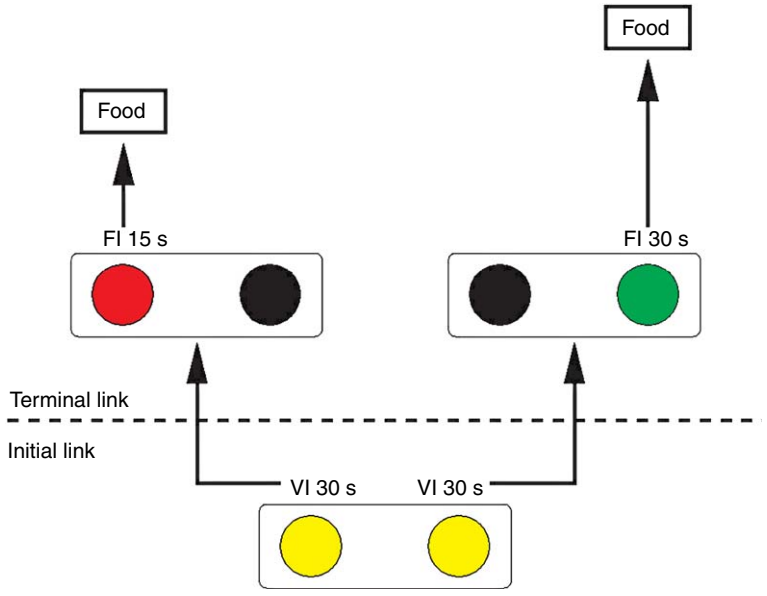

Figure 2 Example of a concurrent chain schedule: One initial link leads to an FI 15 s (red key; other key dark), whereas the other leads to an FI 30 s (green key, other key dark). The rate of entry in the initial link is determined by independent VI 30-s schedules (two yellow keys).

Functions relating response rate to reinforcement rate in VI are actually negatively accelerated (Catania and Reynolds, 1968; Herrnstein, 1970; Shull, 2005; **Figure 3**), but because rats are much more sensitive to reinforcement rate than pigeons, a linear approximation is reasonable for them. By contrast, pigeon functions quickly reach an asymptote (Shull, 2005; **Figure 3**). In this view, response rate in simple schedules is more determined by arousal than by the response-reinforcer contingency, although this might be masked by the fact that different response topographies might be selected by different schedules. For example, VR schedules lead to a higher rate of responding than VI schedules, even when matched for obtained reinforcement rates (i.e., Baum, 1993), presumably because VR schedules selectively reinforce shorter interresponse times than VI (Peele et al., 1984; Dawson and Dickinson, 1990).

Arousal is reinforcer-specific: Animals are more likely to engage in behavior related to the kind of reinforcers delivered. For instance, golden hamsters engage in activities directed at the environment (locomotion, active contact with the environment such as wall-scratching) when food deprived, more rarely in self-care activities such as grooming or scent-marking (Shettleworth, 1975). Similarly, rats receiving electric shocks will most likely freeze or flee (Bolles and Riley, 1973; Karpicke et al., 1977).

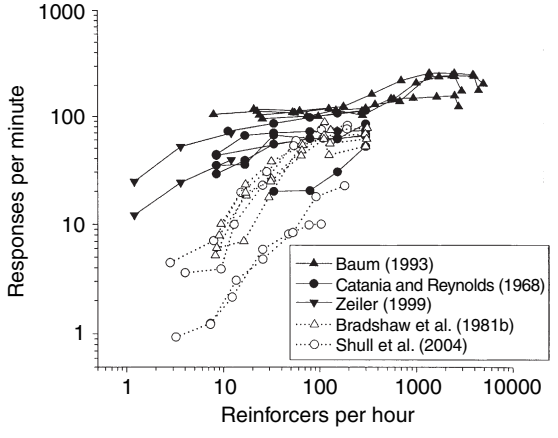

Figure 3 The relation between response rate and (food) reinforcement rate in simple VI schedules collected from various studies. Overall, it is hyperbolic, but rats (empty symbols) are much more sensitive to variations in the reinforcement rate than pigeons (filled symbols). From Shull RL (2005) The sensitivity of response rate to the rate of variable-interval reinforcement for pigeons and rats: A review. *J. Exp. Anal. Behav.* 84: 99–110, with permission from the Society for the Experimental Analysis of Behavior, Inc.

This provides the necessary behavioral variation from which the reinforcement contingency will select the appropriate response.

As a consequence, a behavior cannot be reinforced by a reinforcer if it is not naturally linked to that reinforcer in the repertoire of the animal (*See* Chapters 1.06, 1.18, 1.22). Hence, environment-related activities can be reinforced by food in hamsters but not self-care responses (Shettleworth, 1975), and rats will learn to press a lever for food (food consumption in rats involves manipulation) but not to avoid an electric shock, although they will quickly learn to freeze, run to another box, or jump over a barrier (all parts of the rat defensive repertoire) to achieve such a result (e.g., Biederman et al., 1964; Hineline and Rachlin, 1969). Although pigeons can learn to peck a key for both food and water, the topography of their responses differs depending on the kind of reinforcer used. They peck at the key the way they peck at food if food is used as the reinforcer (beak open until contact with the target), and the way they peck at water (beak closed until contact with the target) if water is used as the reinforcer (Jenkins and Moore, 1973).

The most spectacular example of the principle according to which only behaviors related to a specific reinforcer can be reinforced by it is instinctive drift (Breland and Breland, 1961), where, in procedures using food reinforcement, a species-specific food-related behavior will replace an operant response not naturally linked to food situations in the repertoire of the organism. For instance, a raccoon reinforced to put coins in a slot machine will learn the task, but then suddenly start washing the coins, while a pig trained in the same procedure will bury them instead (Breland and Breland, 1961).

Besides the reinforcement contingency, other variables contribute to the selection of the response, notably the Pavlovian stimulus–stimulus contingency that any operant procedure creates between the experimental context and the reinforcer. In some cases, this effect is so strong that there is nothing left for the response-reinforcer contingency to select for. This is notably the case of pigeon key pecking; simply illuminating the key briefly before intermittently delivered food is sufficient to trigger key pecking, a procedure known as autoshaping (Brown and Jenkins, 1968). This happens even if key pecking actually postpones food delivery (Williams and Williams, 1969). Other responses in other species, including lever pressing in rats, can be autoshaped. The exact nature of the autoshaped response depends on the

relation between the reinforcer-predicting stimulus and the reinforcer-elicited behaviors. Pigeons peck at small circular objects (like grain), and this is probably why they will peck at a key, a small circular object, when that stimulus becomes a predictor of food: This behavior is compatible both with the kind of reinforcer delivered and with the stimuli present in the environment. Indeed, if a small dark dot is added to the center of the key, hence making it even more similar to the stimulus naturally supporting pecking, autoshaping is faster (Jenkins et al., 1981). In rats, if the stimulus predicting food is another rat instead of a lever, autoshaped responding will take the form of social behaviors directed at the stimulus rat (Timberlake and Grant, 1975).

Another aspect of the performance that seems to be determined by Pavlovian relations between the context and the reinforcer, at least in simple schedules, is the temporal regulation of behavior. If food is delivered at a specific time relative to trial onset (in an FI, for instance), animals adjust to this regularity, and their response rate is a function of time-to-reinforcement (Skinner, 1938), a phenomenon known as interval timing (more on this later). Wynne and Staddon (1988) exposed pigeons to a response-initiated schedule where the first peck on the key after trial onset started a fixed delay-to-food and measured the waiting time (the time between trial onset and the first response). This should have reinforced short waiting time, but instead, the pigeons waited an amount of time equal to a fixed proportion of the last time-to-food interval. On the same issue, Baum (1993) showed that if the reinforcement rate (which is the inverse of the average time of reinforcement) is equalized, wait times in VI and VR are identical (see also Jozefowiez et al., 2005, for additional experimental evidence). Note that, on the other hand, interval timing also occurs in concurrent schedules. For instance, Jozefowiez et al. (2005) exposed pigeons to a concurrent FI 20 s FI 60 s and observed temporally regulated choice: The pigeons started responding on the FI 20 s, then as time in a trial increased, switched to the FI 60 s. This is obviously operant timing, as it requires the animal to know with which response a specific time of reinforcement is associated. This argument has been used by Jozefowiez et al. (2005, 2006) to argue that different processes control responding in simple schedules versus concurrent schedules.

A corollary of interval timing is that if the animal is more likely to engage in reinforcer-related activity as the time of reinforcement grows nearer, it is less likely to engage in those activities when the time of reinforcement is far away and so more likely to engage in other activities at those times (*See* Chapters 1.12, 1.19). Staddon (1977) has divided the activities taking place during an interreinforcement interval into three classes. On one end of the interval, close to the time of reinforcement, is the terminal response – reinforcer-related activities such as key-pecking in pigeons or lever-pressing in rats. At the other end of the interreinforcement interval, close to trial onset, are interim activities (also termed adjunctive behavior). Interim activities, although unrelated to the reinforcer in the repertoire of the animal, are affected by the experimental parameters, their rate of emission being an inverted U-shaped function of the reinforcement rate (Staddon, 1977; Reid and Staddon, 1990). The classic example is polydipsia in rats (Falk, 1961): In any procedure where food is delivered at fixed intervals, rats will drink to excess just after food delivery – up to several times their daily water requirement – if given the opportunity. The excessive nature of polydipsia clearly indicates that it cannot be merely explained by efficient time allocation or homeostasis.

The type of adjunctive behavior observed depends on species-specific interaction between motivational systems and the connections existing between these systems and the stimuli present in the environment: If presented with another rat instead of water, rats will attack it (Thompson and Bloom, 1966; Gentry and Schaeffer, 1969), but on the other hand, if given access to both water and another member of their species, they will display schedule-induced polydipsia rather than schedule-induced aggression (Knutson and Schrader, 1975). In the same situation, pigeons only display schedule-induced aggression (Yoburn and Cohen, 1979). The motivation to engage in adjunctive behaviors is so strong that they can be used as reinforcers for other activities. For instance, a pigeon will learn to peck a key to be able to attack another pigeon (Cherek et al., 1973).

Finally, the time not filled by interim or terminal behavior is filled with facultative activities. In contrast to adjunctive behavior, they are not affected by the reinforcement rate and tend to be suppressed if more time is required by interim and terminal behavior (Staddon and Ayres, 1975).

So there is much more going in operant conditioning than simply operant learning. Yet there is clear evidence that the response-reinforcer contingency also plays a role. This is obviously the case in concurrent schedules, but it is also true for simple

schedules. Even though pigeons will peck at a key and rats will press a lever anyway if these stimuli are signals for food, they are still more likely to do so if there is also a response-reinforcer contingency (Rescorla and Skucy, 1969; Woodruff et al., 1977), especially for rats (Lowe and Harzem, 1977). An omission procedure, where emission of the response postpones the delivery of the reinforcer, also has an effect on the behavior – on rats' approach behavior (Holland, 1977) or pigeons' key pecking (Schwartz and Williams, 1972).

There is also good evidence that animals can discriminate when a stimulus is a consequence of their behavior or not. In an experiment by Killeen (1978), pigeons were pecking on a key that turned black from time to time. If this change was the consequence of peck, reinforcement was scheduled on a second key; but if the change was spontaneously caused by a scheduling computer, they were reinforced for a peck on a third key. Pigeons had no problem mastering this task.

1.06.2.2 Determinants of Operant Learning

The operational distinction between Pavlovian and operant learning is clear: The animal learns a relation between a response and a stimulus in operant learning but a relation between two stimuli (the conditioned stimulus, CS, and the unconditioned stimulus, US) in Pavlovian learning. But are these two different forms of associative learning or does the same mechanism underlie both? The data favor the second hypothesis because the conditions leading to the learning of a CS–US relation in Pavlovian conditioning also lead to the reinforcement of a response in operant conditioning.

One important variable known to affect Pavlovian learning is the temporal contiguity between the CS and the US (Rescorla, 1988; *See* Chapter 1.03). Although testing to see if contiguity is also important in operant learning is a bit more complicated than it appears (for instance, if a response is emitted and scheduled for reinforcement D seconds later, do we allow more responses during the interval? If yes, the delay will be less than D. If no, we might artificially reduce responding), all studies that have looked at it have found that response rate is a decreasing function of the delay (Sizemore and Lattal, 1977; Lattal and Gleeson, 1990; Dickinson et al., 1992; Bruner et al., 1998; Stuphin et al., 1998). Also, even though it is commonly acknowledged that small delays have catastrophic consequences on the acquisition of operant responding, recent studies have shown that after appropriate training, a substantial response rate can be sustained even with 30-s delays in rats, pigeons, and even Siamese fighting fish (Lattal and Gleeson, 1990; Lattal and Metzger, 1994; Bruner et al., 1998; Stuphin et al., 1998).

The other important determinant of Pavlovian learning is that the CS must be a good predictor of the US (Rescorla and Wagner, 1972). Once again, this seems also to be the case for operant learning, where the response has to be a reliable predictor of reinforcement. Responding is suppressed when the probabilities of response-dependent and response-independent reinforcement are equal, and it actually seems that the amount of responding is proportional to these two probabilities (Hammond, 1980; see also Lattal, 1974. In similar fashion, Pavlovian learning depends on the difference between the probability that the US is presented in the presence vs. absence of the CS; Rescorla and Wagner, 1972). This effect is reinforcer-specific: Response-independent food delivery reduces the rate of responding of a food-reinforced response but has no effect on a water-reinforced one (Dickinson and Mulatero, 1989). Moreover, response-independent food delivery has no effect if signaled by a stimulus, a manipulation that preserves the predictive value of the response (Hammond and Weinberg, 1984; Dickinson and Charnock, 1985).

Another line of evidence comes from a study by Williams (1999) that showed that operant learning does not occur if the reinforcer delivery is predicted by a stimulus. Naive rats were placed in a Skinner box, and lever-pressing led to food delivery 30 s later. There were three conditions. In the control condition, the delay of reinforcement was unsignaled. Consistent with earlier results of Lattal and Gleeson (1990), lever pressing increased in frequency despite the 30-s delay. In another condition, pressing of the lever turned on a house light that stayed on until food delivery. This kind of procedural arrangement is known to considerably aid delay conditioning because of the supposed conditioned-reinforcement properties of the food-predicting stimulus. Indeed, Williams (1999) found a higher response rate in that condition than in the unsignaled-delay-of-reinforcement one. But if the house light was turned on 5 s before reinforcement instead of just after response emission, responding was totally suppressed. According to Williams (1999), the higher reinforcement-predicting value of the light, which could not be compensated in this case by its

conditioned reinforcement properties, blocked the learning of the response-reinforcer relation (see Williams, 1999, for additional experimental support for this hypothesis).

1.06.2.3 The Content of Operant Learning

Operant behaviors are emitted because of their consequences: A pigeon in a Skinner box is pecking at the key because it gives access to food. But does the pigeon 'know' that? In the framework of associative theory, this question is about whether operant learning leads to the formation of stimulus-response associations between the experimental context and the response or response-outcome associations between the response and its consequence.

Data seem to support the latter view. They come mainly from the reinforcer devaluation procedure where, after an operant behavior has been established, the value of the reinforcer to which it gives access is modified to see if this has any impact on the performance. For example, Colwill and Rescorla (1985) first trained a rat to press a lever for food. The rat was then given free access to food and made sick by injection of lithium, a procedure that creates a strong aversion for the food consumed prior to the poisoning (taste aversion learning; Garcia et al., 1966). When reintroduced into the Skinner box after that manipulation, response rate was massively depressed compared to baseline performance. At the same time, another operant response (chain pulling), which had been reinforced with water, was unaffected by the devaluation of the food reinforcer. The experiment by Dickinson and Charnock (1985) that we discussed previously, showing that response-independent food delivery had no effect on a water-reinforced response, points to the same conclusion. On the other hand, responding is not totally suppressed following reinforcer devaluation. That could be a clue that stimulus-response associations are also formed and partly control operant performance along with response-outcome associations (see Hall, 2004, for further discussion).

1.06.3 Interval Timing

Now that we have considered the conditions in which operant learning takes place, we can turn to the second issue regarding operant behavior – how it is regulated by its consequences. This is mainly the study of schedules of reinforcement, which has been heavily skewed toward interval schedules and concurrent schedules, the former because they provide a way to study interval timing, whose influence seems pervasive in operant conditioning, and the latter because they are an experimental model of choice and decision making. We deal with interval timing in this section and with concurrent schedules and choice in the section titled 'Operant choice.'

1.06.3.1 Basic Facts

Interval timing is the ability of animals to perceive temporal relations between two events, ranging from seconds to several minutes (*See* Chapter 1.19) (based on neurological evidence, it seems that timing in the milliseconds range and circadian timing are different processes (e.g., Lewis and Miall, 2003; Lewis et al., 2003). In interval timing, the first event is termed the time marker because it starts the to-be-timed interval. On FI, where the time marker is trial onset and the interval is ended by reinforcement, interval timing leads to some temporal regulation of behavior. In most species, the animal pauses after trial onset and then, as time in a trial increases, starts responding at an increasing rate, reaching its maximum shortly before the time of reinforcement (Ferster and Skinner, 1957; Lejeune and Wearden, 1991). Some have argued (e.g., Gibbon, 1991; Cheng and Westwood, 1993) that this pattern of responding, called a scallop, is an artifact caused by averaging many trials together and that performance in individual trials actually follows a break-and-run pattern, with the animal moving abruptly, at a point varying from trial to trial (the break point), from a state of low responding to a state of high responding. But scallops were initially described based on the real-time performance of individual animals (Ferster and Skinner, 1957). Data from Schneider (1969), usually cited in support of the break-and-run hypothesis, actually show that although the break-and-run pattern dominates performance for short fixed intervals, scalloping is characteristic of longer intervals. Staddon (2001, Box 13.1) showed that this is what should be expected if the probability of responding increases monotonically during a trial.

For this reason, the pattern of local response rate across a trial, an estimate of the pattern of probability of responding across a trial, seems a better dependent variable than partial measures such as pause or break point. In FI, response rate increases during a trial, following a sigmoid, Gaussian function (Killeen et al., 1978; Lejeune and Wearden, 1991; **Figure 4**). What would happen if reinforcement was not delivered?

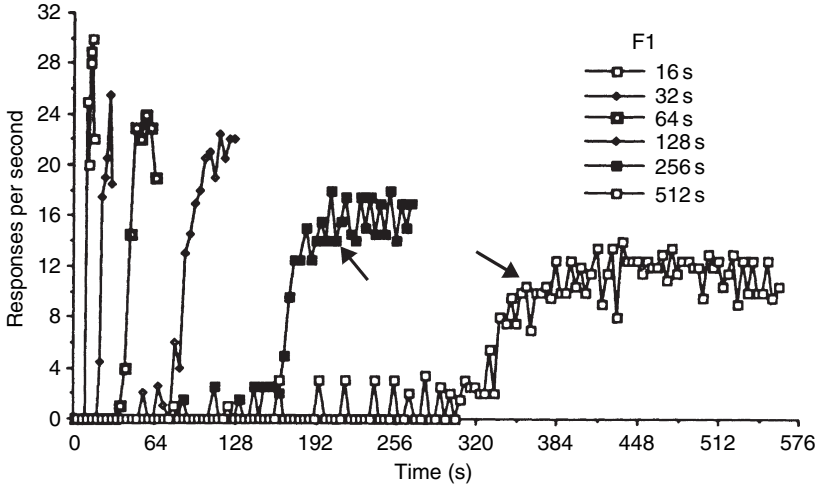

Figure 4 Proportional timing in FI: Response rate in FI is a sigmoid function of the time-to-reinforcement. Plotted in relative time, curves from FI with different intervals would superimpose. From Gibbon J (1991) Origin of scalar timing. *Learn. Mot.* 22: 3–38, with permission from Elsevier.

The peak procedure where, along with standard FI trials, empty trials lasting three or more times longer than the FI trials and ending without reinforcement are thrown in has been designed to answer this question (Catania, 1970; Roberts, 1981). After sufficient training with this procedure, response rate increases according to a sigmoid function up to the time of reinforcement and then decreases from that point, still according to a sigmoid function (**Figure 5**). The time of maximal responding (peak time) corresponds more or less to the time of reinforcement. It is not much affected by the number of peak trials, which mostly affect the absolute response rate, partly through their effect on arousal, because adding peak trials reduces the overall reinforcement rate.

Timed behavior, as observed in FI and the peak procedure, has two fundamental characteristics. The first is proportional timing: Performance is tuned to the time of reinforcement (**Figures 4** and **5**). Although this temporal adaptation of behavior was once believed to emerge only after extensive training with the procedure, recent research (Innis and Staddon, 1971; Wynne and Staddon, 1988; Higa et al., 1991; Higa and Staddon, 1997) has now shown that pigeons and rats can modify their behavior immediately following a change in the FI interval. Second is the scalar or timescale invariance property: Response curves superimpose when plotted in relative time (Dews, 1970; **Figure 5**). These properties have skewed theoretical thinking about interval timing toward a psychophysical framework.

In a psychophysical task, the subject is presented with two stimuli and asked if they are of similar intensity (or frequency, or color, etc.). The subject's responses are usually variable, assumed to be because of noise in sensory systems, but the probability that the two stimuli are judged identical is a function of their difference in intensity. If one stimulus is held constant, the curve showing how the probability that the subject judges the two stimuli identical as a function of the intensity of the second stimulus is called a psychometric function. A general property of many sensory systems is that they respect Weber's law: The higher the intensity of a stimulus, the more difficult it is for the subject to perceive differences when it is varied, an outcome that could result from a logarithmic encoding of stimulus intensity, a conjecture known as Fechner's law. One interesting consequence of Weber's law is that if psychometric functions are plotted on a relative stimulus scale, they superimpose (Falmagne, 1985).

This has led researchers to consider that the response rate curves obtained from animals in FI and peak procedures are indeed psychometric functions: The subject is comparing a representation of the current time in a trial to a representation of the time of reinforcement; the closer they are, the higher the probability of responding. Timescale invariance is observed because time perception follows Weber's law.

1.06.3.2 Scalar Expectancy Theory

Most theories of timing agree on this framework (Staddon, 2001) but differ about what is the basis for the representation of time. For many years, the most

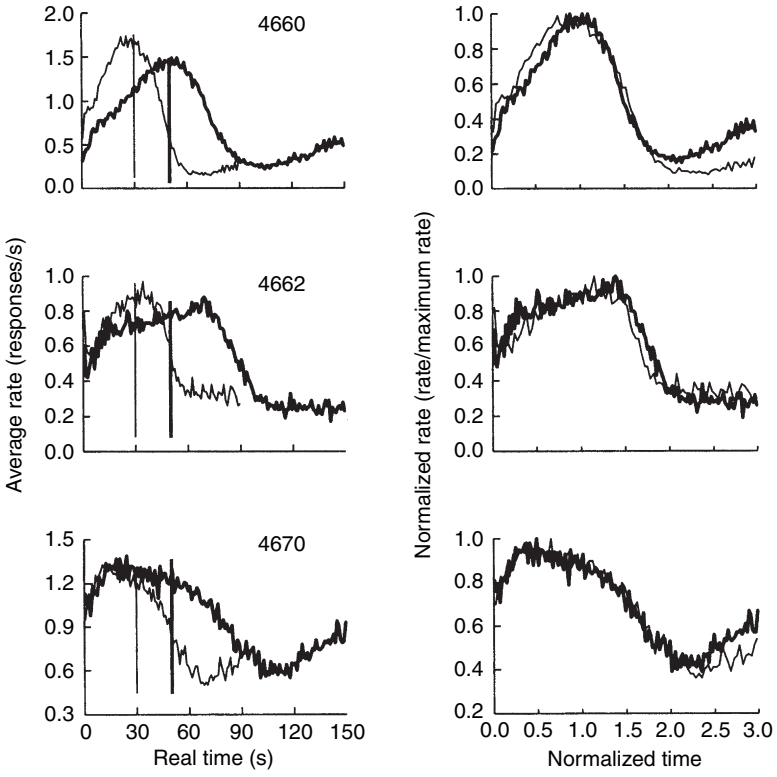

Figure 5 Proportional timing and timescale invariance in the peak procedure: Response rate in the peak procedure increases up to the time of reinforcement and then decreases, in both cases in a sigmoid fashion. Plotted in relative time, curves from peak procedures with different intervals superimpose. From Gallistel CR and Gibbon J (2000) Time, rate and conditioning. *Psych. Rev.* 107: 289–344. influential model was scalar expectancy theory (SET, Gibbon, 1977; Gibbon et al., 1984; **Figure 6**). SET assumes an internal pacemaker generating pulses at a more or less constant rate as soon as the time marker is presented (like most theories of timing, SET does not say how the animal identifies a time marker). These pulses accumulate in short-term memory, providing the basis for the representation of time which, as a consequence, is linear. When a reinforcer is delivered, the number of pulses currently accumulated is stored in long-term memory, but error is supposed to occur during the encoding process, leading to a Gaussian long-term memory distribution of time of reinforcement with a standard deviation proportional to the mean: This ensures that Weber's law is respected (Falmagne, 1985), even though Fechner's law is not (time is supposed to be encoded linearly, not logarithmically). At the beginning of a trial, the animal is supposed to sample one value from this distribution, which it will constantly compare to its representation of the elapsed time-in-trial to decide if it responds or not.

The empirical basis for SET is its ability to account for the basic data in timing procedures. But alternative theories of timing (i.e., the behavioral theory of timing, Killeen and Fetterman, 1988, and its neural network version, the learning-to-time model, Machado, 1997; the multiple timescale theory, Staddon, 2001, 2005; the packet theory of timing, Kirkpatrick, 2002) do just as well. Moreover, SET's achievement comes at the cost of parsimony. In adding to an already substantial number of free parameters, details of the models are usually modified to fit results from different procedures. For instance, the comparison rule between the representation of the current time in trial and the representation of the time of reinforcement is not the same depending on whether the data to be accounted for have been collected in an FI, a peak procedure, a bisection procedure, or a time-left procedure (Wearden, 1999; see the following paragraphs for a description of the latter two timing procedures).

In any event, it seems that the basic data about timing can be simulated by any model respecting

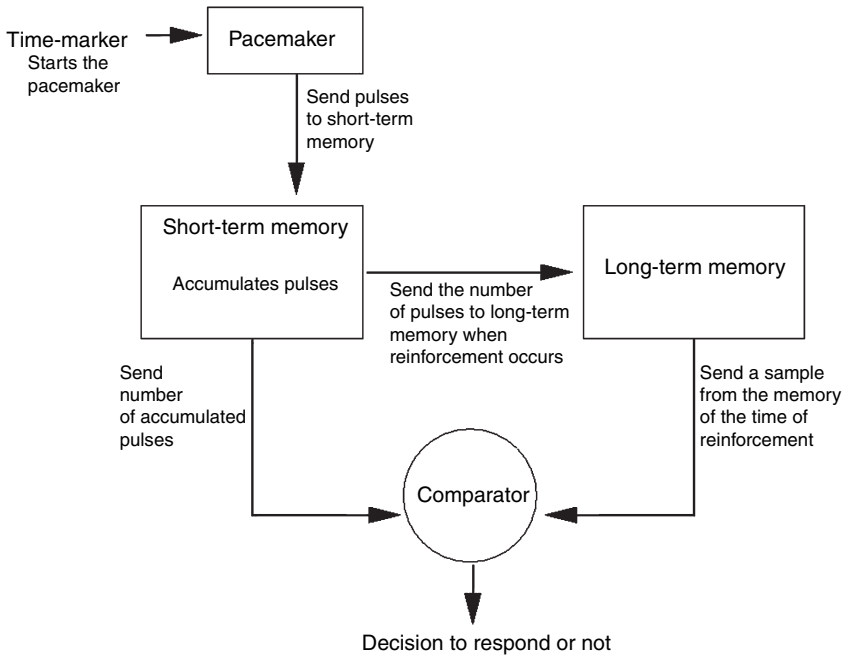

Figure 6 Scalar expectancy theory. When a time-marker is presented, the pacemaker starts emitting pulses at a more or less constant rate into short-term memory, where they are accumulated. When reinforcement occurs, the number of pulses currently in short-term memory is transferred to long-term memory. During a trial, the current number of pulses in short-term memory is continuously compared to a sample of the time of reinforcement retrieved from long-term memory to decide if a response should or should not be emitted.

Weber's law, and so it is not sufficient for a timing model to account just for those data. It must have additional empirical support for its assumptions. The behavioral theory of timing, for instance, is rooted in the data about adjunctive behavior we reviewed in the previous sections, considering that the sequence of behaviors an animal goes through a trial (from interim to facultative to terminal behavior) is the basis for interval timing instead of its consequence, as we have proposed. The multiple timescale theory is based on a model of memory developed to account for habituation data. What data support the existence of SET's internal pacemaker?

The best evidence is from the study of drug effects on timing performance. Meck (1996) proposed that dopamine agonists, such as amphetamine, accelerate the rate of the pacemaker. (Dopamine antagonists are supposed to have the reverse effect. Meck's (1996) model also has predictions concerning the effect of cholinergic drugs, but we will focus on dopamine antagonists in this review.) Then, in the peak procedure, chronic injection of a dopamine agonist should (1) immediately move the peak time to the left because the criterion number of pulses at which the animal starts responding is reached faster, but (2) the peak time should gradually return to its original value as a new criterion is learned due to the fact that, with each reinforcement, the number of pulses in memory is transferred to long-term memory and a new representation of the time of reinforcement, generated by the drug-accelerated pacemaker, progressively overrides the previous one generated by the slower pacemaker. Once the dopamine agonist injection is discontinued, the same process takes place in reverse: The peak time shifts to the right and then progressively comes back to its original value. Similar effects should be observed for other measures of temporal control, such as the bisection point in the bisection procedure (see following paragraphs for a description of that procedure).

Although some studies have found the predicted effect of dopamine agonist on temporal dependent variables (i.e., Maricq et al., 1981; Maricq and Church, 1983; Spetch and Treit, 1984, with a bisection procedure; Maricq et al., 1981; Eckerman et al., 1987; Frederick and Allen, 1996; Kraemer et al., 1997, with a peak procedure), at least as many have failed to find such an effect (e.g., Lejeune et al., 1995; Chiang et al., 2000; Odum and Schaal, 2000, with a bisection procedure; Bayley et al., 1998; Knealing and

Schaal, 2002, with a peak procedure; see Odum et al., 2002, for a complete review). Moreover, studies using the peak procedure usually report only the peak time, whereas SET predictions are much broader and implicate the whole response function. It should be shifted to the left, and because of the scalar property, its variance should decrease. Saulsgiver et al. (2006) found that this is not what happens: Low responding early in a trial increases, while high responding before the time of reinforcement decreases; response rate after the time of reinforcement is mainly unaffected. As a consequence, the peak time shifts to the left, but the variance of the response-rate function increases, a result opposite to the SET interpretation.

In a critical review of the literature, Odum et al. (2002) argued that rate dependency provides a unifying account of drug effects in timing procedures, explaining results from experiments showing an effect and from those failing to find one. Rate dependency is a well-established and general empirical effect of drugs on operant behavior (Dews, 1958, 1981): High response rates are reduced by drug administration, whereas low response rates are increased. In an FI, for instance, this leads to a flattening of the whole response function. Odum et al.'s (2002) own studies, using a procedure borrowed from Catania and Reynolds (1968) that allowed them to differentiate timing from rate dependency (see Odum, 2002; Odum et al., 2002, for further details), seem to confirm that the dopamine-agonist effect in timing procedures is mainly due to rate dependency. (On the other hand, Odum (2002) found more support for an effect on timing of cholinergic drugs such as atropine or physostigmine, although the effect was small for physostigmine and the reverse of what is predicted by SET (Meck, 1996) for atropine.)

The results are just as problematic for other predictions of SET, like the progressive tolerance effect predicted if the dopamine agonist is injected chronically (Maricq et al., 1981, reported such an effect, but Frederick and Allen, 1996; Chiang et al., 2000; McClure et al., 2005; and Saulsgiver et al., 2006, failed to find it) or the rebound in peak time predicted after chronic injections of amphetamine cease (i.e., Saulsgiver et al., 2006). All in all, drug effects on timing performance provide no support for a pacemaker account of interval timing. The effects that are observed seem to be more a consequence of rate dependency than of a perturbation by the drug of an isolable temporal-information-processing mechanism.

An indirect way to prove the existence of an internal pacemaker would be to show that animals represent time linearly. Two experimental procedures have been designed to tackle this issue. The older one is the bisection procedure (Stubbs, 1968; Church and Deluty, 1977). It is a trial-based procedure where, following the presentation of one of two temporal stimuli, short or long, the animal is given a choice between two response alternatives. The animal is trained to make one response if the stimulus was short and another one if the stimulus was long. Then, on unreinforced probe trials, the animal is presented with stimuli having intermediate durations between the short and long stimuli used during training.

The closer the duration of the test stimulus to the duration of one of the stimuli used in training, the higher the probability the subject picks the response associated with that stimulus. Of special interest is the point of bisection, that is to say, the stimulus duration for which the animal picks each response with the same probability. On the animal's subjective timescale, the representation of that stimulus duration is supposed to be halfway between the representations of the duration of the two stimuli used during training. It usually falls around the geometric mean between these two durations. On a straightforward psychophysical interpretation, this result implies that time is represented logarithmically, rather than linearly, as the pacemaker approach implies. However, the linear assumption of SET can be made consistent with geometric-mean bisection by suitable modifications to other parts of the model (Gibbon, 1981).

In an attempt to resolve this issue, a more complex procedure, the time-left procedure (Gibbon and Church, 1981), was devised (**Figure 7**). Basically, it is a concurrent-chain procedure with VI initial links. At a random time T varying from trial to trial, the animal's response will commit it either to the time-left side, where food will be delivered C-T s later, or to the standard side, where food will be delivered S s later. According to Gibbon and Church (1981), the performance in this task is based on a series of mental computations. If we denote by $f(x)$ the animal's representation of an interval of x s, and by t the time elapsed since trial onset, then at each time step, the animal is supposed to compute the difference $f(C) - f(t)$ (time left to reinforcement on the time-left side) and compare it to $f(S)$ (time to reinforcement on the standard side): if $f(C) - f(t) > f(S)$ (which is more likely early in a trial since $S < T$), the animal

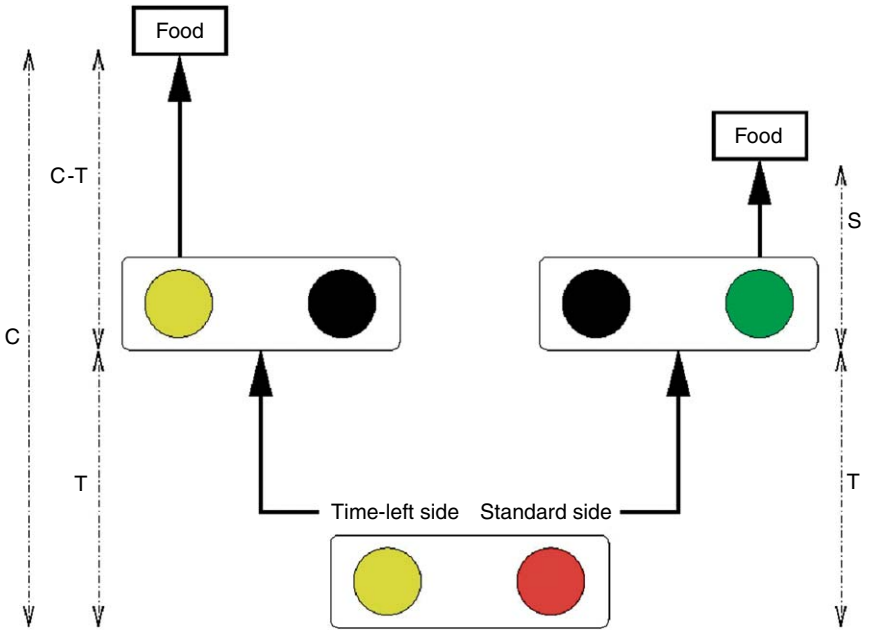

Figure 7 The time-left procedure for pigeons. The two keys are available to the pigeon for T s with T varying randomly from trial to trial. If, at time T s in a trial, the pigeon pecks on the time-left side, then (a) the standard side becomes unavailable and (b) reinforcement is delivered on the time-left side C-T s later so that time-to-reinforcement from trial onset on the time-left side is always fixed at C s. On the other hand, if at time T s in a trial, the pigeon pecks on the standard side, then (a) the time-left side becomes unavailable, (b) the standard side key color changes (by contrast, the time-left side key color remains the same), and (c) reinforcement is delivered on the standard side S s later.

picks the standard side; if $f(C) - f(t) < f(S)$ (more likely later in a trial when t is large enough), the animal should pick the standard side.

Because of noise, the animal's actual choice will be, of course, not as clear cut, but the preference of the animal for the time-left side should increase as a function of time in a trial, which is indeed what is observed (**Figure 8**). Moreover, when $f(C) - f(t) = f(S)$, the animal should be indifferent between the time-left and the standard side. $f(C) - f(t)$. Different hypotheses about the representation of time (linear vs. logarithmic) predict different locations of this point of subjective equality. Additionally, according to Gibbon and Church (1981), if the representation is logarithmic, the location of the point of subjective equality should be determined by the C/S ratio: if $C = 30$ s and $S = 20$ s, the point of subjective equality will be the same as if $C = 15$ s and $S = 10$ s. This highly counterintuitive prediction is, of course, not observed (Gibbon and Church, 1981), and although the point of subjective equality is not located precisely where it should be if time representation is linear (the animal switches to the time-left side well before it should), it is more compatible with this hypothesis than with Gibbon and Church's version of the logarithmic one (**Figure 8**).

There are both philosophical and empirical problems with the Gibbon–Church analysis (Staddon and Higa, 1999). Their argument relies on the postulate that the animal's behavior is based on mental subtraction and comparison between the various durations involved in the procedure, but this assumption has no empirical basis. If different assumptions are made, notably concerning the way subjective time maps onto preference (see Cerutti and Staddon, 2004a, and Dehaene, 2001, for two examples), results from the time-left procedure can readily be reconciled with a logarithmic (or other monotonic) representation of time.

At an empirical level, puzzling results obtained in some other explorations of the time-left procedure (e.g., Preston, 1994; Cerutti and Staddon, 2004a; Machado and Vasconcelos, 2006) have shown that the processes involved in it are far from clear, a conclusion that should not surprise given its complexity. As **Figure 7** shows, in a standard time-left with pigeons, the color of the time-left side key is constant, whereas the standard side key color changes

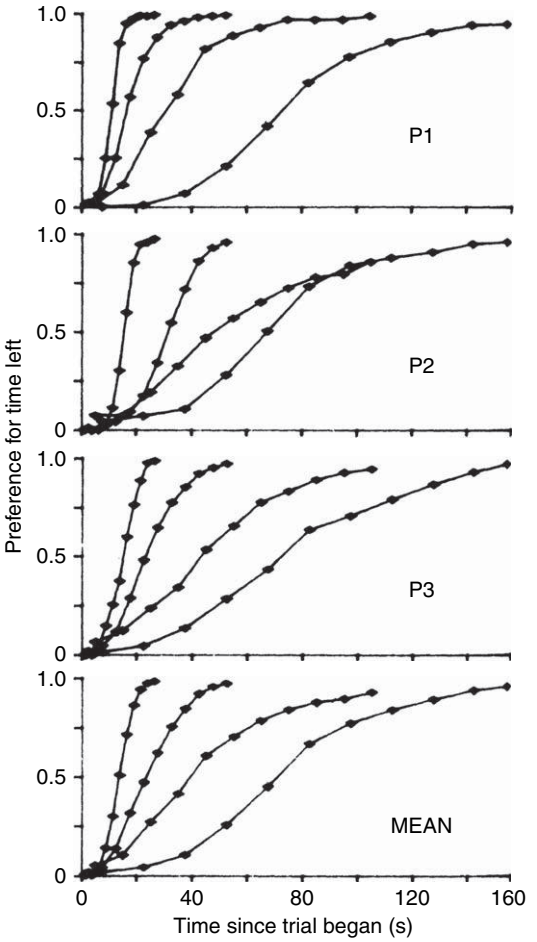

Figure 8 Results from Gibbon and Church's (1981) time-left procedure. The three top panels show individual subjects, whereas the bottom panel shows the group average. For each graph, the overall time-to-reinforcement on the time-left side (C) was (from the most leftward curves to the most rightward) 30, 60, 120, and 180 s. The duration of the standard side (S) was always half of the duration on the time-left side. Preference for the time-left side increases with time in a trial. From Gibbon J and Church R (1981) Time left: Linear versus logarithmic subjective time. *J. Exp. Psychol. Anim. Behav. Process* 22: 3–38. Copyright American Psychological Association. Reprinted with permission.

when the animal becomes committed to that side. Cerutti and Staddon (2004a) showed that this is the only configuration leading to an increase in the preference for the time-left side as time in a trial increases; every other variant (e.g., the color of the key changes on both sides or on the time-left side but not on the standard side or on neither side) leads to an exclusive preference for the time-left side – despite the fact that the temporal relations (the only ingredient in the Gibbon–Church analysis) are the same for all arrangements.

Machado and Vasconcelos (2006) found that if the animals are trained separately with the time-left and standard sides, their performance changes when the two schedules are put together in a concurrent schedule, a result not expected if the animal was basing its behavior on the comparison of the temporal intervals involved in the experiment (the performance should be perfect from the start in this case).

Finally, in a simplified variant of the time-left procedure, Cerutti and Staddon (2004a) found that pigeon performance was strongly influenced by when the animal could be committed to a schedule. In their study, $C = 60$ s and $S = 30$ s. The pigeon could be committed to a schedule either anytime between 5 s and 55 s in a trial, anytime between 5 s and 30 s in a trial, or anytime between 30 s and 55 s in a trial. The pigeon's response allocation differed in each condition, a result that cannot be reconciled with the idea that the animal's behavior is controlled by a set of mental comparisons between the various intervals used in the experiment. Before we know more about the actual controlling variables in the time-left procedure, no definitive conclusion can be drawn from it regarding the shape of the representation of time.

1.06.3.3 Beyond Psychophysics

There is currently no proof that interval timing relies on an internal pacemaker. Actually, the whole framework for the study of interval timing may need some revision. First, the emphasis on Weber's law needs to be reevaluated, as many studies have now reported what look like violations of it (e.g., Dreyfus et al., 1988; Stubbs et al., 1994; Zeiler and Powell, 1994; Crystal, 1999; Bizo et al., 2006), although this needs to be considered carefully. A performance might appear to violate Weber's law, not because the underlying timing mechanism does not follow it but because processes other than timing influence the performance (e.g., Jozefowiez et al., 2006).

But beyond Weber's law, the whole psychophysical approach, the idea that interval timing relies on some kind of 'knowledge' the animal has of the intervals involved in the experiment, may need to be abandoned. In the peak procedure, the animal is usually first trained on an FI for several sessions before peak trials are thrown in. As we saw, during those peak trials, their response-rate pattern evolves according to a kind of bell-shaped function that peaks at the time of reinforcement. But this behavior

is observed only after several sessions where the animal is exposed to a mix of reinforced FI trials and unreinforced peak trials. The first time a peak trial is introduced, the animal just keeps on responding until the end of the trial, apparently never noticing that the time of reinforcement has passed (an example of something studied many years ago as the reinforcement-omission effect, Staddon and Innis, 1969; Kello, 1972). This is a surprising result if we assume, as most theories of timing do, that the time of reinforcement is precisely what the animal learns when exposed to an FI.

Even more damaging evidence comes from a recent series of experiments by Machado and collaborators (Machado and Keen, 1999; Machado and Pata, 2005; Machado and Arantes, 2006). They trained pigeons in two bisection tasks simultaneously. In one task, response R1 (i.e., pecking on a red key) is reinforced after a 1-s stimulus while response R2 is reinforced after a 4-s one. In the other task, response R3 is reinforced after 4 s, whereas response R4 is reinforced after a 16-s one. Hence, both R2 and R3 are associated with a 4-s stimulus, so according to the psychophysical approach, they should be equivalent. But they are not. If given the choice between R2 and R3 after a test stimulus is presented, the pigeons are not indifferent as they should be according to the cognitive view. Instead, they switch their preference from R2 to R3 as the duration of the stimulus is increased (Machado and Keen, 1999; Machado and Pata, 2005). If these same animals are exposed to a new bisection procedure, performance is stable from the start if R3 is reinforced after a 1-s stimulus and R3 after a 16-s stimulus but is greatly disturbed in the reverse case (Machado and Arantes, 2006; **Figure 9**).

These data cannot be reconciled with the traditional psychophysical/cognitive account of interval timing and suggest the involvement of a simpler associative process, such as the one described in Machado's (1997) Learning-to-Time model. Instead of the time associated with each response, pigeons in a bisection task would learn through reinforcement and extinction to (1) approach the key associated with the short-duration stimulus and avoid the one associated with the longer-duration stimulus early in a trial and (2) do the reverse (i.e., avoid the key associated with the short-duration stimulus and approach the stimulus associated with the longer-duration stimulus) late in a trial (Machado and Arantes, 2006). Hence, when given the choice between R2 and R3 in Machado and Keen (1999) and Machado and Pata's (2005) studies, the pigeons would behave as they have learned previously, approaching R3 early in a trial while avoiding R2 and doing the reverse later. This pattern of approach/avoidance behavior is perfectly compatible

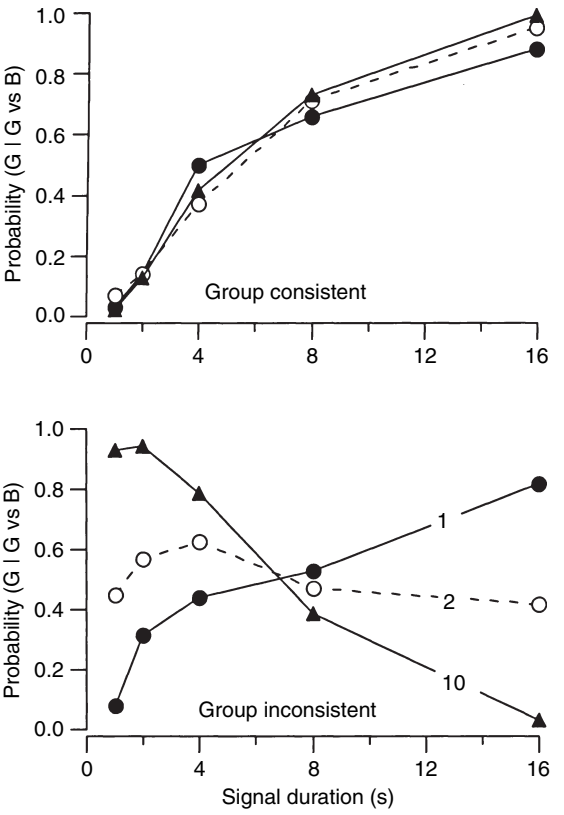

Figure 9 Group data from Machado and Arantes (2006). Pigeons were initially trained in two bisection procedures, one pitting a 1-s stimulus versus a 4-s one, the other pitting a 4-s stimulus versus a 16-s one. They were then trained in a third bisection task using the same two responses reinforced after a 4-s stimuli in the previous tasks. For the group whose data are shown in the top panel, the response previously reinforced after the 4-s stimulus pitted against a 1-s stimulus was now reinforced after a 16-s stimulus, whereas the response previously reinforced after the 4-s stimulus previously pitted against a 16-s stimulus was now reinforced after a 1-s duration. The y-axis of each graph shows the probability of emitting the response previously associated with a 4-s duration. For the second group, whose data are shown in the bottom panel, the reverse arrangement was used. Each curve in the graph represents the performance of the pigeons during the first (filled circles), second (empty circles), and tenth (filled triangles) sessions of the new bisection task. As can be seen, the pigeons' performance from the first group is stable from the first session. On the other hand, for the second group, performance takes several sessions to settle down. From Machado A and Arantes J (2006) Further tests of the Scalar Expectancy Theory (SET) and the Learning-to-Time model (LeT) in a temporal bisection task. *Behav. Processes* 72: 195–206, with permission from Elsevier.

with a new bisection procedure associating a 1-s stimulus with R3 and a 4-s stimulus with R2, and hence, the performance in this case is stable from the beginning. Otherwise, the pigeon has to relearn a new pattern of approach/avoidance behavior.

1.06.4 Operant Choice

1.06.4.1 The Matching Law

In a seminal experiment, Richard Herrnstein (1961) studied pigeons in concurrent VI VI schedules. He found that once behavior had stabilized, the ratio of response rates matched the ratio of reinforcement rates:

$$\frac{x}{y} = \frac{R(x)}{R(y)} \quad [1]$$

where x and y are response rates on the two keys, and $R(x)$ and $R(y)$ are the reinforcement rates obtained.

The matching law is a fairly general phenomenon. It has been found with several species, including, of course, rats but also humans (e.g., Bradshaw et al., 1976). Instead of having a schedule associated with each response key, an alternative, called a Findley procedure (Findley, 1958), is to have both associated with the same key but signaled by different colors that are under the animal's control. The animal switches between the two schedules by pecking a second key, called a change-over key. Matching is still observed in this case. When different feeding schedules are associated with different places (e.g., the two ends of a long box), animals allocate the time spent in the two places to the relative rate of associated reinforcement (Baum and Rachlin, 1969). Matching is also observed in trial-based procedures where the animal is only allowed one response per trial, which leads either to reinforcement or to a blackout (Sugrue et al., 2004; Lau and Glimcher, 2005).

Matching behavior is consistent with reinforcement-rate maximization in concurrent VI schedules (Staddon and Motheral, 1978; Baum, 1981), but large deviations from matching lead to only a small reduction in the obtained reinforcement rate, so it is unlikely that matching is the result of any kind of explicit maximizing process. Moreover, Equation (1) rarely fits experimental data exactly, which has led to the proposal of a popular alternative termed the generalized matching law (Baum, 1974; see also Staddon, 1968):

$$\frac{x}{y} = b\left[\frac{R(x)}{R(y)}\right]^a \quad [2]$$

where a and b are free parameters. Equation (2) can also be converted to logarithmic form, which has the advantage that the response-rate ratio remains a linear function of the reinforcement-rate ratio, allowing parameter b to be interpreted as bias and a as a measure of the sensitivity to the reinforcement rate ratio.

Violations of matching indicate that rather then being some kind of primary behavioral process (Herrnstein, 1970), matching is the outcome of more basic behavioral mechanisms. Unfortunately, determining these mechanisms can be difficult, as it seems that almost any model incorporating some form or the other of the law of effect predicts matching (Hinson and Staddon, 1983). Hence particular attention should be devoted to violations of the matching law as a way to limit the range of possible models.

Parameter b in the generalized matching law is a measure of any bias the animal might have toward one schedule. For instance, it can be systematically varied by using different kind of reinforcers for each schedule (e.g., wheat vs. buckwheat for pigeons; see Miller, 1976). The controlling variables for parameter a, on the other hand, remain more mysterious. Parameter a measures sensitivity to the reinforcement-rate ratio: When a is lower than 1, the animal is less sensitive to the reinforcement rate ratio than it should be according to the matching law (undermatching); when a is larger than 1, the animal is more sensitive to that ratio than it should be (overmatching). Reviews of the literature (e.g., Baum, 1979; Wearden and Burgess, 1982) have concluded that undermatching is more the rule than the exception, parameter a usually taking values between 0.8 and 0.9. Overmatching is seldom observed, except in very special situations (like concurrent VI FI schedules, Nevin, 1971; Trevett et al., 1972).

The causes of undermatching are not clear. The way the VI is scheduled (RI schedules lead to less undermatching, Taylor and Davison, 1983), the number of trials in a session (fewer trials lead to less undermatching; Todorov et al., 1983), and the number of conditions to which the subject has been exposed (more undermatching is obtained if the

subject has been exposed to more conditions; Keller and Gollub, 1977) are a few of the variables that have an effect. The last two variables seem to indicate an effect of interference in memory. Animals seem also to be more sensitive to reinforcement-rate ratio when the overall reinforcement rate is high (Alsop and Elliffe, 1988; MacDonall, 2006), a problem for the matching law, which implies that animals should be sensitive only to the ratio of reinforcement rates, not to their absolute values.

The variable most often cited as having an effect on the sensitivity to the reinforcement rate ratio is the presence or absence of a procedural arrangement known as a changeover delay (COD). COD works like this: When the animal switches from one schedule to the other (called a changeover), there is a small period of time (the COD, typically between 0.5 and 2 s) during which no reinforcement can be delivered. The rationale for a COD is to avoid reinforcement for a third class of behavior, switching between schedules. In the limit, switching could predominate over 'stay' choice responses, leading to apparent indifference between the two choices – extreme undermatching. According to this analysis, the main cause of undermatching would be the occasional reinforcement of switching behavior; indeed, adding a COD generally reduces the amount of undermatching (Shull and Pliskoff, 1967). On the other hand, a COD is not essential to obtain matching (e.g., Shull and Pliskoff, 1967; Heyman, 1979; Hinson and Staddon, 1983).

1.06.4.2 The Structure of Choice

Moreover, other studies have shown that some reinforcement of switching behavior is necessary to obtain matching in concurrent schedules. If pigeons are trained separately on two simple VIs and then allowed to choose between them in the usual concurrent procedure, they will respond exclusively on the VI associated with the higher reinforcement rate (extreme overmatching; Crowley and Donahoe, 2004; Gallistel and Gibbon, 2000).

This result has potentially far-reaching implications for theories of operant choice. It suggests that switching is reinforced when a switch to a schedule is followed by reinforcement (switch reinforcers), whereas staying on a schedule is reinforced by reinforcers collected while responding on that schedule (stay reinforcers; Skinner, 1950; Houston and McNamara, 1981; MacDonall, 1999). The final performance is the outcome of both stay and switch reinforcement. Consider, for instance, a concurrent VI 40 s VI 60 s. In this view, responding on the VI 40 s is reinforced according to a VI 40 s, but switching over from the VI 40 s is reinforced according to a VI 60 s.

This view is all the more plausible given that the tendency for an animal to switch between schedules is a function both of the probability that a switch is followed by reinforcement and the duration of the COD (e.g., Shull and Pliskoff, 1967; Pliskoff, 1971; Shull et al., 1981; Shahan and Lattal, 1998). Shull et al. (1981) also showed that a reinforcer delivered just after a changeover response has a massive impact on the rate of switching back and forth between the schedules. Also, in contrast to concurrent VI VI, concurrent VR VR schedules do not generate matching but exclusive preference for the schedule with the higher ratio (Herrnstein and Loveland, 1975); a reinforcer will not be scheduled on a VR until the animal works on it and hence, switching behavior will never be reinforced. If responses on a VR are counted not only for the schedule the animal is currently working on but also for the other one (hence leading to the reinforcement of switching behavior), matching is observed (MacDonall, 1988).

Another study by MacDonall (2005), in which he explicitly manipulated the reinforcement contingency for switching behaviors, provides additional support. Rats were exposed (for example) to a concurrent VI 36 s VI 360 s. In one condition, the schedule worked exactly as a traditional concurrent VI VI: Reinforcement for staying on the VI 36 s (respectively on the VI 360 s) was collected according to a VI 36 s (respectively VI 360 s), whereas reinforcement for switching away from the VI 36 s (respectively VI 360 s) was collected according to a VI 360 s (respectively VI 36 s). In the second condition, reinforcements for both staying and switching from the VI 36 s (respectively VI 360 s) were scheduled according to a VI 36 s (respectively 360 s). MacDonall (2005) reported that the latter condition yielded strong deviation from matching – unexpected by traditional views of operant choice but perfectly understandable in terms of the stay/switch framework.

From this view, the important empirical question is to understand how run length (number of responses emitted on a key between a changeover to that schedule and a changeover to the other schedule) and dwell time (time elapsing between a changeover to a schedule and a changeover to the other schedule) are determined by schedule parameters. The analysis is made easier by the fact that, in concurrent VI

schedules, both of these dependent variables are distributed exponentially, indicating a constant probability through time of terminating a visit to a schedule (i.e., Heyman, 1979; Gibbon, 1995). Two contradictory accounts have been proposed.

The first one is by MacDonall (1998, 1999, 2000, 2005), who found that run length and dwell time on a schedule were power functions of the ratio of switch and stay reinforcers plus a bias, a kind of molecular generalized matching law. MacDonall (2006) also found some modulating effect of the overall reinforcement rate.

The second one can be inferred from an influential experiment on paradoxical choice by Belke (1992) in which pigeons were exposed to a concurrent VI 20 s VI 40 s and to a concurrent VI 40 s VI 80 s. Their behavior allocation conformed to matching in both conditions. On unreinforced probe trials, the pigeons were given the choice between the two VI 40 s, the one associated with the VI 20 s and the one associated with the VI 80 s. Even though both schedules signaled the same reinforcement rate, the pigeons preferred the VI 40 s associated with the VI 80 s in a proportion of 4 to 1. Even more surprising, Gibbon (1995) showed that, if given the choice between the VI 20 s and the VI 40 s usually presented along with the VI 80 s, they preferred the VI 40 s to the VI 20 s in a proportion of 2 to 1.

These results have a surprisingly simple explanation (Gallistel and Gibbon, 2000): They can be predicted if we simply assume that the probability to leave a schedule is a linear function of the reinforcement rate on the other schedule, that is to say, the rate of switch reinforcement. Indeed, in Gibbon's (1995) experiment, the dwell-time distribution on the VI 20 s is identical to the dwell-time distribution on the VI 80 s (Gallistel and Gibbon, 2000); both were pitted against a VI 40 s.

Further research is necessary to decide between MacDonall's account and the one that incorporates Belke's results. MacDonall did not directly measure run length and visit duration but deduced them from the number of responses made on a schedule and the number of changeovers to that schedule, which might not provide accurate estimates. On the other hand, it is surprising that stay reinforcers would have no effect on performance, although that could be explained by the fact that most of the reinforcers in concurrent VI schedules are collected just after a changeover (i.e., for switching) (Dreyfus et al., 1982). We also note the existence of a few other puzzling results (i.e., Williams and Bell, 1999; McDevitt and Williams, 2003), which suggest that the determinants of performance in procedures such as Belke's (1992) are still not completely understood.

1.06.4.3 Local and Global Control of Behavior in Concurrent Schedules

Experiments on the matching law are typical of most studies of operant choice where the focus is on stable, asymptotic behavior obtained after many sessions in which the animal is continually exposed to the same condition. But recently, there has been more interest in the study of choice in transition.

Davison and Baum (2000) exposed pigeons to a concurrent VI schedule where, during a single session, the reinforcement-rate ratio changed after a fixed number of reinforcers (usually 10). The change was signaled by a 10-s blackout. Averaging across conditions and subjects, they were able to show that each reinforcer had an effect on choice, pushing the animal's preference toward the reinforced side. The effect of successive reinforcers on the same side had a diminishing effect on performance, whereas a 'disconfirming' reinforcer, for a switch response, on the other side had a stronger effect in pushing preference toward its side (**Figure 10**). This result has now been replicated in several studies, some using rats (Aparicio and Baum, 2006) or more traditional concurrent-schedule procedures where the reinforcement rate ratio does not change several times during the same session (Landon et al., 2002). This suggests some kind of surprise-driven learning mechanism similar to the one described in the Rescorla and Wagner (1972) model of Pavlovian conditioning: Behavioral change occurs when unexpected events take place in the environment.

Another interesting finding is that this local effect of reinforcement on behavior is modulated by more global variables. For instance, Davison and Baum (2000) reported that the change in behavior following reinforcement was larger when the overall reinforcement rate was high, leading to a more extreme preference for the schedule associated with the higher reinforcement rate (**Figure 10**). This is similar to Alsop and Elliffe's (1988) finding that sensitivity to the reinforcement rate ratio is higher when the overall reinforcement rate is higher. In other words, control of performance was more local with the higher reinforcement rate, with the last reinforcement delivered to the animal having a more important influence on performance in this case.

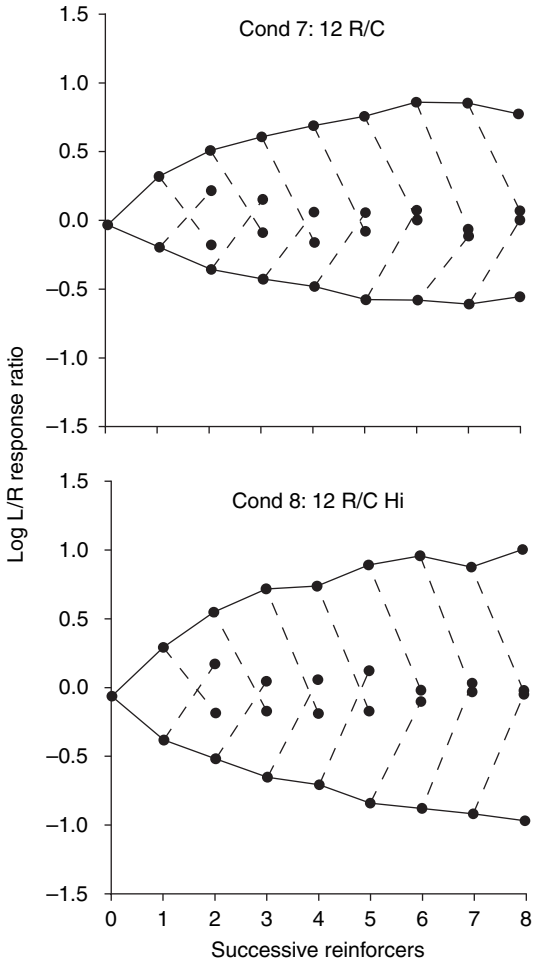

Figure 10 Effect of individual reinforcers on preference in concurrent VI schedules. Each reinforcer drives preference toward its schedule, although each successive reinforcer has a diminishing effect on behavior. The overall reinforcement rate was higher for the data presented in the bottom panel: The effect of individual reinforcers is more important in that condition than in the other. From Davison M and Baum WM (2000) Choice in a variable environment: Every reinforcer counts. *J. Exp. Anal. Behav.* 74: 1–24, with permission from the Society for the Quantitative Analysis of Behavior, Inc.

The best-documented global influence on the local control by reinforcement is the effect of overall environmental variability: When animals are submitted to the same experimental condition for many sessions, their behavior tends to change slowly when this condition is changed, whereas, on the other hand, when the environment is highly unstable, with experimental conditions changing often and unpredictably, they show more immediate behavioral change in response to a modification of the environment, with less carryover effect from past conditions (e.g., Davis et al., 1993; Mazur, 1997; Schofield and Davison, 1997; Gallistel et al., 2001; see Staddon and Frank, 1974, for similar effects in multiple schedules). Other variables that have an influence on the local effect of reinforcement are the range of variation in the reinforcement-rate ratio (Landon and Davison, 2001; the more distinct the two schedules, the more local the control of behavior) and in the location of reinforcement (Krageloh et al., 2005). If reinforcement is alternating between the two schedules, behavioral control is more local than if several reinforcers are collected in a row on the same schedule.

1.06.5 Reinforcement Theory

Through operant learning, animals are able to learn about the consequences of their behavior. If these consequences have reinforcing value, they will be able to modulate the emission of the behavior that caused them. But not every event is a reinforcer. What, then, makes a reinforcer reinforcing? The answer depends on whether we are considering primary reinforcers (whose effect on behavior seems to be largely innate) or conditioned reinforcers (whose effect on behavior is due to the fact that they signal the delivery of a primary reinforcer; *See also* Chapter 1.03).

1.06.5.1 Primary Reinforcement

An accurate summary of our current knowledge of why primary reinforcers are reinforcing is still Skinner's (1953) definition of a reinforcer, which all in all boils down to "a reinforcer is something that reinforces behavior." In other words, we recognize a primary reinforcer through its effect on behavior, but we are hardly able to explain why it has such an effect. This is fine if your main interest is how a reinforcer modulates behavior, which indeed is the main topic of operant research, but is more problematic if you want to know why a reinforcer modulates behavior, a legitimate question, especially in an applied setting. The elaborate theories of primary reinforcement developed during the heyday of general learning theory in the 1950s (such as Hull's 1943 drive-reduction theory) have not stood the test of time but have not been replaced. Little more than commonsense generalities can be said about primary reinforcers. Primary reinforcers affect behavior presumably because they contribute to the Darwinian

fitness of the organism (Skinner, 1966), but this is little help in identifying them. The fact that food, water, and sex are powerful primary reinforcers seems to indicate that they are linked to basic biological needs. But this is not very helpful either, as this kind of explanation becomes quickly circular. Wheel running is reinforcing in rats (i.e., Belke and Heyman, 1994; Belke, 1997) just like the opportunity to observe complex stimuli is in monkeys (Butler and Harlow, 1954; Butler and Alexander, 1955). Do we have to postulate a wheel-running drive in rats and an observation drive in monkeys? Does this add anything to our understanding of the reinforcing effect of wheel running or observation?

The most creative attempt to address the problem of primary reinforcement derives from Premack's (1962, 1965) proposal that behavior with a high probability of emission can be used as a reinforcer for behavior with a lower probability. Hence, feeding, a behavior with a high probability of emission in a hungry animal, can be used to reinforce lever pressing or key pecking, behaviors with a low probability of emission. Although the theory does not tell how the probability of emission of a behavior is set, it is an improvement over explanations of primary reinforcement in terms of biological needs because probabilities can be measured prior to conditioning.

In one experiment, Premack (1965) measured the preference of children for playing pinball versus eating candy. He then showed that making eating candy contingent on playing pinball reinforced this activity only in children preferring candy over playing pinball, whereas it had a punishing effect for the other children, and vice versa. In another study (Premack, 1962), rats had a restricted access to wheel running but unlimited access to water in one condition, whereas the reverse was true in another condition. Access to wheel running was an effective reinforcer for water drinking in the first condition, whereas water drinking was an effective reinforcer for wheel running in the second condition. As a last example, Chalop et al. (1990) found that echolalia and perseverative behavior, activities with a high probability of responding in autistic children, were very efficient reinforcers for these subjects, whereas food reinforcement had no effect.

Premack's view has been developed into behavioral-regulation models of operant performance (Timberlake and Allison, 1974; Rachlin, 1974; Allison, 1993; Staddon, 1979, 2001, 2003/1983). In these views, the animal has a preferred allocation of behavior, which works as a behavioral bliss point. By making access to one behavior contingent on the omission of another, the animal is forced away from the bliss point. Behavior then adjusts to restore the system as close to the bliss point as possible. For instance, a hungry rat would prefer to spend most of its time eating and only a small portion of its time pressing a lever. By creating a contingency between pressing a lever and food delivery, an operant procedure does not allow the rat to settle on this preferred distribution of activity and forces it to increase its rate of lever-pressing to increase its rate of eating so that it is closer to the preferred allocation of behavior than it would be if it did not press the lever.

In contrast to Premack's theory, behavioral regulation makes the counterintuitive prediction that in some circumstances, a behavior with a low probability of responding may reinforce a behavior with a high probability of responding (e.g., Eisenberg et al., 1967; Mazur, 1975). Staddon (1979, 2003/1983) showed how basic data for simple schedules could be accounted by the bliss-point model. It can also be shown that this approach leads to a view of operant behavior equivalent to the classical microeconomic theory of consumer demand (i.e., Staddon, 2001, 2004/1983) and has favored the development of an economic approach to operant performance (Hursh, 1984).

Behavioral regulation is an original and elegant approach to the problem of primary reinforcement. It is radical in the sense that it denies what is implicit in most treatments of operant behavior – that there are special events (i.e. reinforcers and punishers) that have the power to modify behavior. This is actually a problem because it is hard to see how to integrate a behavioral regulation account of operant performance with the causal analysis we presented in the previous part of this chapter. How can we, for instance, interpret the effect of the delay of reinforcement and of the predictive value of the response, data that make a lot of sense within a more traditional associative account of operant learning, within the framework of behavioral regulation? The Irish mathematician Hamilton showed that the laws of Newtonian physics, the very model of causation, could be expressed as an optimality model. It is possible that this is the case also for operant behavior. Even though behavioral regulation looks like a model of the causality of operant behavior, the real mechanism would be the more traditional strengthening and weakening of behavior by reinforcement and punishment postulated since Thorndike's original formulation of the law of effect, even though the effects of this mechanism can often

be predicted by an optimality model such as behavioral regulation. In this case, we should expect behavioral regulation to fail when animals are exposed to very unusual reinforcement schedules, which is exactly what was observed in a study by Ettinger et al. (1987), for instance.

1.06.5.2 Conditioned Reinforcement

In contrast to primary reinforcers, the question of why conditioned reinforcers affect behavior is less problematic: It is because they signal primary reinforcement. Learning with delayed reinforcement is much aided if a conditioned reinforcer is used to bridge the delay, as in the experiment by Williams (1999) discussed earlier. The question, then, is how do parameters of primary reinforcement determine the effectiveness of a conditioned reinforcer? The procedure usually used to address this question is the concurrent-chain schedule we described previously (**Figure 2**). The basic assumption is that response allocation during the initial link follows the matching law (i.e., the response-rate ratio during the initial link matches the conditioned reinforcement rate ratio). Hence, the response-rate ratio during the initial link is supposed to be a measure of the preference of the animal for one terminal link over the other.

When terminal links are both variable schedules (VI or VR), the response-rate ratio during the initial link sometimes matches the rate of primary reinforcement during the terminal links (Herrnstein, 1964b), suggesting that the value of a conditioned reinforcer could simply be equal to the rate of primary reinforcement in its presence. But, when given the choice between a variable schedule (VI or VR) or a fixed schedule (FI or FR), animals are strongly biased toward the variable alternative, even when they arrange identical reinforcement rates (Herrnstein, 1964a; Killeen, 1968; Davison, 1969, 1972; Mazur, 1986). They are indifferent between the two only when the reinforcement rate is computed using the harmonic mean of the various intervals used in the schedule instead of the arithmetic mean, as it is usually done. This is consistent with data collected in behavioral ecology showing preference for variable delay to food over fixed delay to food and relative indifference between variable and fixed amount of food (Staddon and Innis, 1966; Bateson and Kacelnik, 1995; Kacelnik and Bateson, 1996). This preference for VI over FI could be explained by assuming that the value of a conditioned reinforcer is an amount-dependent hyperbolic function of the delay to primary reinforcement it signals (Mazur, 2001).

This would also account for data from self-control procedures where animals are given the choice between a small immediate reward and a larger delayed one. The classical result (Ainslie, 1974; Green et al., 1981; Laibson, 1997; Green and Estle, 2003 for data in rats, pigeons, and humans) is that, for short delays, the animal will pick the smaller reward (impulsive behavior) while, for long delays, it will pick the larger reward (self-controlled behavior). This choice pattern emerges automatically if we assume that choice between delayed reinforcers is based on their value and if these values are an amount-dependent hyperbolic function of the delay of reinforcement. As **Figure 11** shows, for long delays, the discounted value of the larger reward is higher than the value of the smaller reward, hence the animal displays self-control; on the other hand, for short delay of reinforcement, the value of the smaller reward is larger than the value of a larger reward, and the animal is impulsive (Rachlin, 1974; Ainslie, 1975; Herrnstein, 1981).

The best evidences for hyperbolic discounting come from studies using an adjusting procedure. The initial link is an FR 1 instead of an RI, so that the first response moves the animal to the terminal link. The delay and amount of reinforcement are held constant at one terminal link. If the subject chooses this link, either the delay (in the adjusting-delay procedure) or the amount (in the adjusting-amount procedure) of reinforcement available at the

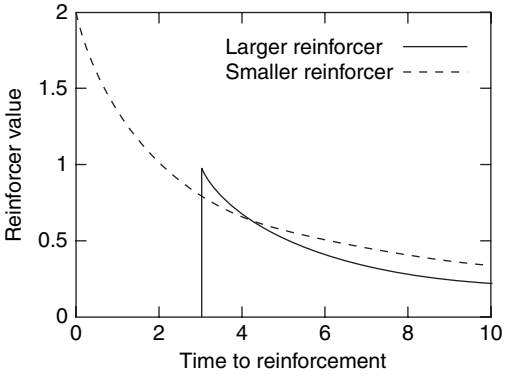

Figure 11 If a reinforcer value is an amount-dependent hyperbolic function of the time to reinforcement, the animal's preference for a large delayed reward over a smaller more immediate one will decrease and will eventually reverse as the time of the smaller reward delivery approaches.

other initial link is reduced (in the case of the delay) or increased (in the case of the amount). The reverse takes place if the subject chooses this terminal link. The goal is to determine a point of subjective equality where the animal is indifferent between the two terminal links. At this point, the values of the two conditioned reinforcers are supposed to be equal. If delay is manipulated, hyperbolic discounting predicts that, at indifference, the delay on the adjusting side will be a linear function of the delay on the constant side. The same way, if the amount is manipulated, hyperbolic discounting predicts that the amount on the adjusting side will be a hyperbolic function of the amount on the constant side. Both predictions have been confirmed empirically (Mazur, 1987, 2000; Rodriguez and Logue, 1988; Richards et al., 1997; Green et al., 2004).

All this research relies on the assumption that choice during the initial link is a function only of the values of the terminal links. But it is not; the longer the initial links, the less extreme the preference for the terminal links, reaching almost indifference with extremely long initial links (Fantino, 1969; Squire and Fantino, 1971; Fantino and Davison, 1983). This indicates that either choice is influenced by variables besides the values of the terminal links and/or that the value of a terminal link is context-dependent. Both kinds of influences have been incorporated in modern theories of conditioned reinforcement (i.e., delay reduction theory, Fantino, 1969; Squire and Fantino, 1971; hyperbolic value-added model, Mazur, 2001; contextual model of choice, Grace, 1994, 1996). All those models are equivalent in terms of their ability to fit the data.

Another interpretation of the surprising fact that a conditioned reinforcer value seems to depend on the context is to question the very notion of conditioned reinforcement and the usual assumption made about the control of behavior in concurrent chain schedules. This is exactly what Staddon and collaborators (Staddon and Ettinger, 1989; Staddon and Cerutti, 2003; Cerutti and Staddon, 2004a,b; Staddon, 2003/1983) have done by proposing that interval timing underlies most effects attributed to conditioned reinforcement. Their analysis is based on some results in simple chain schedules that are puzzling for a conditioned-reinforcement account. For example, no more than six FI or FR links can be linked together in a chained schedule without extreme pausing developing in the early links – leading to a dramatic drop in the obtained reinforcement rate (Kelleher and Gollub, 1962). Weak responding during the early links is sometimes observed with as few as three schedules chained together (Catania et al., 1980; Davison, 1974), and extreme pausing can develop even in a three-link chain schedule if the time from trial onset to primary reinforcement is long enough (Kelleher and Fry, 1962). On the other hand, if the change from one link to the other is not signaled by a stimulus change (tandem schedule) or if the stimuli used to signal such transitions change randomly after each trial (scrambled chain schedule), the animals have no difficulty mastering these tasks and achieve close to the maximum possible reinforcement rate (Kelleher and Gollub, 1962).

These results are surprising because stimulus changes in a chain schedule are supposed to act as conditioned reinforcers, so should aid performance, not disrupt it. Another surprising result is that it does not make any difference if the stimulus change from one link to the other is response-dependent or not (Catania et al., 1980), whereas we saw previously that an actual response-reinforcer contingency (as opposed to mere contiguity between the emission of the response and reinforcement) is critical to operant learning.

Based on these data, Staddon and collaborators proposed that stimuli in chain schedules work not as conditioned reinforcers but as time-markers. Hence, they lead the animal to pause an amount of time proportional to the time between the onset of the stimulus and primary reinforcement. This accounts for the excessive pausing observed in chain schedules (Staddon and Ettinger, 1989; Staddon and Cerutti, 2003). Supporting this view, Staddon and Cerutti (2003) showed that pause duration in the first link of a two-chain schedule was a linear function of time to primary reinforcement in data from Davison (1974). Innis et al. (1993) studied two-link chain schedules with one link of fixed duration and the other varying from reinforcer to reinforcer according to an ascending then descending sequence. Pauses in each link tracked their respective time to primary reinforcement with a lag of one interval.

Applied to concurrent chain schedules, this view considers preference for terminal links during the initial link to be an artifact of interval timing. Consider, for instance, a concurrent chain schedule with FI 15-s and FI 30-s terminal links (**Figure 12**). The animal will pause longer on the initial link leading to the FI 30 s because the time-to-reinforcement is longer on that side. Hence, the animal will respond more on the initial link leading to the FI 15 s,

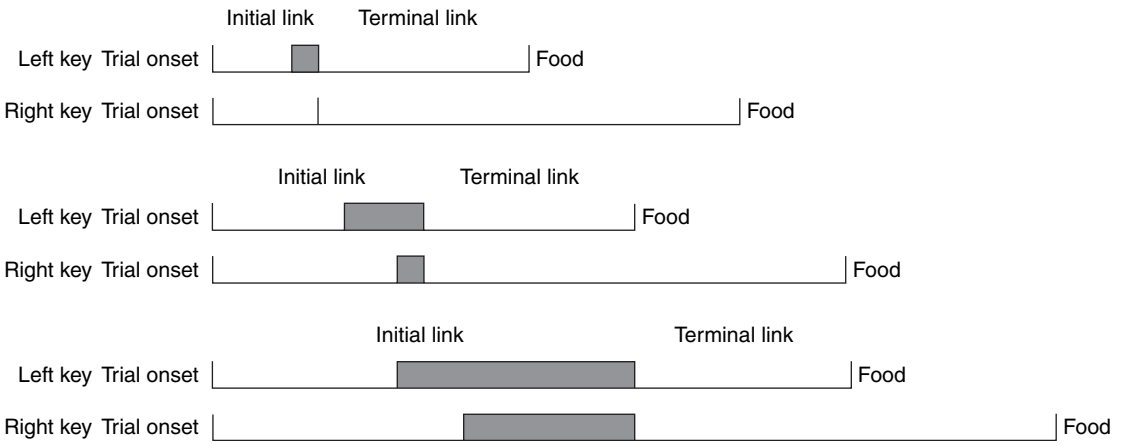

Figure 12 Interval timing account of concurrent chain performance. The animal pauses on an initial link for an amount of time proportional to the time between the onset and the initial link and primary reinforcement. As a consequence, it looks as if it prefers the initial link leading to the terminal link with the higher reinforcement rate. As the initial link duration is increased, the difference in pausing makes less and less of a contribution to the reinforcement rate ratio, and preference converges on indifference.

which will look like a preference for the FI 15-s initial link. Note that as the initial link duration is increased (while the terminal-link duration remains the same), pausing takes up a smaller fraction of the total first-link time so that the time available for responding becomes more equal on the two sides (**Figure 12**), eventually reaching indifference – as the data show. This analysis also explains the preference for variable over fixed terminal-link schedules because variable time-to-reinforcement leads to shorter pausing than fixed. Finally, Staddon and Ettinger (1989) and Staddon and Cerutti (2003) showed how this timing view of concurrent performance can account for hyperbolic discounting and data on self-control (the equations derived from the timing view turn out to be identical to those derivable from hyperbolic discounting).

More research will be needed to conclude if the timing approach of Staddon and collaborators is a better account of concurrent-chain performance than more traditional explanations in terms of conditioned reinforcement, but strong support for it can be found in a study by McDevitt and Williams (2001). They used terminal links associated with a 5-s and a 15-s delay-to-reinforcement. In one condition, each initial link was correlated with a different stimulus (as in standard concurrent-chain schedules), whereas the same stimulus was associated with both of them in another condition. A conditioned reinforcement approach would lead one to expect no differential responding during the initial link in the single-stimulus terminal-link condition because the consequences of responding are identical for both choices. But McDevitt and Williams (2003) actually found the same strong preference for the 5-s terminal link in both conditions, concluding that time-to-reinforcement, not conditioned reinforcement, was the main controlling variable.

1.06.6 Conclusion

Operant behavior involves adaptation to the consequences of responding; it is the prototype of adaptive behavior during the life of the individual – the ontogenetic equivalent of Darwinian natural selection in phylogeny. Techniques for exploring operant behavior exploded with the invention of the Skinner box and the discovery of the orderly and powerful effects of schedules of reinforcement. In the 1950s and 1960s, much research addressed the limits of operant conditioning and in particular the intimate relationship between the processes underlying operant and classical conditioning. In recent decades, two research areas, interval timing and choice, have dominated the field. We have reviewed these topics and, in addition, discussed post-Skinner developments in the economics of operant behavior. We hope, with this chapter, to have aroused the interest of the reader for this fascinating and lively field of behavioral science.

1.07 Perceptual Learning

G. Hall, University of York, York, UK

1.07.1 Introduction

It is not the aim of this chapter to provide a review of all the work that has been published in recent years under the heading of perceptual learning. The aim is more specific and is guided in part by theoretical considerations; it is to set perceptual learning in the context of what we know about learning more generally – to assess the extent to which the phenomena of perceptual learning can be explained in terms of known learning processes, to identify aspects of perceptual learning that cannot be explained in this way, and to attempt to outline the nature of any new learning process that may be required.

Nonetheless, the first major section of the chapter will offer a selective review of what may be considered to be the most important recent (and some not-so-recent) experimental findings. This is necessary not only to provide the grist for the explanatory mill of later sections, but also to allow us to define the field. As we shall see, the range of phenomena that have been studied under the heading of perceptual learning is exceedingly broad. However, it is possible to discern a set of important issues that is common to most of them and that constitute the core features of perceptual learning. The attempt to explain – to understand the psychological mechanisms responsible for – these core features is dealt with in the next two major sections of the chapter. The first of these deals with the application of the principles of associative learning theory to perceptual learning effects; the second is concerned with the role of nonassociative (principally attentional) learning processes.

1.07.2 Phenomena

All the studies to be described in this section have been regarded, by their authors or by later commentators, as involving perceptual learning. The variety is impressive. All major sensory systems have been subject to study; vision perhaps predominates, but there are also many studies of hearing, touch, olfaction, and taste. The stimuli used have varied, from the apparently simple (e.g., a touch with a pointer), to the undeniably complex (e.g., pictures of human faces). The stimuli used have often been difficult to discriminate from one another – for simple stimuli because they are chosen to lie close together on the dimension of difference; for complex stimuli, largely because of the presence of a host of irrelevant, nondistinguishing features in each of the displays. But perceptual learning has also been investigated in

experiments using stimuli that, on the face of things, seem readily discriminable one from another – one of the earliest and most influential studies in nonhuman animals (Gibson and Walk, 1959) looked at the effects of training with two simple geometrical shapes, a triangle and a circle. This example serves to make the further point that relevant phenomena have been studied in a range of species – our own species is best fitted for psychophysics, but experiments on laboratory animals have some advantages when it comes to investigating basic mechanisms of learning. Finally, although all the work to be considered concerns the effect of experience with stimuli on the subject's subsequent response to them, the exact form of the experience given has been varied – notably some experimenters have been concerned with the effects produced by mere exposure to stimuli, whereas others have given explicit training with feedback (also called knowledge of results, or reinforcement).

In an attempt to impose some order on this apparent chaos, the sample of experimental work reviewed next is organized under a set of convenient headings. It will be evident, however, that these do not form exclusive categories and that many of the experiments described could legitimately be placed under more than one of the headings (*See* Chapters 1.08, 1.13).

1.07.2.1 Simple Sensory Thresholds

The study of perceptual learning appeared early in the history of experimental psychology. No sooner had psychophysics been established as a coherent enterprise than its proponents began to study the effects of experience on the sensory threshold measures that were one of its primary concerns. In 1859 A. W. Volkmann (Fechner's brother-in-law; Woodworth and Schlosberg, 1954) published a study of the effects of practice on the two-point tactile threshold (Volkmann, 1859). He found that with practice, the ability of a subject to make the discrimination – two points or one – was dramatically increased; that after a hundred or so trials, the minimum distance required for a judgment of two points was reduced by about half. The effect was limited to the general area of skin on which the stimuli had been applied, except that positive transfer was observed when the test was carried out on the equivalent region of the other hand or arm.

We can say straightaway, on the basis of these results, that the conventional title for studies of this sort is potentially misleading. Although the stimulus may be simple, the mechanism responsible for the change in threshold is not. The fact that training failed to transfer to an adjacent patch of skin on the same arm indicates that the improvement is not a consequence of some general learning process (such as might result simply from familiarization with the procedure). But the fact that it did transfer to the other limb indicates that it is not a consequence of some change in the particular receptors that were stimulated in training – a more central mechanism must be involved.

Modern studies of difference thresholds have confirmed, for a range of stimuli, the essence of Volkmann's (1858) findings. Practice at the task (usually some version of a two-alternative forced-choice task in which the subject is presented briefly with two events, one after the other, and has to say whether they are the same or different) will produce a reduction in the magnitude of the difference that can be reliably detected. This is true for auditory frequency (e.g., Demany, 1985), for the orientation of visually presented lines (Shiu and Pashler, 1992), for hyperacuity (the ability to judge whether or not two line segments are colinear, e.g., McKee and Westheimer, 1978), for complex sinusoidal gratings (Fiorentini and Berardi, 1980), for the direction of motion of an array of moving dots (Ball and Sekuler, 1982; Liu and Weinshull, 2000), for the discrimination of visual texture (Karni and Sagi, 1991), and for many other tasks (see Fahle and Poggio, 2002). In most of these studies, the subjects were given feedback during training, but its role in producing the effect is unclear. Shiu and Pashler (1992) included subjects given no feedback, and these showed no within-session improvement, but this procedure was still capable of producing learning, as the subjects showed an improvement from one training session to the next.

As for Volkmann, the extent to which the effects of training transfer to other stimuli has been a focus of interest for modern experimenters. The intention has been to identify the stage in the perceptual system at which the training has had its effects – for instance, training that produces effects specific to the area of the visual field to which the stimuli were presented points to processes occurring at an early stage in the visual system, where retinotopic organization is still maintained. And, as was true for Volkmann's study, the pattern of transfer has turned out to be far from simple. For most of the visual tasks described, a degree of retinal specificity has been obtained, with performance falling to the starting

level when the stimuli were presented in a different retinal location. But this does not mean that no transfer occurred – both Liu and Weinshull (2000) and Shiu and Pashler (1992) found that the new task was learned more rapidly than the original. And Ahissar and Hochstein (1997), using a version of the texture discrimination task of Karni and Sagi (1991), found transfer to a new retinal location when the initial training had been given on an easy version of the task (Liu and Weinshull, 2000, obtained a similar result for direction of motion). In other cases, the effect of training has proved specific to the particular stimuli used, but not to the receptors stimulated. Demany and Semal (2002) found that the effects of auditory training transferred readily to the other ear but not to a new discrimination involving a different frequency range (see also Amitay et al., 2005). And to return to the topic of tactile discrimination with which we began, Sathian and Zangaladze (1997) have demonstrated that the effects of training on a discrimination of the roughness of a pattern of ridges will transfer to a finger other than that used in training, but not to a new task in which the orientation of the pattern must be judged. The only conclusion justified by these observations at this stage is that although practice can facilitate performance on these simple discriminations, it would be foolish to conclude that these examples of a perceptual learning effect are to be explained solely in terms of processes occurring very early in the sensory/perceptual processing system.

1.07.2.2 More Complex Stimuli

In a study directly inspired by those described in the previous section, Furmanski and Engel (2000) looked for a perceptual learning effect with more complex visual stimuli. These were degraded pictures of everyday objects (e.g., a telephone, a pencil sharpener; see **Figure 1**) presented very briefly. The subjects had to name the object and were told if they were right or wrong. Initially performance was poor, but training (800 trials a day over several days) produced a sizable reduction in threshold (in the exposure duration necessary for correct identification). This effect was specific to the pictures presented in training, but not to retinal location – transfer was good when the size of the image was changed. Enhanced discrimination when the stimulus set is familiar appears to be a quite general phenomenon. An example for a very different procedure (and species) is provided by Todd and Mackintosh (1990). Their subjects, pigeons, were presented with 20 pictorial slides in a training session, each being presented twice, in random order. They were rewarded for pecking at the first but not at the second presentation. The pigeons learned this discrimination, but did so less well when a new set of pictures was used each session than when the same set was used throughout. This result – better performance on a judgment of relative recency than of absolute novelty – may seem surprising, but it makes sense if we accept that prolonged experience with a given set of pictures will enhance the subject's ability to discriminate among them.

Figure 1 Two of the pictures of objects used by Furmanski and Engel (2000). To render discrimination difficult, the contrast was reduced to 12.5%, and each presentation was followed by the mask shown at the bottom of the figure. Used with permission.

Intriguing as the examples just cited may be, popular interest in the phenomenon of perceptual learning is most readily evoked by description of the special skills shown by experts in dealing with even more complex stimuli – the experienced radiographer who can detect a tumor on an x-ray where the rest of us see only a meaningless blur (Myles-Worsley et al., 1988) or the chicken sexer who can make a determination after inspecting the pinhead-sized genital eminence of the day-old chick for less than 0.5 s (Biederman and Shiffrar, 1987). These are abilities acquired through experience. Knowledge of results may play a role in this (if only because the chicken sexer will soon hear about it if a large proportion of the hens turn out to be cocks), and often there will be explicit training in which an established expert instructs the novice in what to look for (see Biederman and Shiffrar, 1987). And however exotic these specialized skills may seem, there are certain areas in which, even in the absence of explicit

instruction, almost all of us have acquired the status of experts – we are all of us experts in dealing with the visual cues responsible for face recognition and the auditory cues underlying our native language.

Despite occasional embarrassing mistakes, our ability to discriminate among people, largely on the basis of their facial characteristics, is impressive. That this ability depends on experience is indicated by the fact that children are less good at it than adults (see Chung and Thomson, 1995). Further evidence comes from the so-called own-race effect – superior discrimination when the faces belong to individuals from our own racial group (Malpass and Kravitz, 1969). This effect depends on the fact that we have (usually) had much more experience of such faces – the magnitude of the effect is much reduced in people who have had extensive interaction with races other than their own (Chiroro and Valentine, 1995). What might be thought as a parallel, own-language effect describes our ability to discriminate the speech sounds of our native language. Native English speakers readily distinguish (on the basis of differences in the third formant) between the phonemes /r/ and /l/, a task that native speakers of Japanese find exceedingly difficult (e.g., Goto, 1971). Japanese speakers, on the other hand, can make distinctions (according to changes in the second formant) within the category of sounds that English speakers regard as all being examples of /r/ (Iverson et al., 2003). Explicit training, in which Japanese subjects were given feedback after being required to distinguish between word pairs such as *lock* and *rock*, has been shown to enhance their discriminative ability (Iverson et al., 2005).

The examples discussed so far in this section have involved training in which feedback has been given; that is, the subjects have been told that their identification of a stimulus has been right or wrong. (This is explicitly arranged in most of the experimental studies, but something equivalent will occur in the natural environment as we learn the discriminations necessary for language or for the recognition of faces.) But perceptual learning effects can be obtained without such feedback, as a result of mere exposure to the stimuli (when this is arranged appropriately). Lavis and Mitchell (2006) required people to discriminate between pairs of checkerboards of the sort shown in **Figure 2**. When they are first presented with the one checkerboard followed, after a short interval, by another, people are poor at answering the question: Same or different? But performance was much enhanced by mere preexposure to the displays when this was organized such that the different stimuli were presented in alternation. Interestingly, preexposure, consisting of a block of trials with one stimulus followed by a block of trials with the other, was much less effective in enhancing subsequent discrimination. This outcome (to be discussed in detail later) is of interest as it accords with the influential analysis of perceptual learning offered by Gibson (1969), who emphasized the role of stimulus comparison in producing the effect (we may assume alternating preexposure is likely to foster the processes involved in comparison).

1.07.2.3 Categorization

The auditory discrimination described earlier is one that involves categorization; that is, faced with a range of different stimuli, the native English speaker learns to put instances of one set (which will differ

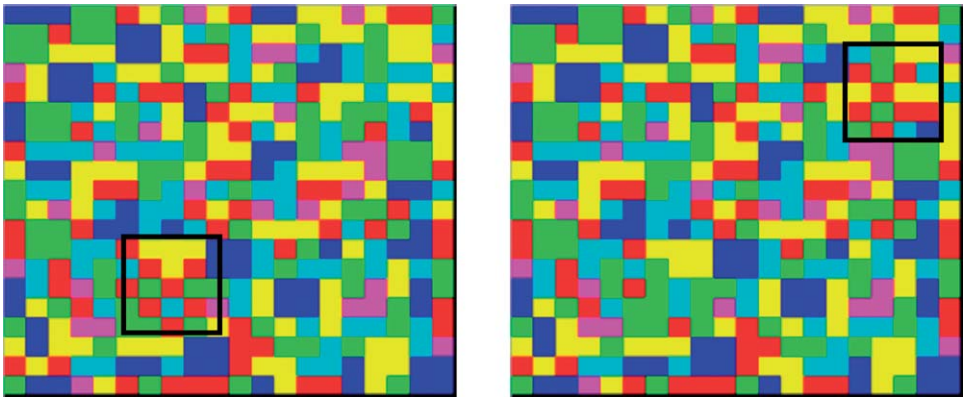

Figure 2 Examples of the colored checkerboard stimuli used by Lavis and Mitchell (2006). The unique elements are indicated (for the purposes of illustration only) by the black squares. Images courtesy of Y. Lavis.

among themselves in some respects) in one category (meriting /r/) and instances of another set in a different category (meriting /l/). The same is true of some of the visual tasks – one male chick will differ from another, but the experienced chicken sexer puts them all in the same category. An experimental demonstration of how such an ability can be acquired through experience comes from a study of face recognition by Quinn et al. (1999). In this experiment, the faces were pictures not of people, but of cats, and the participant's task was to sort them into two categories, male and female. The discrimination was difficult – initial performance was at chance level – but reinforced training with a subset of the pictures, those most easily identified as male or female, produced positive transfer to the ability to categorize other pictures.

Successful performance on a categorization task such as that used by Quinn et al. (1999) may seem to involve a reversal of the sort of perceptual learning effect that we have been concerned with so far – although discrimination between male and female is enhanced, the subjects appear to be less sensitive to differences among individuals that fall into a given category. But whether this is really the case requires explicit investigation. It is quite possible that the within-category discrimination was also enhanced – that, had they been asked, the trained subjects would have been better able to distinguish between Lucky and Widget, while still categorizing both as male. This is certainly true of human faces – we have no trouble in telling Ann from Zoe, and Andrew from Zach, while still distinguishing male from female.

The issue has been investigated experimentally, using complex artificial stimuli, by McLaren et al. (1994); see also McLaren, 1997). The stimuli used were based on the checkerboards shown in **Figure 3**.

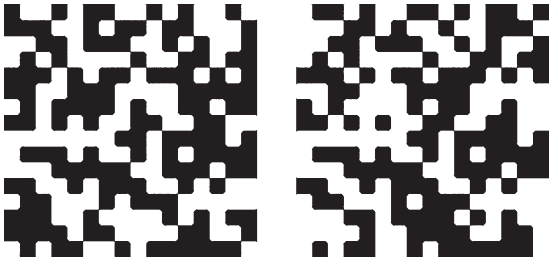

Figure 3 Checkerboard stimuli used by McLaren et al. (1994). Those shown were the prototypes. Discrimination was between exemplars, produced by changing a proportion of the elements of each prototype from black to white, or vice versa. Image courtesy of I. McLaren.

Changing a proportion of the elements from black to white, or vice versa, produced two sets of exemplars of these prototypes. Training consisted of a categorization task in which subjects learned to assign exemplars to type 1 or to type 2. In the test, two stimuli were presented side by side, and the subjects were reinforced for reliably choosing one rather than the other. They proved to be very good at this discrimination when the two stimuli were the original prototypes and also when the test stimuli were novel exemplars of these prototypes not used in the original training. But although the effect of preexposure was less profound in this case, the participants were also at an advantage when required to discriminate between two exemplars drawn from the same category. These effects are not confined to our own species. Aitken et al. (1996), using similar stimuli, generated essentially the same pattern of result in an experiment that used pigeons as the subjects.

1.07.2.4 Taste and Smell

Unusually among psychologists, students of perceptual learning have paid almost as much attention to the chemical senses as to vision and hearing. Perhaps this derives in part from the fact that some of the most dramatic examples of acquired perceptual skills are found in these modalities. Foremost among these are the well-documented achievements of expert wine tasters (e.g., Soloman, 1990), but who can forget William James's description of "the blind-deaf mute . . . Julia Brace [who] is said to have been employed in the Hartford Asylum to sort the linen of its multitudinous inmates, after it came from the wash, by her wonderfully educated sense of smell" (James, 1890, pp. 509–510).

These are obviously very special cases, but evidence that an approach to skills of this sort can be established in any of us comes from experimental studies. Thus, Peron and Allen (1988) found that novice beer drinkers, who were initially unable to tell one brand from another, became able to do so after training in which they simply sampled a range of beers and reflected on the flavor qualities that came to mind. (Training with the specialist vocabulary of master brewers conveyed no special advantage; see also Melcher and Schooler, 1996.) Rabin (1988), who asked subjects to make same/different judgments after sniffing two unusual odors, found that discrimination was enhanced when the subjects had been given prior exposure to the odors (and in this case, training in which a distinctive

label was attached to each odor during preexposure was found to help). Preexposure is not always beneficial, however. Stevenson (2001) gave training in which his subjects sniffed two odor mixtures (call them AX and BY). Subsequent discrimination between components of separate pairs (e.g., A vs. B) was good, but discrimination between components of a compound (e.g., A vs. X) was poor.

Studies of perceptual learning using animal subjects have made extensive use of tastes – adding a flavor to the drinking water of a thirsty rat ensures that the animal receives full exposure to the relevant stimulus, and the flavor-aversion conditioning technique provides an effective way of assessing discrimination. **Figure 4** shows the results of one study (by Symonds and Hall, 1995, Experiment 1) that made use of this procedure. All the rats received a test phase consisting of aversion conditioning with flavor A, followed by a test with flavor B (A and B were solutions of salt and sugar, rendered more similar by the addition of the sour taste of acid to each). In rats given no previous experience of the flavors (group W in the figure), the aversion conditioned to A generalized readily to B; that is, they failed to discriminate between A and B. The same was true of rats given prior exposure either to A or to B. But rats given prior exposure consisting of alternating presentations of A and B (group A/B in the figure) showed poor generalization (i.e., an enhanced ability to discriminate). As in the experiments by Lavis and Mitchell (2006), described earlier, this alternating

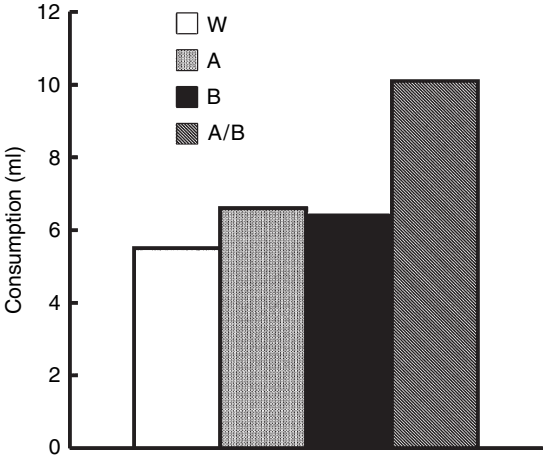

Figure 4 Group mean scores for consumption of flavor B, after aversion conditioning with flavor in the experiment by Symonds and Hall (1995). Before conditioning, different groups had received exposure to A, to B, to both (A/B), or just to plain water (W).

arrangement turned out to be critical. A subsequent study (Symonds and Hall, 1995, Experiment 3) showed that preexposure consisting of a block of A trials followed by a block of B trials (or vice versa) did not produce the same enhancement. It is interesting to note that closely parallel effects have been obtained with human subjects given initial training in which they tasted the compound flavors saline-lemon and sucrose-lemon either on alternating trials or on separate blocks of trials. Subsequent same/different judgments were found to be more accurate in those given the alternating schedule during preexposure (Dwyer et al., 2004).

1.07.2.5 Acquired Distinctiveness

The experiments discussed so far have commonly used a procedure in which the subjects received explicit discrimination training, with feedback or knowledge of results being given. But (as the authors of several of these studies have noted), it can often be difficult to be sure of the source of the improved discriminative performance that is obtained in these conditions. Is there a change in the way in which the stimuli are being perceived, or is the learning occurring at a later stage in the sequence of processes that connect input to response? Transfer studies in which the stimuli are presented to a different set of receptors (e.g., at a different retinal location) constitute one way of addressing this issue. It is usually assumed that effects that fail to transfer cannot be a consequence of some general learning process, but must be specific to the stimuli used in training. An alternative strategy is to retain the original stimuli, but to require the subjects to learn some new discrimination on the basis of them. In this case, we are looking for positive transfer. Such transfer could not be based on knowledge of general task requirements (these having been changed) but must be a consequence of some learned change in the properties of the stimuli.

This experimental design was first introduced in the classic study of animal discrimination learning reported by Lawrence (1949). In outline, rats were trained initially on a food-rewarded choice discrimination between black and white. They were then shifted to a new task involving the same cues but with a different response requirement – when given two black cues, they were required to choose the left (for example), and when given two white cues to choose the right. The responses acquired in the first stage (e.g., to approach black and avoid white) will be irrelevant in this new task; nonetheless, Lawrence

found positive transfer from stage 1 to stage 2, transfer, he said, that must depend on something that has been learned about the stimuli. The effect has been called the acquired distinctiveness of cues, the implication being that the initial training in which black and white were associated with different responses and different outcomes had rendered those stimuli more distinguishable. The idea that training in which cues are associated with differing outcomes will enhance their subsequent discriminability goes back at least as far as James (1890).

Lawrence's (1949) study was followed by a rush of similar transfer-of-training experiments, some with animal subjects (reviewed by Sutherland and Mackintosh, 1971) and many with human participants. The latter, for the most part, concentrated on a procedure in which participants learned to apply verbal labels in the first stage of training followed by a discrimination involving overt motor responses to the same stimuli in the second stage. It was usually found (see Hall, 1991, for a review) that stage-1 training facilitated learning of the second task, although whether or not this effect was a consequence of changes in the distinctiveness of the cues is open to debate. In many of the classic experiments (e.g., Battig, 1956; Gagné and Baker, 1950; Holton and Goss, 1956), comparison was made with a control condition given no stage-1 training, raising the possibility that the advantage shown by the experimental condition simply reflected some general facilitatory effect produced by the first stage of training. What is needed is to compare the effects of initial discrimination training with those of some control stage-1 procedure that will be equally effective in producing general transfer effects but that does not involve the consistent stimulus-outcome associations characteristic of the experimental condition.

One strategy, illustrated in a study by Goldstone (1994), is to use compound stimuli. In Goldstone's experiment, the stimuli were squares, differing in size and brightness. One aspect of the stimuli (e.g., their size) was irrelevant to the discrimination (based, e.g., on brightness) trained in stage 1. Thus, when it came to the test phase (involving either a further brightness discrimination or one based on shape), all subjects were familiar with the stimuli and had received discriminative pretraining. It was found that the test task was performed more readily by those subjects for whom the same dimension (brightness, in this example) was relevant in both stages. Analogous effects, which have been interpreted as reflecting an acquired enhancement of the distinctiveness of an entire dimension of stimulus variation, have been obtained in studies of animal discrimination learning (see, e.g., Mackintosh and Little, 1969).

An alternative strategy (also based on a design successfully used with animal subjects; see Bonardi et al., 1993) is presented schematically in **Table 1**. (At this point, we are concerned only with the first two stages shown in the table; the implications of Stage 3 will be taken up later). In this example, which comes from an experiment by Hall et al. (2003), people received stage-1 training with four different stimuli, four different geometrical shapes (A–D in the table). Two, A and B, were followed by one outcome (presentation of a red rectangle); two (C and D) by another outcome (a green rectangle). No overt response was required at this stage. Stage 2 consisted of a discrimination learning task in which the subjects had to learn to make one motor response rather than another to each of the shapes. Performance was good when the subjects were required to make different responses to stimuli that had been associated with different outcomes in Stage 1 (the consistent condition of the table) but was relatively poor in the inconsistent condition, when they had to make the same responses to shapes previously associated with different outcomes. Positive transfer in the consistent condition is what would be expected if cues associated with different outcomes had acquired distinctiveness.

It should be noted that with this experimental design (as with most others in this area; see Hall,

Table 1 Experimental design used by Hall et al. (2003)

Stage 1	*Stage 2*	*Stage 3*
Group Consistent		
A → red	A → left	
B → red	B → left	red → left/right?
C → green	C → right	green → left/right?
D → green	D → right	
Group Inconsistent		
A → red	A → left	
B → red	B → right	red → left/right?
C → green	C → left	green → left/right?
D → green	D → right	

Note: A, B, C, and D represent visual stimuli presented on a computer monitor; red and green refer to colored rectangles. Left and right refer to keyboard response required (left = backslash; right = forward slash). Feedback was given after responses in Stage 2. All subjects in a given group received all types of trial listed under a given stage of training. Source of data: Hall G, Mitchell C, Graham S, and Lavis Y (2003) Acquired equivalence and distinctiveness in human discrimination learning: Evidence for associative mediation. *J. Exp. Psychol. Gen*. 132: 266–276.

1991), it is possible that the effect derives, in whole or in part, from negative transfer in the inconsistent condition – that associating cues with the same outcome renders them less distinctive (an effect referred to as acquired equivalence; Miller and Dollard, 1941). But it should also be noted that acquired equivalence in itself constitutes an example of perceptual learning, one that is worth our attention. Our topic is how experience can change the way in which things are perceived. Although in almost all the examples given so far, the change has been for the better (that is, discriminability has been enhanced by experience) there is no reason why this should always be the case, and our analysis of the phenomenon would be incomplete if it failed to encompass acquired reductions in discriminability.

1.07.3 Theoretical Issues

In all the experiments described earlier, the test task requires the subject to discriminate between two similar stimuli. The situation is presented schematically in **Figure 5**. Each circle represents the set of features or elements that define or constitute a particular stimulus, A or B. Each stimulus will have a set of unique features that are not found in the other (and these are represented by the areas containing the elements labeled a and b). The fact that A and B are similar is represented by the overlap – the area marked containing the c elements designates a set of features that they hold in common. Successful discrimination is evident when the subject shows the ability to make one response to A (i.e., ac) and a different response to B (bc). It follows that the job of a theory of perceptual learning is that of explaining

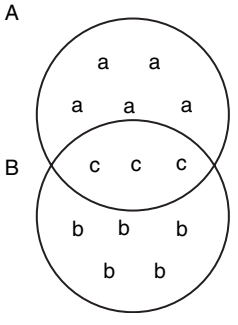

Figure 5 Each circle represents a stimulus (A or B) that is made up of a set of features (or elements). Some features are unique to a given stimulus (the a elements for A; the b elements for B); other features (c) are held in common and thus fall into the area of overlap of A and B.

how experience or training allows behavior to come to be controlled by the unique features (a and b), rather than by the common features (c). The behavior in question may be a gross overt movement, as when a rat approaches one stimulus object and avoids another; or it might be as minor as the verbal response of "higher" from a human participant presented with one of a pair of tones.

The scheme shown in **Figure 5** can be applied quite generally. It may need slight modification when the stimuli are drawn from a simple continuum, such as tonal frequency – here a given tone might be regarded as consisting of the elements a, b, c, d (say); its neighbor by the elements b, c, d, e; its neighbor by the elements c, d, e, f; and so on – but the principle remains the same; discrimination between adjacent (similar) tones requires control by the unique elements that distinguish between stimuli.

This characterization prompts an attempt at a definition of perceptual learning. It is the learning process (or processes) that increases the effectiveness of unique stimulus elements and/or reduces that of common stimulus elements, thus facilitating discrimination between similar stimuli. (Although this will serve for almost all the cases discussed in the previous section, we should note the possibility of instances in which training reduces discriminability. For these we must assume that the effectiveness of common elements is increased, that of the unique elements is reduced, or both; *See* Chapter 1.08 for configural processing).

This definition may allow us to rule out, as instances of true perceptual learning, some of the processes that result in improved performance during practice on a discrimination task. It is often found, for instance, that performance on even the simplest difference threshold task can show a dramatic improvement on the early trials, and this improvement could well be a consequence of the participant learning to deal with the requirements of the procedure. If, for example, the subject is initially a little unclear as to which button to press for the high tone and which for the low tone, practice will establish the relevant associations and remove one obstacle to accurate performance – but this improvement would not be a consequence of a change in the effectiveness of the unique or common features of the stimuli and thus would not count as perceptual learning.

This is not to say, however, that we would want to dismiss what some (e.g., Liu and Weinshull, 2000) have called 'cognitive' learning, as a possible

mechanism of perceptual learning. For example, McLaren and Mackintosh (2000) suggest that we should exclude from consideration cases in which participants, instructed to look for differences between stimuli, learn to focus on aspects that enable them to solve the task required of them. But surely a strategy as simple as learning to attend to or fixate on a particular part of a visual display deserves to be regarded as a mechanism of perceptual learning if it serves to increase the effectiveness of unique features (which happen to be located at a particular point in space). Again, Bruce and Burton (2002), discussing the discrimination of faces, question the extent to which enhanced discrimination depends on the acquisition of verbal labels for the different faces as opposed to reflecting (true) perceptual learning. But the distinction may not be a useful one. It has long been thought (e.g., James, 1890) that the acquisition of associates, such as verbal labels, might be a way of increasing the range and number of distinctive features activated by the presentation of a given stimulus; if this is so, the consequent improvement in discrimination becomes an example of perceptual learning under our definition.

The general point is that our proposed definition is silent as to the nature of the learning processes involved. The approach taken here contrasts with that sometimes taken by other students of perceptual learning. For example, Fahle and Poggio (2002) began their survey of the topic by ruling out, by means of their definition of perceptual learning, a number of possibilities that we would want to consider. Perceptual learning, they say, is independent from conscious experience and leads to implicit memory; it is not declarative, as it does not consist of consciously memorized facts or events; it is not associative, as it does not bind things together, and does not rely on the mechanisms of classical and operant conditioning; it differs from other forms of learning in that it principally involves functional and anatomical changes in primary sensory cortex. It may well be that some of the examples of enhanced discrimination that were described earlier in this chapter are a consequence of the type of learning envisaged by Fahle and Poggio (and we will try to identify them in subsequent sections of the chapter). But declining to subscribe to such a restrictive definition leaves us free to consider a range of other possible mechanisms, including several (such as various cognitive, associative, and attentional learning processes) that have been well studied in other contexts. We begin by considering the extent to which the associative analysis of learning can supply an explanation for perceptual learning phenomena.

1.07.4 The Role of Associative Processes

It may seem odd to give pride of place to a learning process that some have emphatically asserted is not responsible for perceptual learning effects; thus Gibson and Levin (1975, p. 23) wrote: "this simple and ancient notion does not work for perceptual learning, because what is learned [in perceptual learning] is not addition of something but rather extraction of something." There are, however, at least two good reasons for doing so. First, associative learning theory, in its modern form (see, e.g., Wagner, 1981; Mackintosh, 1983), provides by far the best worked out and most comprehensive account of basic learning mechanisms, and it seems a sensible first step to attempt to explain some (supposedly) new form of learning in terms of what we already know about learning more generally. Second, one of the earliest attempts to explain an instance of perceptual learning was, in fact, precisely in terms of the notion that it depended on the associative 'addition of something.'

1.07.4.1 Acquired Distinctiveness and Acquired Equivalence

Figure 6 (top part) presents a schematic version of the associative account offered by James (1890) for the acquired distinctiveness of cues. Recall that in this procedure, discrimination training, in which the cues are followed by different outcomes, enhances their subsequent discriminability. **Figure 6** shows the associations assumed to be formed when two similar cues (A and B) have been given training in which each has become linked to a different associate (X and Y); the associates are less similar (they share few common features) than are A and B. Discrimination between A and B prior to training will be difficult as they share many common elements. But the formation of the associative links means that presentation of A will produce associative activation of the representation of X, and presentation of B will associatively activate Y. As a result, discrimination between A and B will be enhanced because the proportion of common features present in the overall patterns of activation produced by these stimuli will

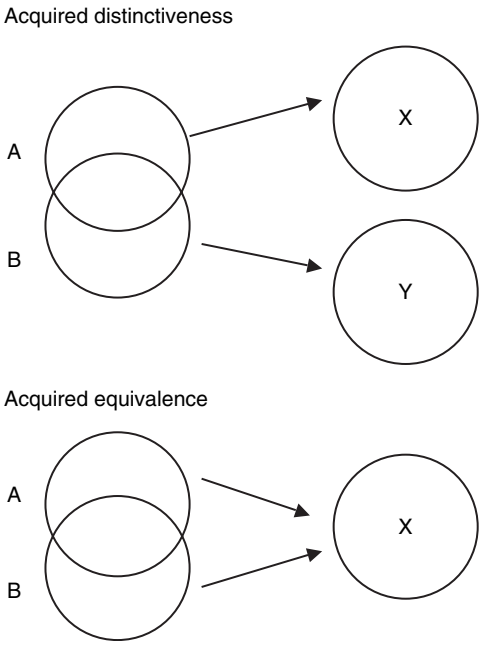

Figure 6 Associative structures in acquired distinctiveness and acquired equivalence. The overlapping circles represent two similar stimuli, A and B (see Figure 5); arrows represent associative links. In the acquired distinctiveness case, A and B have formed associations with quite different stimuli (X and Y). In the acquired equivalence case, both have become associated with the same stimulus.

be low, given the distinctiveness of their associates. The lower part of **Figure 6** shows the situation for the acquired equivalence procedure in which the two stimuli are given the same associate. Here the proportion of common elements is increased, and discriminability should go down. James focused on the case in which the associates were distinctive names, but the analysis applies (and the effect is found) when other events are used (as in experiments with animal subjects, or that presented in **Table 1**).

That stimuli can acquire new, and potentially distinctive, properties by associative means is nicely demonstrated by studies of odor perception. It has been noted that an odor such as vanilla is often described as smelling sweet, even though it is in itself tasteless. The suggestion that this quality is acquired as a result of associative learning (vanilla is often present in sweet foods) is supported by the results of a study by Stevenson et al. (1998), who gave subjects presentations of a novel odor (e.g., lychee) along with a sweet taste. Their subjects started to describe lychee as smelling sweet, a phenomenon that Stevenson et al. referred to as learned synesthesia. (Parallel effects have also been found with sour and bitter tastes.)

Whether associations of this sort are actually responsible for acquired distinctiveness effects is another matter. Gibson (1969), in her influential discussion of the topic, argued that although associations might indeed be formed during training designed to establish acquired distinctiveness, they did not provide the mechanism for the effect. Rather, the role of discrimination training was simply to ensure that the subjects concentrated on the stimuli, noting their similarities and differences, with the result that there was an increase in the perceptual effectiveness of (and attention paid to) their intrinsic distinctive features. This is what was meant by the phrase 'extraction of something,' rather than 'addition of something.' The evidence that is currently available to us does not allow a clear choice between the alternatives, but suggests, rather, that both processes may play a role.

Evidence that the associations formed during initial training can influence subsequent discrimination performance comes from the experiment by Hall et al. (2003), outlined in **Table 1**. Why, in Stage 2, did subjects in the inconsistent condition find it difficult to assign different responses to cues (such as A and B) that had shared a common associate (red) in Stage 1? According to the associative theory, this is because the representation of red was activated by both A and B during Stage 2. When subjects learned to respond left to A, this response would come under the control both of the cue actually presented (A) and its associate (red). Small wonder, then, that they found it difficult to respond right to B, given that its associate already controlled a tendency to make a different response. For subjects in the consistent condition, on the other hand, the response tendency acquired by red on a trial with A would allow the correct response to emerge immediately when B was presented. In a final test (Stage 3 of the table), subjects were asked to choose left or right when presented with the colors used as associates in Stage 1. Those in the consistent condition made appropriate choices (choosing left for red and right for green, in our example), as would be expected if the associatively activated representations of these colors had been involved in the discrimination test of Stage 2.

A reason to think that associative processes are not wholly responsible for acquired distinctiveness effects comes from the observation that mere exposure to a pair of similar stimuli (if this is appropriately arranged – as we have seen, alternating presentations

that give the opportunity for comparison to occur are particularly effective) can enhance subsequent discriminability. That is, distinctiveness can be acquired when the preexposure procedure seems to preclude the formation of links with distinctive associates. For humans, this argument may not be particularly convincing – members of this species may well provide their own associates (names or labels), no matter what the experimenter tries to arrange. But the effect is also seen with animal subjects (rats given alternating presentations of two flavors are better able subsequently to discriminate between them). If another, nonassociative, perceptual learning process is at work during mere exposure, might it not also be active when the exposure phase involves explicit discrimination training? Evidence in favor of this view comes from a study by Bonardi et al. (2005), who modified the procedure used by Hall et al. (2003) to rule out associative mediation and yet still found an acquired distinctiveness effect. Bonardi et al. concluded that the preexposure procedure had, in addition to establishing associations, modified the perceptual effectiveness of the various elements of the stimuli (specifically had enhanced the attention controlled by their distinctive features). The learning mechanisms that might be responsible for such an effect will be taken up in the final major section of this chapter, after we have considered the contribution of other associative mechanisms to perceptual learning effects.

1.07.4.2 Unitization

It has frequently been suggested (e.g., Goldstone, 2000; McLaren et al., 1989) that a process of unitization is, in part, responsible for perceptual learning effects. The idea has been expressed in a variety of different ways, but the central notion is that exposure to a complex and multifaceted stimulus will result in the formation of a unitary representation of that stimulus, in which the various features are somehow bound together. The concept has been much used in the study of complex visual perception (with its talk of object representations, face representations, and so on) but can readily be applied to other modalities (it forms the basis of the account of odor perception proposed by Stevenson and Boakes, 2003), and to seemingly simple stimuli (even a pure tone, for example, has many features – frequency, intensity, location, duration, etc).

When it comes to specifying the learning mechanism responsible for unitization, the only developed proposal has been in terms of associative processes (see Goldstone, 1998). Presentation of a complex stimulus will, it is assumed, activate a set of units that correspond to its various constituent features. Concurrent activation of these units will lead to the formation of a network of excitatory links among them, and it is this network, in the simplest interpretation of the idea, that is taken to constitute the unitized representation. In terms of the diagram of **Figure 5**, experience of stimulus A will establish connections among all the a elements. (It will also, initially, allow the formation of a–c connections too; but because the c elements may also be activated in the absence of the a elements, when a stimulus such as B is presented, these will be weakened and eventually drop out of the picture.) A slightly more elaborate version of this analysis supposes that experience of the stimulus results in the formation of a separate configural unit (see, e.g., Pearce, 1994) that is not directly activated by any feature of the stimulus itself but that comes to receive its input from the units that correspond to those features.

The formation of a simple network of excitatory associations is enough in itself to explain a range of perceptual learning phenomena. As we have already seen, the learned synesthesia of Stevenson et al. (1998) depends on associations formed between two aspects of a compound stimulus (its taste and smell). And our difficulty in discriminating among the aspects of a previously experienced compound odor (Stevenson, 2001) can be explained in similar terms. When people have sniffed the AX compound, excitatory associations will form between A and X. Discrimination between A and X will be poor because the presentation of A will produce associative activation of the representation of X, and presentation of X will associatively activate A. It is usually assumed that the state produced by associative activation of a representation will be distinguishable from that produced by direct activation (if nothing else, the intensity of activation is likely to be less; see Hall, 1996), and accordingly, discrimination between A and X should still be possible. But the existence of association between A and X will increase the similarity of the overall patterns of activation elicited by A and X and render the task more difficult.

Further support for this interpretation of unitization comes from its ability to explain the finding that preexposure to a complex stimulus or event can enhance the ease with which that complex is subsequently learned about. An example from animal

conditioning is supplied by Kiernan and Westbrook (1993), who gave rats a few minutes of exposure to a distinctive context prior to a session in which the context was paired with shock. On a subsequent test, these rats showed more evidence of learned fear in that context than did rats not given preexposure. (See also Fanselow, 1990; Bennett et al., 1996.) The only additional assumption needed to deal with this finding is that the animal's capacity to process all aspects of a complex stimulus will be limited, so that only a subset will be sampled at any one time. As the rat explores the context during preexposure, it will sample a range of contextual features, and connections will form among them. On the subsequent conditioning trial, only some of these features will be sampled, and only these will become associated with shock. A different set may be sampled on the test trial, but for animals given preexposure, the conditioned response should still be evoked, as those sampled on the test will be able to activate those that formed links with the shock during conditioning. Although presented in modern associative terminology, the central idea is essentially that popularized long ago as redintegration (by Hollingworth, 1928).

It will be apparent that the principle illustrated by this example from fear conditioning in the rat will be applicable to any case in which animals (including people) are given exposure to a stimulus containing more features than can be processed all at once. Appropriate response to a complex visual event (such as putting a name to a face) will be able to proceed more rapidly if inspection of one part of the display is able to activate representations of other features, or to activate a configural unit that is connected to the response-output mechanism. In the case of faces (and indeed other complex visual stimuli), it must be assumed that the configural unit is sensitive not just to the co-occurrence of various features but also to their spatial relationships. One of the classic findings from studies of face recognition is the inversion effect – the finding that faces are so much less well recognized when upside down; or, put another way, are especially well dealt with when they are the usual way up (Yin, 1969). This phenomenon is explained by assuming that experience of a face in the normal orientation establishes a configural unit that encodes the spatial relationships of the various features; when the face is inverted, these relationships are disrupted, and the unit will not be activated. Evidence for this interpretation comes from a study by Gauthier and Tarr (1997), who required people to learn the names of nonsense objects of the sort shown in **Figure 7**. An inversion effect was found for these stimuli too – performance was poor when the stimuli were presented upside down – but only for people who had received extensive prior experience with the cues. The effect is specific not to faces but to complex familiar visual cues.

1.07.4.3 Associative Inhibition

McLaren et al. (1989; see also McLaren and Mackintosh, 2000) have pointed out that standard associative theory predicts that certain schedules of exposure to a pair of similar stimuli (such as A and B of **Figure 5**) will allow the formation of other associations, in addition to those considered so far. They were concerned in particular with a preexposure schedule in which A and B were presented in alternation. Gibson (1969) has argued that a process of comparison plays an important part in the enhancement of discrimination that follows exposure to similar stimuli. The exact nature of the comparison process was not specified, but it can be agreed that alternating presentations are likely to enhance its operation, making this schedule of special interest.

We have already discussed how exposure to the stimuli will allow unitization to occur, with the various elements of each stimulus becoming linked together. McLaren et al. (1989) noted that the within-stimulus links formed would include excitatory connections between common and unique elements (which we may summarize as c–a, for stimulus A, and c–b, for stimulus B). As a consequence, presentation of A would, by way of the c–a association, be able to activate the representation of the unique features of B (the b elements); similarly, presentation of B by way of the c–a link would activate the a elements. On the face of things, therefore, preexposure might be expected to hinder subsequent discrimination, as these excitatory links would render the patterns of activation produced by A and B more similar to one another. Such indeed would be the outcome but for another factor that comes into play when the alternating schedule is

used – this schedule will allow the formation of inhibitory associative links. According to standard associative theory (e.g., Wagner, 1981; espoused by McLaren and Mackintosh, 2000) an inhibitory link will form between a directly activated stimulus representation and one that is activated associatively. The alternating schedule ensures that the subject experiences a sequence of trials in which a is associatively activated in the presence of b, and b is associatively activated in the presence of a. In these circumstances, inhibitory associations will form between a and b. Activation of an inhibitory link is assumed to oppose the effects of excitatory influences acting on a given representation, restricting the ability of that representation to be activated.

This analysis can supply an explanation for the results of the experiments described previously, in which discrimination was enhanced by intermixed preexposure (compared to a control condition in which the stimuli were presented in separate blocks of trials). Consider the experiment by Lavis and Mitchell (2006). When asked to make same–different judgments about stimuli like those shown in **Figure 2**, the excitatory links formed by subjects in the control condition mean that each stimulus would tend to activate, to some degree, the unique features of the other. Presentation of A would activate a and c directly and b associatively; presentation of B would activate b and c directly and a associatively. That is, all the same units would be activated in each case, and the judgment would therefore have to be made in terms of degree (or type) of activation. For subjects given intermixed exposure, on the other hand, inhibition between a and b would mean that A would activate only a and c, and B would activate only b and c, qualitatively different patterns of activation.

The difference between intermixed and blocked preexposure schedules has also been obtained in studies of animal conditioning (e.g., Symonds and Hall, 1995; see also Bennett and Mackintosh, 1999; Mondragón and Hall, 2002; Dwyer et al., 2004), and the associative inhibition analysis applies readily to this case too. In these experiments, subjects received conditioning with stimulus A followed by a generalization test with stimulus B. The poor discrimination (good generalization) produced by blocked exposure is explained in terms of the within-stimulus excitatory links formed during preexposure; specifically when tested with B, the c–a link will allow this cue to activate a stimulus representation (a) that had acquired associative strength during conditioning with A. For the intermixed condition, on the other hand, the inhibitory association between b and a established during preexposure would prevent activation of a on the test trial, eliminating its contribution to responding and thus reducing the degree of generalization.

The role of associative inhibition as a mechanism of perceptual learning deserves our serious attention because it provides one of the few fully worked out accounts of the processes by which stimulus comparison might have its effects. It remains to be determined, however, whether or not this theoretical possibility is, in fact, responsible for the effects observed. There is some supportive evidence from a study by Dwyer et al. (2001; see also Dwyer and Mackintosh, 2002). Rats were exposed to intermixed presentations of the compound flavors, AX and BX, where A and B represent unique flavors, and X an explicitly added common element. According to the associative principles outlined earlier, alternating presentations of AX and BX should establish inhibition between A and B (just as alternating presentations of ac and bc establish inhibition between a and b). Dwyer et al. found that after extensive intermixed exposure, animals were retarded in learning an excitatory association between A and B – what would be expected if the prior training had established inhibitory associations between these cues. It seems likely that associative inhibition plays a role in the perceptual learning effect under these training conditions.

It should be noted, however, that this example of perceptual learning (better discrimination after intermixed than after blocked preexposure) can be obtained in the absence of associative inhibition. Inhibitory learning can take many trials to develop (Dwyer et al., 2001, gave extensive initial training), but the perceptual learning effect can be obtained after just a few preexposure trials, well before there is any evidence of inhibition between A and B (Artigas et al., 2006). What is more, the effect can be observed when the training procedure is modified so as to preclude the formation of inhibitory links. **Table 2** (Experiment 1) shows the design of an experiment (Blair and Hall, 2003, Experiment 1a) devised to demonstrate the basic effect using a within-subject design and a conditioning procedure. The subjects (rats) received intermixed preexposure to the compound stimuli AX and BX and a separate block of trials with CX. A response subsequently conditioned to AX was found to generalize less readily to BX (the stimulus presented intermixed with AX during preexposure) than to the control stimulus CX. This result in itself is compatible with the suggestion that the

Table 2 Experimental designs used to investigate the effects of preexposure on flavor discrimination in rats

	Preexposure	*Conditioning*	*Test*
Experiment 1	AX/BX _ CX	AX +	BX and CX
Experiment 2	AX/BX _ CX	X +	BX and CX
Experiment 3	X/BX _ CX	AX +	BX and CX
Experiment 4	AX/BX _ CX	—	B+ or C+

Note: A, B, C represent flavors that could be presented in compound with flavor X. In preexposure, AX (or X, in Experiment 3) was presented in alternation with BX. The CX compound was presented in a separate block of trials. In the conditioning phase of experiments 1–3 and the test phase of Experiment 4, flavors were presented along with (+) an aversive reinforcer. The test phase measured the extent of the aversion shown to the test stimuli (a generalized aversion in the case of experiments 1–3). Experiments 1 and 2 were fully reported by Blair CAJ and Hall G (2003) Perceptual learning in flavor aversion: Evidence for learned changes in stimulus effectiveness. *J. Exp. Psychol. Anim. B*. 29: 39–48; Experiment 3 by Hall G, Blair CAJ, and Artigas AA (2006) Associative activation of stimulus representations restores lost salience: Implications for perceptual learning. *J. Exp. Psychol. Anim. B*. 32: 145–155; and Experiment 4 by Blair CAJ, Wilkinson A, and Hall G (2004) Assessments of changes in the effective salience of stimulus elements as a result of stimulus preexposure. *J. Exp. Psychol. Anim. B*. 30: 317–324.

presence of B in the test inhibits activation of the representation of the (conditioned) A element. But this argument cannot apply to the modified design shown as Experiment 2 in the table (Blair and Hall, Experiment 5a). Here the same result was found (less generalization to BX than to CX) despite the fact that conditioning was given to the X element alone. If A has not been conditioned, then any ability that B might have to inhibit activation of the A representation would be irrelevant to the outcome of the procedure. The experiment presented as Experiment 3 in the table (Hall et al., 2006) makes the same point in a different way. Here the intermixed preexposure procedure involved alternation, not of AX and BX, but of BX and X alone. Obviously, inhibition between A and B cannot be established with this procedure. Nonetheless, conditioning to AX was still found to generalize less well to BX than to CX on the test (see also Rodriguez and Alonso, 2004).

The new results just described serve to support Gibson's (1969) suggestion that a preexposure procedure that allows comparison between two similar stimuli (such as alternating presentations of AX and BX) is particularly effective in enhancing discrimination between them. They also show that associative inhibition mechanism can supply only a partial explanation for these effects. Gibson's own interpretation was that comparison served to enhance the perceptual effectiveness of the distinguishing features of the stimuli (A and B in this case). This notion can help explain the results produced by the experiments summarized in Table 2. In these experiments, performance on the generalization test will be largely determined by the response controlled by the X element, the response that was established during the conditioning phase. To the extent that the presence of another element (such as B or C) detracts from the ability of the animals to perceive stimulus X, the magnitude of the response will be reduced. It follows that if alternating preexposure enhances the perceptual effectiveness of the B element, this element will be better able to interfere with the ability of X to evoke its response on test and generalization will be restricted – the result obtained. What we need to consider now, therefore, is the mechanisms by which the perceptual effectiveness of stimuli might be modified; this issue is taken up in the next section of the chapter.

1.07.5 Attentional Learning Processes

The only learning process utilized so far has been one that results in the formation of links (excitatory or inhibitory) between the central representations of stimulus elements. Perhaps surprisingly, this notion has proved helpful in explaining some perceptual effects. But however powerful an explanatory tool this "simple and ancient notion" may be, it is not, on its own, enough to explain even simple associative learning. A number of learning theorists (e.g., Mackintosh, 1975; Pearce and Hall, 1980; McLaren and Mackintosh, 2000) have argued that the associative principle needs to be supplemented by another learning process, one that is capable of changing the properties of the stimulus representation, modulating its sensitivity to activation, for example, or modulating the readiness with which it will enter into association.

Because these theories are usually described as involving a process of attentional learning, it would be useful to clarify what is meant by attentional in his context, as the use of the term (which is really more of a chapter heading than a well-defined psychological construct) can vary widely. It is not meant to indicate a form of learning that occurs only when learners focus their attention on the task at hand (a characteristic that, in any case, would be difficult to identify in the experiments using animal subjects that will be considered shortly). Rather, it indicates a form of learning that modifies the processing that a

stimulus will receive. As for the nature of the modification, two principal suggestions have been advanced. One is that experience might change the effective salience of a stimulus (making a dim light function as if it were bright or a loud noise as if it were soft) and thus modify the ability of the stimulus to command attention. The other, not necessarily alternative, suggestion is that experience might change the associability of a stimulus, the readiness with which it will be learned about. (A significant event might deserve attention, even if its salience is low.) Both of these possibilities merit the description attentional, but it will be noted that they have somewhat different implications, and where necessary, they will be distinguished in what follows.

1.07.5.1 Latent Inhibition and Associability Modulation

Prior exposure to an event that is to be used as the conditioned stimulus (CS) in a classical conditioning procedure produces a marked retardation in the subsequent rate of learning. The source of this phenomenon (known as latent inhibition; Lubow, 1989) is still a matter for debate (some possibilities will be considered shortly). For our present purposes, however, we may simply note that mere exposure to a stimulus can produce a reduction in the readiness with which it can be learned about, and then go on to explore the implications of this fact of perceptual learning.

McLaren et al. (1989) have proposed an interpretation of perceptual learning effects in which latent inhibition plays an important part. They point out that it is important to distinguish between the ease with which a stimulus can be learned about and the ease with which it can be discriminated from other similar stimuli (which is our major concern). A process that reduced the former might enhance the latter. Consider the stimuli of **Figure 5**. A response conditioned to A will generalize to B (i.e., a failure of discrimination will occur) because the common (c) elements acquire strength during conditioning with A (ac) and are present in the test stimulus B (bc). Prior exposure to A will reduce generalization (enhance discrimination) because the c elements will suffer latent inhibition and thus acquire little strength during conditioning. This effect will be most marked if the subjects are given preexposure to both A and B, as the c elements will be present in both types of exposure trial, thus having twice the opportunity to acquire latent inhibition. Generalization should, therefore, be particularly weak after preexposure to both A and B – just the result obtained by Symonds and Hall (1995) and shown in **Figure 4**.

This simple notion generates an interesting prediction that has received experimental support. A perceptual learning effect (enhanced discrimination after preexposure) should only be found when the stimuli share a substantial number of common elements. When the stimuli are very different (as, in the limiting case, when A consists only of a elements and B only of b elements), latent inhibition of the c elements can play no part, and discrimination between A and B will be poor, as the latent inhibition suffered by the a and b elements will retard the acquisition of the (different) responses required to these stimuli. Trobalon et al. (1991; see also Prados et al., 1999) have demonstrated this result in a study of maze learning in rats. When the two maze arms that the rats had to choose from were very similar, preexposure to these arms facilitated discrimination learning; when the arms were made distinctively different, preexposure hindered learning.

Latent inhibition can provide an explanation for the result reported by McLaren et al. (1994) that people who had learned to assign checkerboard patterns (**Figure 2**) to different categories showed an enhanced ability to discriminate between new examples drawn from the same category. This result is unexpected, given that examples from the same category will have a common associate, in that both will elicit the same category label. Associative processes might be expected act to hinder discrimination between stimuli that have a common associate (the acquired equivalence effect). But this is to reckon without latent inhibition. McLaren et al. (1994) point out that during initial categorization training, the features common to all exemplars of that category occur on every trial. These features will therefore suffer extensive latent inhibition. Performance on the within-category discrimination will be facilitated, as this task requires precisely that the choice response should come under the control of features that distinguish the displays rather than features they hold in common.

The arguments just advanced hold whatever the mechanism of latent inhibition. Of the various possibilities (see Hall, 1991, for a review), perhaps the most widely accepted is that it reflects a loss of associability, this being expressed in formal terms as a reduction in the value of a stimulus-specific learning rate parameter (symbolized alpha in the influential learning model of Rescorla and Wagner,

1972; see Pearce and Hall, 1980). To adopt this interpretation raises a further interesting possibility. Latent inhibition itself involves only reduction in associability, but might it not be possible for the alpha-value of a stimulus to be increased under appropriate conditions? Mackintosh (1975) has adopted this proposal and devised a theory in which the associability of a stimulus is held to increase as a result of training in which it is a reliable predictor of its consequences (see also Kruschke, 2001). Direct tests of the validity of this proposal have generated mixed results (e.g., Hall and Pearce, 1979; Le Pelley, 2004). But if it could be confirmed, it would usefully extend the explanatory reach of the associability concept. In particular, it could supply an explanation for acquired distinctiveness effects. The acquired distinctiveness training procedure is one in which the subject experiences each of the critical stimuli in reliable association with another event (in **Table 1**, for example, A reliably predicts red, and B reliably predicts green). In addition to any associations that may be formed, Mackintosh's theory says that the associability of A and B will go up under these conditions. Subsequent discrimination between these cues would be enhanced, even in circumstances in which associative mechanisms do not seem to operate (Bonardi et al., 2005).

Whatever the fate of Mackintosh's (1975) theory of associability change, it will be evident that the basic latent inhibition process plays an important part in many perceptual learning effects. There is, however, one critical version of perceptual learning that defies explanation in terms of latent inhibition. This is the well-established, and already much-discussed, finding that discriminability is especially enhanced when the subject is able to compare the stimuli during preexposure. **Table 2** (Experiment 1) presents a simple experimental demonstration of the effect. In this experiment, the subjects can compare A and B during preexposure (they are presented on alternate trials), but will be less able to compare C with the others, as this stimulus is presented on a separate block of trials. But because the subjects experience the critical cues, A, B, and C, the same number of times, all three cues should acquire latent inhibition to the same extent. There are no grounds, therefore, for the latent inhibition account to predict the result obtained – poorer generalization from AX to BX than to CX. Further analysis of this finding is one of the topics of the final section of the chapter.

1.07.5.2 Habituation and Salience Modulation

Whatever other factors may play a part, there is no doubt that the effectiveness of a stimulus depends on its intensity. A strong stimulus will normally elicit a more vigorous response than a weak one (we show a bigger startle response to a loud noise than a soft one); associative learning occurs more rapidly when the events to be associated are intense. Formal theories of these phenomena (see, e.g., Hall, 1994) incorporate a notion of salience, a parameter associated with each stimulus and set by its intensity.

Stimulus salience will influence performance on the tests used in studies of perceptual learning. Subjects will be best able to discriminate (on a same-different test, say) between A and B when the unique features (a and b) are intense, and the common features (c) are not. And generalization between such stimuli will be poor, as the a element will dominate during conditioning with A, restricting the acquisition of control by the c element, and the b element will dominate on test with stimulus B, restricting the ability of c to influence performance. In most studies of the topic, we use stimuli with nonsalient unique features and salient common features; that is, we study the effects of experience on discriminations that are difficult. Perceptual learning effects would be obtained, then, if experience with stimuli was capable of boosting the effective salience of the unique features of stimuli (or of lowering that of common features, or both). What evidence is there that effective salience can change? We have discussed how simple exposure to repeated presentations of a stimulus can produce a loss of associability (latent inhibition), but there is reason to think that this procedure can also bring about a change in effective salience.

Repeated stimulus presentation results in habituation – the waning of the response unconditionally elicited by that stimulus. Explanation of this simple phenomenon turns out to be surprisingly complex (see Hall, 1991, for a review in the context of perceptual learning). But what we need to note for our present purposes is that the habituation procedure makes a salient stimulus behave like a less-salient one. After extensive habituation training, the startle response evoked by a loud noise will be much the same as the (weaker) response evoked by the first presentation of a softer noise. The habituation effect is most easily observed with motivationally significant events, as these evoke obvious responses; but the

learning process responsible for it presumably operates for any stimulus, including those used as cues in experiments on perceptual learning. For a few of these, the effect can in fact be observed directly. Rats show neophobia to foods (that is, they are reluctant to consume a substance with a novel taste), and habituation of neophobia is commonly observed over the preexposure phase of perceptual learning experiments using flavor stimuli (Blair et al., 2004). Observations like these make it a reasonable presumption that the (unobservable) response evoked by presentation of a checkerboard, say, will also undergo habituation, or, in other words, that these stimuli too will lose effective salience with repeated exposure.

Blair et al. (2004) have investigated the role of salience modulation in perceptual learning, focusing on the differing effects of intermixed and blocked preexposure. Recall for the experiment shown as Experiment 1 in **Table 2** that rats consume more of BX than of CX on test, and that this difference is explained by the fact that at the end of preexposure, B has greater effective salience than C (the more salient a cue, the more it will interfere with expression of the response controlled by X). Blair et al. (2004, Experiment 3) tested the salience of B and C using the design shown in as Experiment 4 in **Table 2**. After preexposure, some rats received conditioning trials with B alone as the conditioned stimulus (CS); others received C alone as the CS. Acquisition occurred more rapidly to B than to C, as would be expected if B were higher in salience than C. In a further study, Blair et al. simply monitored the unconditioned response evoked by B and C at the end of preexposure. The neophobic reaction evoked by these flavors was found to have habituated to some extent over the course of preexposure, but it was still observable, particularly for flavor B. Thus the effective salience of both B and C was reduced by preexposure, but critically, the reduction was less for the cue presented in alternation with a similar cue in preexposure.

The conclusion that emerges from these and related studies (Hall, 2003; Hall et al., 2006) is that mere exposure to a stimulus will cause a loss of effective salience, but that with some schedules of preexposure, this loss can be attenuated or reversed. The critical arrangement appears to be one in which the cue in question is presented in alternation with another similar cue. Why this schedule should have the effects it does is not yet clear. There is some evidence from the experiments by Hall et al. (2006) to suggest that an important feature of this schedule is that on each trial the subject is likely to be (slightly) surprised at the omission of one of the unique features and at the occurrence of the other. (With the blocked schedule the same stimulus occurs trial after trial.) It seems plausible that an event that evokes surprise might also maintain its salience, but the precise learning mechanisms that might underlie such an effect remain to be specified.

1.07.6 Conclusions

The material reviewed in this chapter has covered a wide range; this is true both for the empirical phenomena considered in the first part and the theoretical analyses dealt with in the second part. The latter point might seem to be a cause for concern, given our customary aspiration to achieve parsimony in explanation. But the concern would probably be misplaced. There is every reason to think that perceptual learning effects are the product (usually the joint product) of several different processes. On the basis of the evidence reviewed in this chapter, a place should be found for associatively mediated acquired equivalence and distinctiveness, effects based on within-stimulus association (unitization) and between-stimulus associations (associative inhibition), latent inhibition (and possibly other learned changes in associability), habituation, and salience modulation.

It may have been noticed that the operation of these various learning mechanisms in perceptual learning has been demonstrated for only a subset of the phenomena described in the first section of the chapter. Analytic studies have, for the most part, made use of just a few well-established and tractable experimental procedures. This may raise the fear that detailed exploration of other paradigms would uncover a whole new set of explanatory principles, in addition to those already listed. But this fear is not justified. As was suggested earlier, the job of a theory of perceptual learning is to explain how experience of similar stimuli can enhance the perceptual effectiveness of features that distinguish them and reduce the perceptual effectiveness of features that they have in common. This description is valid generally – it applies equally, for example, to rats learning to discriminate between flavors and to people learning to distinguish between speech sounds. We have every reason to hope that explanatory principles established in one of these paradigms will also apply in the other.

1.08 Discrimination and Generalization

E. J. Kehoe, University of New South Wales, Sydney, NSW, Australia

1.08.1 Introduction

Studies using discrimination and generalization methods have been intimately intertwined with research and theory in learning and memory. All or nearly all the other articles in this volume will describe findings based on discrimination and generalization tasks (*See* Chapters 1.03, 1.05, 1.07, 1.11, 1.12, 1.22). From a biological perspective, learning to respond distinctively to different stimuli and transferring that learning to new situations are essential to survival in all but the most static of environments. From a cognitive perspective, understanding distinctions and perceiving similarities underpins processes of attention, perception, recognition, categorization, and reasoning, all of which usually require learning and memory for developing their content and expression.

In brief, discrimination training tests how well a learner can distinguish among stimuli, while generalization procedures test how well training with one stimulus transfers to another stimulus. These two procedures have been used in three major ways. First, they provide psychophysical techniques for

revealing the processes of stimulus encoding. Second, they have been used in delineating the roles of excitation and inhibition in learning. Third, they have contributed to the investigation of cognitive processes, particularly in nonverbal creatures. In the present article, key examples of each of these uses will be outlined after the basic methods have been described.

1.08.2 The Basics

This section describes the basic procedures and outcomes of discrimination training and generalization testing. In addition, this section treats generalization testing in the wider context of transfer of training.

1.08.2.1 Discrimination Learning

Basic discrimination training entails the presentation of two stimuli, one of which is associated with the reinforcer (S+), and one of which is not (S−). In classical conditioning, one conditioned stimulus (CS+) is consistently paired with the unconditioned stimulus (US), and the other conditioned stimulus (CS−) is not paired with US. Similarly, in operant conditioning, the target response is reinforced whenever one discriminative stimulus (SD) is present, and the target response is not reinforced whenever the other discriminative stimulus (SΔ) is present. Discrimination learning is said to occur when the level of responding is greater during S+ than S−. **Figure 1** shows discrimination learning curves obtained under different circumstances in different species.

Discrimination training using stimuli that differ along a single dimension is commonly called intradimensional training. When the S+ and S− differ along multiple dimensions, including their sensory modalities, the procedure is called either interdimensional or extradimensional training. Across investigators, there is no apparent convention for using these latter two terms.

Go/no-go discriminations. **Figures 1(a)** and **1(b)** illustrate differential classical conditioning of the eyeblink response in rabbits and humans (Gynther, 1957; Moore, 1972). For the rabbits, the stimuli were tones of different frequencies (400 Hz, 1600 Hz), and for the humans, red and white lights were used. The assignment of the two stimuli as CS+ and CS− was counterbalanced across subjects. In both cases, the likelihood of a conditioned response (CR) to both CS+ and CS− increased during the early trials of training. Thereafter, respondes to CS+ continued to rise, while respondes to CS− either stabilized or declined to a lower level.

Figure 1(c) shows results of a free-operant discrimination procedure. Rats were initially trained to press a lever bar for intermittent reinforcement (Herrick et al., 1959). Discrimination training was conducted by switching between periods in which an indicator lamp was on (S+) and periods in which the lamp was off (S−). During the S+ periods, barpresses were intermittently reinforced. During the S− periods, barpresses were never reinforced. The rate of barpressing during S+ rose steadily and approached a level around 70 responses per minute. In contrast, responses during S− gradually disappeared.

Choice discriminations. The examples of discrimination learning shown in **Figures 1(a)–1(c)** are all based on procedures in which the S+ and S− stimuli are alternated in a successive fashion. Such successive discriminations are also labeled as *go/no-go discriminations*, because the subject's task is to either display or withhold the target response, depending on the stimulus. Operant conditioning procedures also allow for *choice discriminations*, in which S+ and S− are presented simultaneously in separate locations. Most commonly, visual stimuli are used. The subject is reinforced for responding toward S+, but not if it responds toward S−. Thus, responding entails choice behavior, in which both correct responses and errors can be observed. Learning is expressed as an increase in 'percent correct responses,' that is, the proportion of trials on which the subject responds toward S+.

Choice discrimination tasks have been investigated in a wide number of species, ranging from honeybees (Couvillon and Bitterman, 1985) to elephants (Nissani et al., 2005). **Figures 1(d)–1(f)** show examples of choice discrimination learning. Specifically, **Figure 1(d)** shows learning curves obtained using a T-maze. As the name implies, the apparatus consisted of three narrow boxes arranged in a T-shaped pattern. The subjects were mice from two strains, specifically, a control strain and a transgenic strain that mimics Huntington's Disease (Lione et al., 1999). On each trial, a mouse was placed in the central arm. The subject then moved of its own accord to the junction of the maze, where it encountered S+ in one arm and S− in the other arm. In this case, the stimuli were created by making

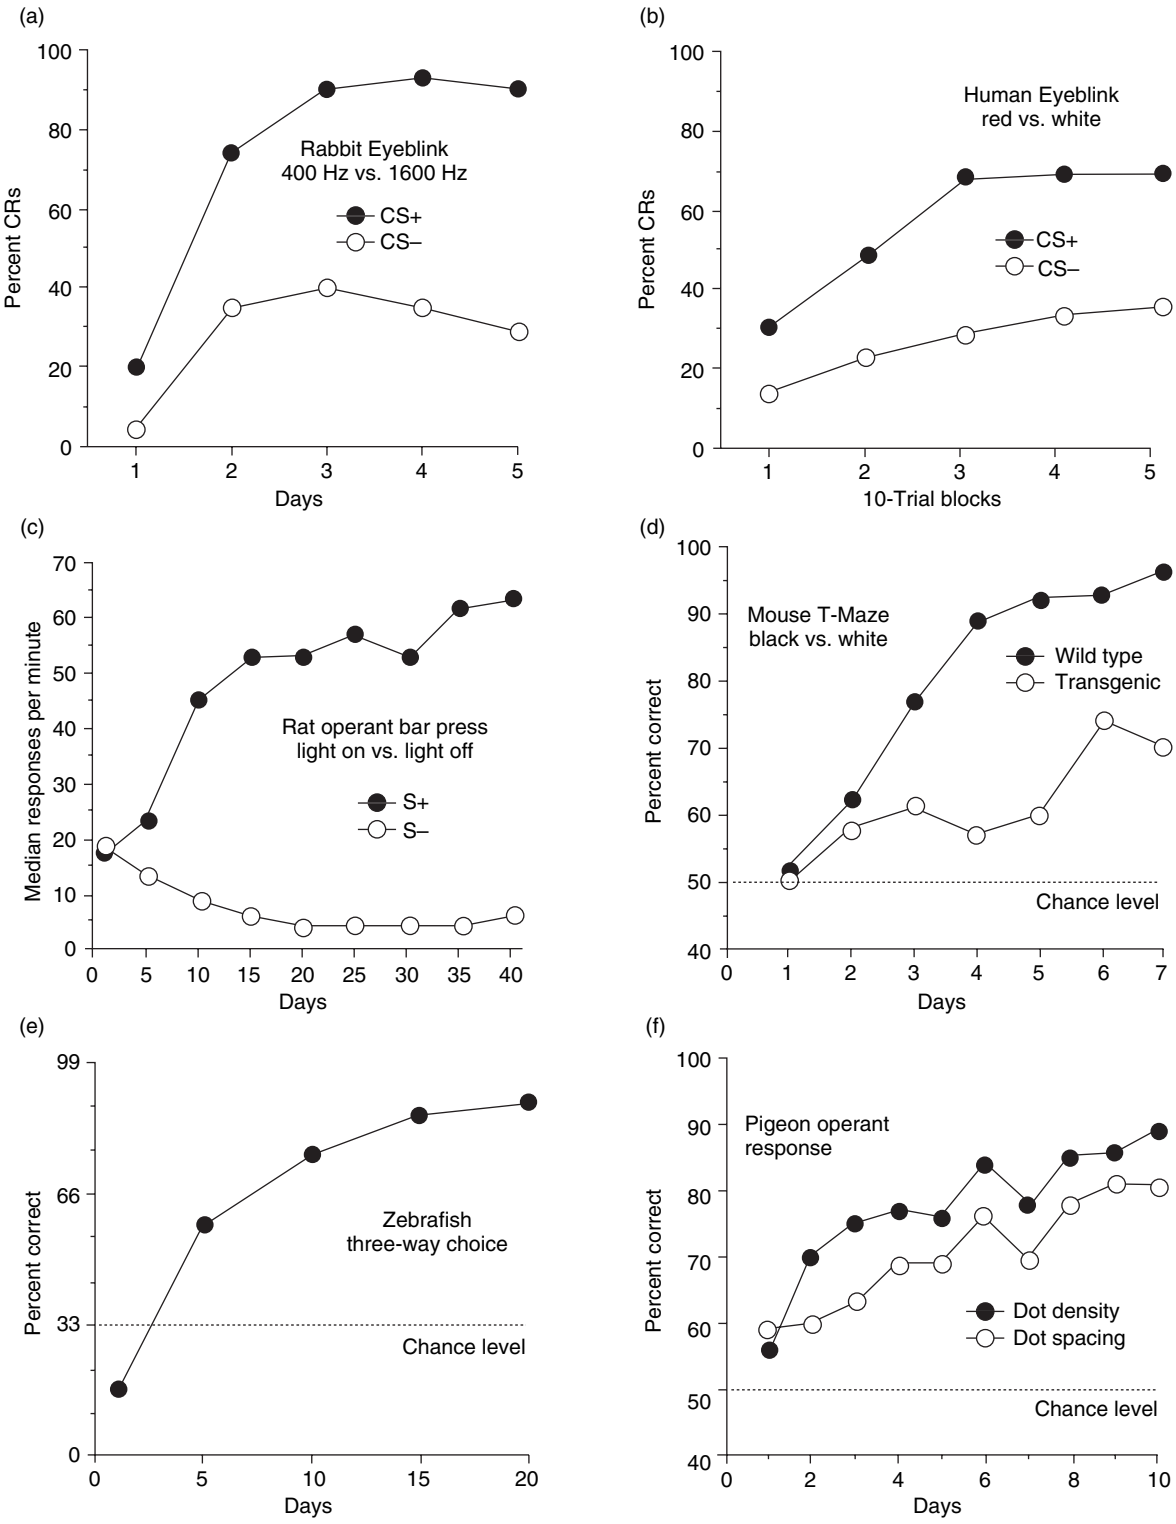

Figure 1 Examples of basic discrimination learning tasks: (a) go/no-go discrimination in rabbit eyeblink conditioning (Moore, 1972); (b) go/no-go discrimination in human eyeblink conditioning (Gynther, 1957); (c) go/no-go discrimination in operant barpress conditioning in rats (Herrick et al., 1959); (d) choice discrimination in two types of mice (Lione et al., 1999); (e) three-way choice in zebrafish (Bilotta et al., 2005); (f) visual on-screen choice in pigeons (Cook, 2001). All figures adapted with permission. CS, conditioned stimulus.

the ceiling of one arm black, and the ceiling of the other arm white. If the subject moved up the S+ arm, it would find a food pellet. If the subject moved up the other arm, there was no food pellet. As can be seen in **Figure 1(d)**, the likelihood of a correct response in the control strain gradually rose from a chance level of 50% correct to a level near 100%, while the transgenic mice only reached a level around 70%.

Figure 1(e) shows the results of a three-way choice discrimination in zebra fish (Bilotta et al., 2005). Each fish was presented with a choice between three windows, one of which was illuminated. The subject was reinforced for swimming through the illuminated window but not the other windows. The location of the illuminated window was randomly altered from trial to trial. Initially, performance was below chance level, because trials on which a subject failed to make any choice were counted. Across days of training, the likelihood of correct responding rose to 80%, at which point training was stopped.

Modern technology allows for the projection of complex visual stimuli on video screens. In some cases, the subject can indicate its choice by touching specific regions on the screen. **Figure 1(f)** shows an example of an on-screen discrimination in which pigeons were presented with a field of regularly spaced dots. The S+ was a square containing either more densely packed dots or irregularly spaced dots. The S+ was placed at a random location on the screen, and the pigeon was reinforced only if it pecked at the S+. As can be seen, the likelihood of pecking at the S+ region reached a level near 90% (Cook, 2001).

In choice discrimination tasks, subjects often display response patterns that prevent them from coming into contact with the discriminative contingencies among the stimuli, responses, and reinforcers. Subjects often adopt a position habit, such as always choosing the left-hand response. Because the S+ and S− appear equally often in left and right positions, a left-hand response will be reinforced 50% of the time. Although this rate of reinforcement is less than the maximum the subjects could obtain, it is sufficient to maintain a position habit. To ensure that the subjects do encounter all the contingencies, a correction procedure may be used. In this procedure, the choice of S− is followed by a *correction trial*, in which only S+ is presented and the subject can only make the correct response. For example, during a correction trial in a T-maze, only the arm associated with S+ will be open.

1.08.2.2 Generalization and Transfer of Training

1.08.2.2.1 Stimulus generalization: immediate, specific transfer

Basic generalization testing entails two stages. The first stage entails reinforced training in which a single stimulus (S+) is used. Once responding to S+ has reached a high level, the second stage begins. In this stage, the subject is presented with a set of test stimuli that differ systematically from S+.

Figure 2 shows three alternative plots for the results of generalization testing (Moore, 1972). In this experiment, three groups of rabbits received eyeblink conditioning in which a 1200-Hz tone was paired with the US (CS+). One group (T1) received single-stimulus training, in which only CS+ trials occurred. The second group (T1-T2) received discrimination training, in which CS+ trials were intermixed with CS− trials using another tone (2400 Hz). The third group (T-L) received training in which CS− was from a different modality, specifically, a brief illumination of the chamber. Following initial training, all three groups were tested with tones of 400 Hz, 800 Hz, 1200 Hz (CS+), 1600 Hz, and 2000 Hz.

Figure 2(a) shows the mean likelihood of a CR as a function of tone frequency. As can be seen, the highest level of responding in all three groups was elicited by the 1200-Hz CS+. As the frequencies of the test tones increasingly deviated from 1200 Hz, responding fell off in a graded fashion. However, the three groups showed some differences in both the absolute height and steepness of their gradients. To make it easier to compare the slopes of the gradients, **Figures 2(b)** and **2(c)** show two types of plots that depict *relative generalization gradients*, which adjust for differences in the level of responding to CS+.

In **Figure 2(b)**, the level of responding to each stimulus is plotted in proportion to the level of responding to CS+. Thus, responding to CS+ is always set to 1.00, and the slopes of the gradients can be readily seen. **Figure 2(c)** shows a method of plotting that emphasizes *stimulus control*, that is, how specific responding is to CS+ relative to the other test stimuli. In this method, the total amount of responding to all tested stimuli is added together, and responding to each stimulus is expressed as a proportion of that total. Thus, taller, sharper gradients indicate greater stimulus control but, conversely, less generalization. Inspection of **Figures 2(b)** and **2(c)** indicate that both discrimination groups showed less generalization, and hence greater stimulus control, than Group T1.

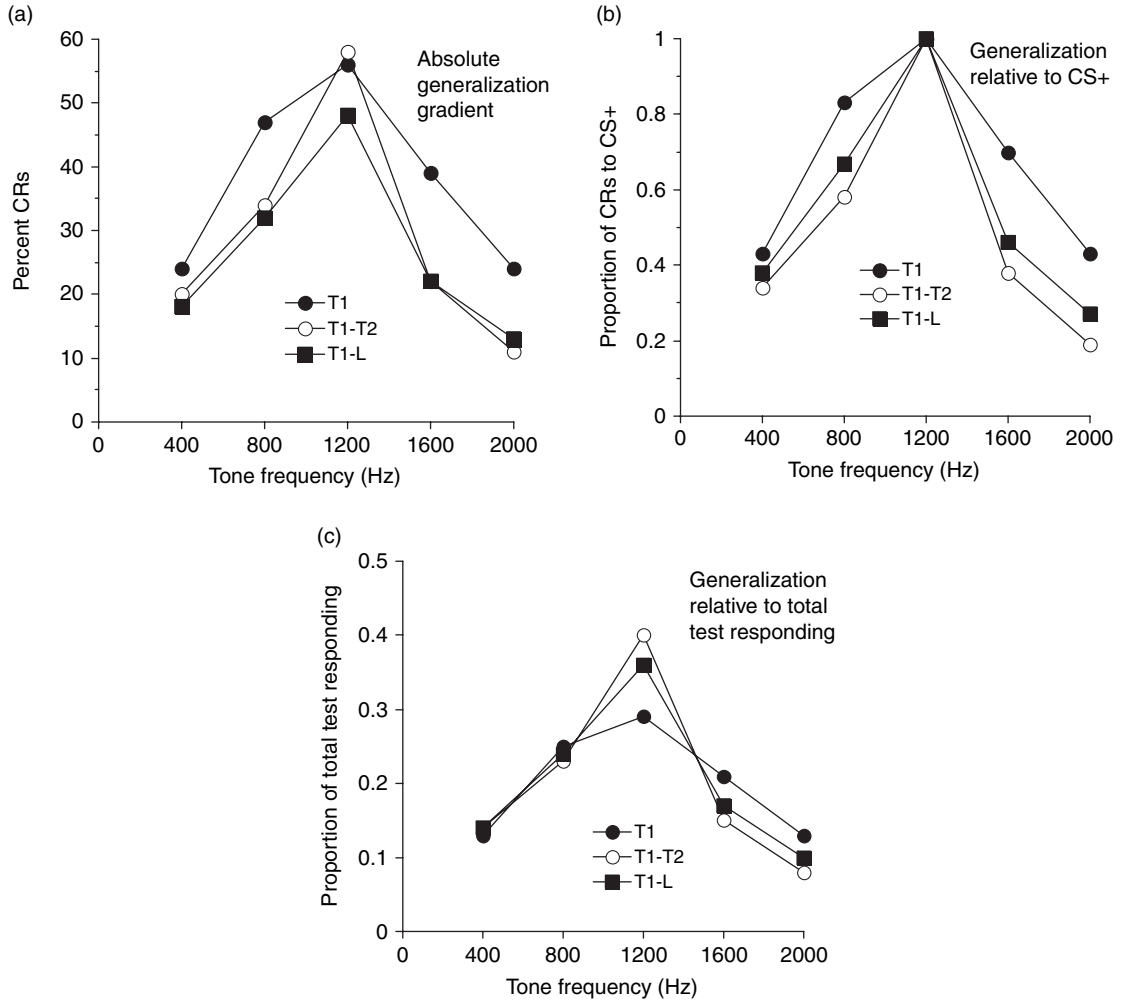

Figure 2 Alternative depictions of generalization gradients in rabbit eyeblink conditioning: (a) Absolute percentage conditioned response (CR) to each stimulus, (b) Responding to each test stimulus as a proportion of responding to CS+, (c) Proportion of total responding to each stimulus, including CS+ (Moore, 1972). All figures adapted with permission. CS, conditioned stimulus.

As shown in **Figure 2**, discrimination training tends to sharpen generalization gradients. Conversely, when efforts have been made to eliminate all potential sources of discrimination training, generalization gradients can be virtually flat. For example, **Figure 3** shows the results of generalization testing after two kinds of operant conditioning in which pigeons were reinforced for pecking a lighted keyswitch (Jenkins and Harrison, 1960). In *nondifferential training*, a 1000-Hz tone (S+) was present whenever the key was lit, which was for 33 s out of every 40 s. The 7-s period without the keylight precluded the pigeons from making the target response. In contrast, in *differential training*, the subjects received training with a go/no-go discrimination, in which S+ trials with a tone were alternated randomly with S− periods in which the keylight was on but the tone was off. The 7-s blackout periods also continued to occur in this latter condition.

In subsequent testing sessions, pecking at the keylight was tested during tones ranging from no tone (0 Hz) to 3500 Hz. As can be seen in **Figure 3**, the level of responding to the test stimuli after nondifferential training was similar to that during S+. That is, there was nearly complete generalization to the test stimuli even though the birds had only ever been trained with a 1000-Hz tone. However, the pigeons were not tone deaf. After differential training, there was a sharp generalization gradient centered on S+.

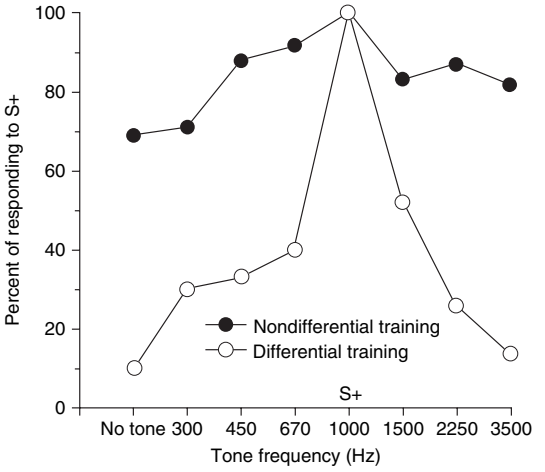

Figure 3 Relative generalization gradients in operant conditioning of pigeon's keypecking after nondifferential training with S+ only versus differential training S+ versus S− (Jenkins and Harrison, 1960). Figure adapted with permission. S, stimulus.

1.08.2.2.2 Other types of transfer

The instances of stimulus generalization described above represent only one of four basic types of transfer. Specifically, stimulus generalization testing reveals the ability of a subject to use its previous learning when it first encounters new stimuli that more or less physically resemble the stimulus used in initial training. This type of transfer can appear immediately on the first test and is specific to stimuli that differ from the training stimulus along one or more sensory dimensions (see Blough, 2001a, for an extensive discussion of the concept of *similarity*.) Provided the appropriate response is retrieved, such immediate specific transfer can be extraordinarily valuable to the survival of subjects when presented with fleeting opportunities and imminent threats. Likewise, human society highly prizes the abilities of paramedics confronted by an accident victim, pilots in an emergency, students in an examination, and even contestants in a quiz show to respond quickly and correctly to situations that are variations on their previous experience.

Despite the premium placed on immediate specific transfer, it is not the sole type of transfer. There are three other ways that transfer can appear. The second type of transfer is immediate but nonspecific. That is, previous learning is applied in situations that bear little similarity at a sensory level to the situations used in training. Instead, nonspecific transfer can be based on structural similarities between the training situation and test situation, for example, analogical reasoning in humans (Gick and Holyoak, 1980; Novick and Holyoak, 1991; Reeves and Weisberg, 1994). The third and fourth types of transfer do not appear on the first encounter with a new situation. Rather, the effect of the previous training is latent and is detected as an increase in the rate of response acquisition during reinforced training in the new situation. A specific form of latent transfer is seen whenever original learning cannot be retrieved immediately but does reappear quickly during refresher training. This type of transfer is known as *savings*. Humans refer to savings whenever they say, "I can't remember how to do it, but I know I can pick it up again quickly." A nonspecific form of latent transfer can appear in situations that share some similarity in their underlying structure, but not in the sensory features of their stimuli. This latent, nonspecific transfer is labeled variously as *learning to learn, learning set*, or *general transfer* (Ellis, 1965, p. 32).

These distinctions among types of transfer are useful for exposition but should not be taken as strict dichotomies. The immediate-versus-latent distinction is relatively clear when the new situations are relatively brief and demand a rapid response. However, when a new situation has less urgent demands, latent transfer could appear during the first encounter if learning occurs as a result of false starts and tentative solutions. As for the specific-versus-nonspecific distinction, it is more accurately construed as a continuum. It is probably difficult, if not impossible, to create situations that differ in every sensory feature from those in original training. In laboratory experiments, however, the number and magnitude of changes can be systematically varied and described.

To ground these distinctions, the remainder of this section will describe examples of the different types of transfer. However, before doing so, a few sentences about the design of transfer experiments are needed. As previously described, the detection and quantification of stimulus generalization uses the level of responding to the training stimulus (S+) as the reference point for comparison to the level of responding to the test stimuli. Such within-subject comparisons are efficient, but one must be confident that there would be little or no responding to the test stimuli in the absence of prior training with S+. Otherwise, a between-subjects design is necessary. At a minimum, there are two groups. The experimental group receives the initial training with S+, and in the basic version, the other group – known as the *rest control* – receives no

training with S+. That is, while the experimental group receives its initial training, the subjects in the rest control group sit either in their home cages or in the experimental chambers. Then, both the experimental and control groups receive the test stimuli for immediate transfer plus any subsequent training with the test stimuli to detect latent transfer. The level responding in the control group provides the reference point for the experimental group. If responding in the experimental group exceeds that of the control group, *positive transfer* or *facilitation* is said to occur. If responding in the experimental group is the lesser of the two, then *negative transfer, interference*, or *retardation* is said to have occurred.

1.08.2.2.2.(i) Immediate, nonspecific transfer A textbook case of immediate, nonspecific transfer would be cross-modal generalization, in which the subjects are trained with a stimulus in one modality (e.g., tone) and then tested with a novel stimulus in another modality (e.g., light). Reports of successful cross-modal generalization are rare. It has been seen in eyeblink conditioning in humans (Marlatt et al., 1966) but not rabbits (e.g., Kehoe, 1992; Weidemann and Kehoe, 2005). Something like immediate, nonspecific transfer, however, has emerged when the test stimuli have previously undergone even a tiny bit of training. **Figure 4** shows the results of two such experiments.

Figure 4(a) shows an example of cross-modal transfer in rabbit eyeblink conditioning (Schreurs and Kehoe, 1987). One group of rabbits (Expt'l) received 15 pairings of the ultimate test stimulus (CSX; e.g., tone) with the US. These CSX-US pairings were too few to yield discernible CR acquisition. At the same time, a rest control group received only exposure to the experimental apparatus. Subsequently, both groups received 240 pairings of a stimulus from another sensory modality (CSA; e.g., light).

During CSA-US training, the subjects were periodically tested with presentations of CSX. As can be seen **Figure 4**, both groups showed CR acquisition to CSA. As CRs were acquired to CSA, Group Expt'l also showed progressive increases in responding on CSX test trials to a level of 34% CRs. In contrast, Group Rest showed no generalized responding to CSX.

Figure 4(b) shows an example of transfer across different visual dimensions (Rodgers and Thomas, 1982). In this experiment, pigeons were given training in which the response key contained a line tilted at either a 60-degree or a 30-degree angle. One group was given go/no-go discrimination training, in which the pigeons were reinforced for pecking at the one line (S+) and not the other line (S−). The other group received *pseudo-discrimination training*, in which pecking at each line was reinforced for a random half of their trials. After this initial training, both

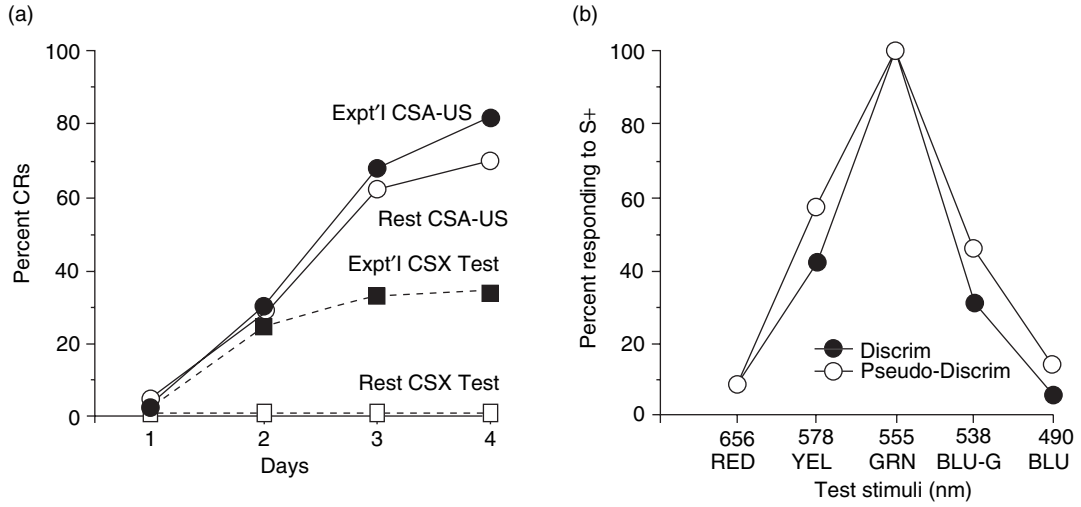

Figure 4 Examples of extradimensional transfer in rabbit eyeblink conditioning (a) and operant conditioning of the pigeon's keypeck (b). Panel (a) shows the results of testing a stimulus from one modality (CSX), while acquisition training was conducted with a stimulus from a different modality (CSA-US). The experimental group had previously received a small number of CSX-US pairings, while the control group had not (Schreurs and Kehoe, 1987). Panel (b) shows the results of generalization testing along the color dimension after pigeons had received either true discrimination training or randomized psuedo-discrimination training with two line-tilt stimuli (Rodgers and Thomas, 1982). All figures adapted with permission. CS, conditioned stimulus; US, unconditioned stimulus; YEL, yellow; GRN, green; BLU-G, blue-green; BLU, blue.

groups were given training in which they were reinforced for pecking at a green (555 nm) keylight. Finally, both groups received generalization tests along the color dimension.

Inspection of **Figure 4** reveals that the discrimination group showed a sharper gradient compared to pseudo-discrimination training. Thus, discrimination training on one dimension altered generalization along an orthogonal dimension.

1.08.2.2.2.(ii) Savings: latent, specific transfer **Figure 5**(**a**) shows two examples of savings. **Figure 5**(**a**) shows percent CRs in four successive cycles of CS-US acquisition and CS-alone extinction in rabbit eyeblink conditioning (Kehoe, 2006). **Figure 5**(**b**) shows the percent correct response in successive reversals of a choice discrimination. Specifically, rats were trained in a T-maze, in which they were reinforced for choosing one arm but not the other. Within each training session, the same choice was always reinforced, but, in the next session, the opposite choice was reinforced (Watson et al., 2006). As can be seen, in both tasks, the successive acquisitions become progressively faster.

1.08.2.2.2.(iii) Learning to learn: latent, nonspecific transfer **Figure 6**(**a**) shows the best known set of curves that demonstrate learning to learn (Harlow, 1949). Rhesus monkeys were trained with a series of 344 discrimination problems, each using a different pair of objects. In each problem, the monkeys were given six or more trials in which to choose between two objects presented on a tray; for example, two different-shaped blocks. If a subject chose the correct object (S+), there was a food reward underneath it. If the subject selected the other block (S−), there was no reward. From one trial to the next, the S+ and S− objects were randomly switched from one side to the other. After a minimum of six trials with one problem, the monkeys were then given another problem using completely different objects; for example, two small toys. Each of the learning curves shows the average percentage of correct choices for successive blocks of problems.

On Trial 1 of each problem, the choice between the two objects was necessarily random. Thus, the learning curve for each problem always starts at 50% correct for Trial 1. For the first set of problems (1–8), the rate of learning was slow. The monkeys' second choice was correct only 52% of the time, and their third choice was correct only 59% of the time. However, as the monkeys accumulated experience with the discrimination problems, the rate of learning progressively accelerated. By the final set (Problems 289–344), the monkeys made nearly 100% correct responses on Trial 2, regardless of their initial choice. In descriptive terms, the monkeys had learned a *win-stay/lose-shift strategy*. That is, if the monkeys won a reward on the Trial 1 by selecting S+, then the monkeys continued to select the same object on

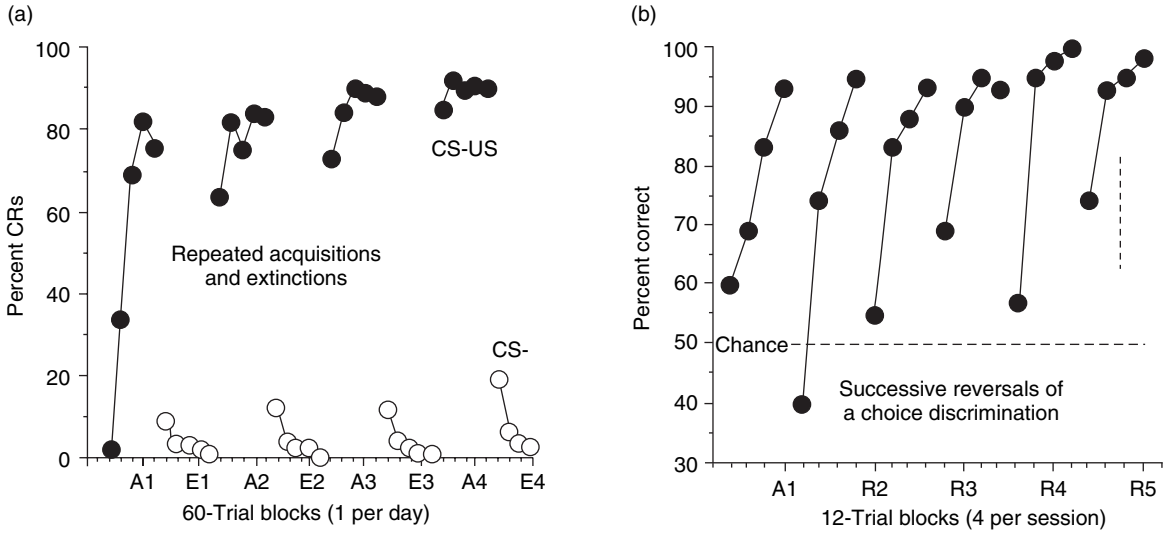

Figure 5 Examples of latent, specific transfer. (a) Repeated acquisitions (CS-US) and extinctions (CS−) in rabbit eyeblink conditioning (Kehoe, 2006). (b) Successive reversals of a choice discrimination in a T-maze by rats (Watson et al., 2006). All figures adapted with permission. CS, conditioned stimulus; US, unconditioned stimulus.

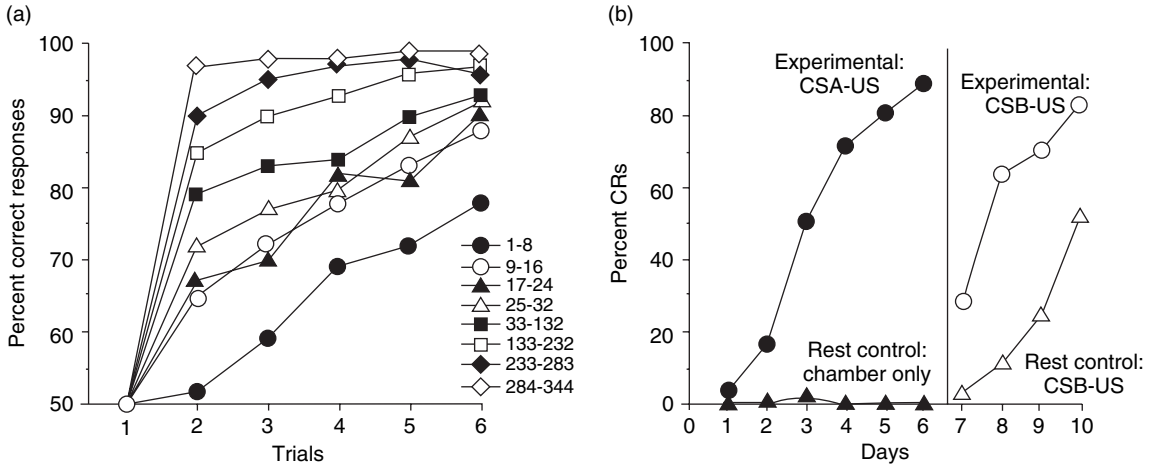

Figure 6 Examples of latent, nonspecific transfer. (a) Learning curves in successive blocks of choice discriminations in monkeys (Harlow, 1949). (b) Learning curves in two successive stages of training with one stimulus from one sensory modality (CSA-US) and a second stimulus from a different sensory modality (CSB-US)(Kehoe and Macrae, 2002). All figures adapted with permission. CS, conditioned stimulus; US, unconditioned stimulus.

subsequent trials. If, however, the monkeys lost by selecting S− on Trial 1, they shifted their choice to S+ on Trial 2 and thereafter.

Learning to learn has also been demonstrated in nonprimate species (Warren, 1960; Kamil et al., 1977). In rats, learning to learn has been obtained using visual patterns in choice discrimination (Wallace and Daniels, 1972), odors in a go/no-go discrimination (Slotnick and Hanford, 2000), and different locations of a platform in the Morris water escape task (Whishaw, 1985). Learning to learn has even been seen in classical conditioning (Kehoe and Holt, 1984; Holt and Kehoe, 1985; Kehoe and Macrae, 1997).

Figure 6(b) shows an example of learning to learn in rabbit eyeblink conditioning. In Stage 1, one group of rabbits (Experimental) received 6 days of CSA-US pairings. For half of this group, the A stimulus was a 1000-Hz tone, and for the other half, the A stimulus was a flashing light. Another group of rabbits (Rest Control) was restrained in the training apparatus without CS or US presentations. At the end of initial training, Group Experimental showed CRs on 90% of CSA-US trials, while Group Rest Control showed only a few, random blinks during blank periods corresponding to CSA.

Subsequently, both groups were tested with a new stimulus (CSB). For Group Experimental, the rabbits initially trained with the tone were tested with the light, and the rabbits initially trained with the light were tested with the tone. Correspondingly, Group Rest Control was also tested with either the light or tone. No immediate transfer was evident in these tests. However, once CSB-US pairings were started, learning to learn became evident. As can be seen in **Figure 6(b)**, Group Experimental showed rapid CR acquisition to CSB. Within the first day of Stage 2, Group Experimental showed CRs on 29% of its CSB-US trials, while Group Rest Control showed CRs on only 3% of its CSB-US trials.

Latent transfer, both in the form of savings and learning to learn, appears to be irreversible and separate from the specific contents of the original learning. **Figure 7** shows the results of two studies that illustrate this point. First, rats were initially reinforced for choosing the right arm of a T-maze (Bunch, 1939). After reaching a criterion of 10 consecutive correct responses, each rat was assigned to one of five groups. All these groups underwent reversal training in which they were reinforced for choosing the left arm of the T-maze. The groups differed in the amount of time that elapsed between initial training and reversal training. One group was immediately switched to reversal training, and the other groups waited in their home cages for 2, 7, 14, and 28 days, respectively. A sixth group was a rest control and only received training with the left-arm task.

Figure 7(a) plots the mean number of errors committed during reversal training by each group prior to achieving 10 consecutive correct responses. Relative to the rest control, Group 0, which received the immediate switch, showed negative transfer. That is, Group 0 showed more errors by persisting in

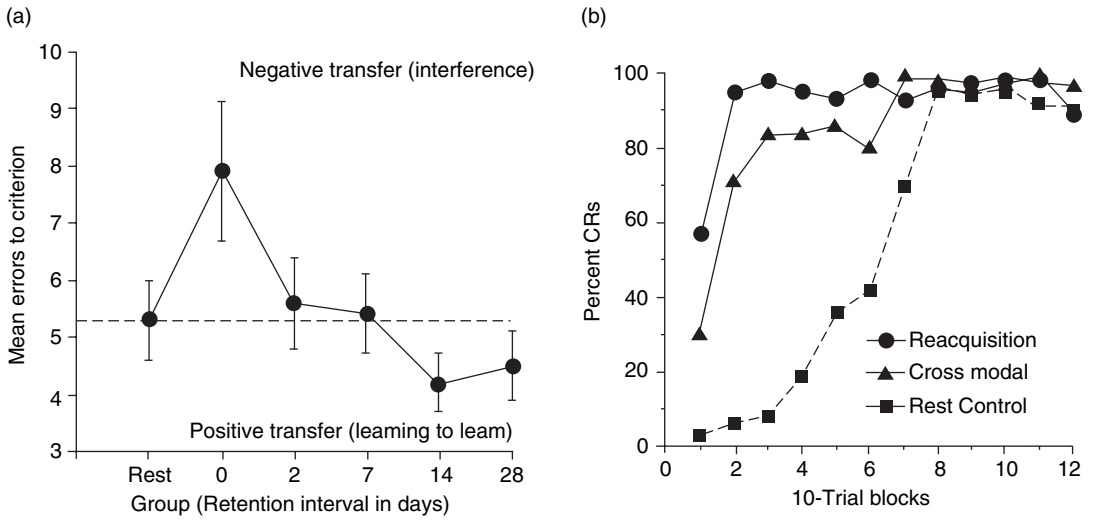

Figure 7 Examples of latent transfer after retention loss and extinction. (a) Reversal of a T-maze response in rats after a range of retention intervals (Bunch, 1939). (b) Reacquisition and cross-modal acquisition after extinction (Macrae and Kehoe, 1999). All figures adapted with permission.

performing the formerly correct response. However, as the retention interval increased, negative transfer progressively disappeared. More importantly, Groups 14 and 28 displayed positive transfer. Specifically, they showed fewer errors during the reversal than the Rest Control group. Thus, as retrieval of the original response faded, learning to learn appeared.

Figure 7(b) illustrates savings and learning to learn after an eyeblink CR was eliminated through extinction (Macrae and Kehoe, 1999). Two groups of rabbits were given initial training with either a tone or light CS. After CRs were established, both groups underwent extinction training using the same CS. After the CR had been thoroughly extinguished, one group (Reacquisition) was tested for savings by recommencing pairings of the original CS with the US. The other group (Cross Modal) was tested for learning to learn by starting pairings of the alternate CS with the US. A third group (Rest Control) was trained with either the tone or light CS. Relative to the rate of CR acquisition in the rest control group, the reacquisition group showed considerable savings. Furthermore, the cross-modal group showed strong learning to learn. In fact, acquisition to the cross-modal CS was nearly as rapid as reacquisition to the original CS.

1.08.3 Psychophysics

A central question in psychology is, "What is the stimulus for a behavior?" Psychophysical research provides the basic methods, results, and theories for answering how a stimulus input is encoded and transformed in the nervous system to eventuate in a behavioral output. In investigating the psychophysics of animals, discrimination learning and generalization testing have played a central role.

1.08.3.1 Sensory Thresholds

There are two kinds of thresholds: absolute and difference. An absolute threshold is the level of intensity of a stimulus at which a subject is able to detect the presence of the stimulus some proportion of the time, usually 50%. A difference threshold is the magnitude of the difference between two stimuli that a subject is able to detect; again, a 50% criterion is common. Figure 8 shows four examples of psychophysical curves using a combination of discrimination training and generalization testing.

1.08.3.1.1 Absolute thresholds

Figure 8(a) shows generalization tests for detecting a sinusoidal modulation in the amplitude of background noise (Kelly et al., 2006). Rats were trained on a lick suppression task, in which a mild shock to the tongue was signaled by a 3-s modulation of the background noise. Training and testing were then conducted by using combinations of modulation depths and modulation rates. The figure shows the mean percent correct as a function of modulation depths for modulation rates of 10 Hz, 100 Hz, and

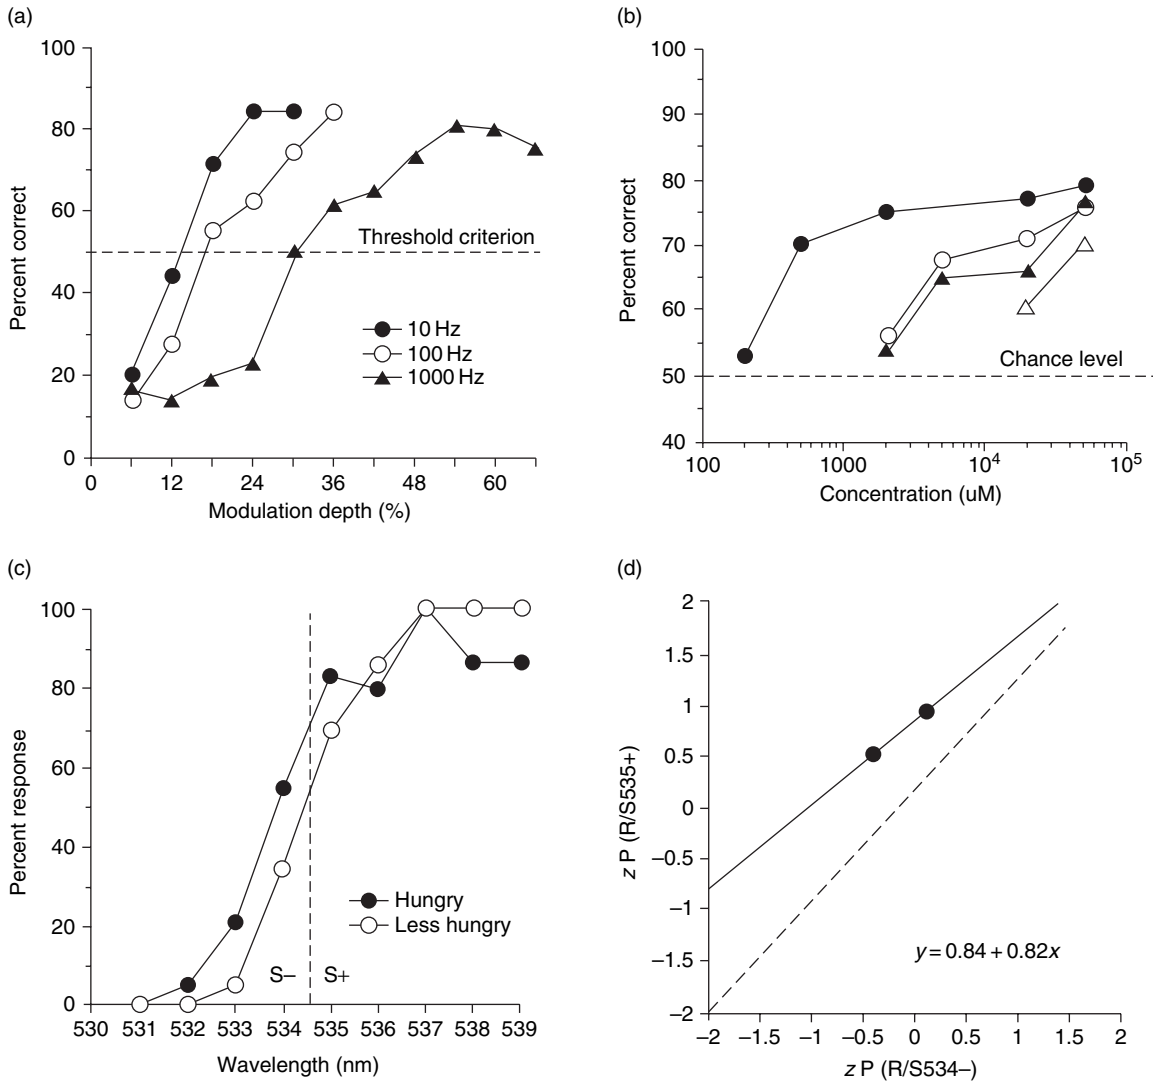

Figure 8 Examples of psychophysical curves. (a) Generalization tests for detection of a sinusoidal modulation in the amplitude of a broadband, background noise by rats (Kelly et al., 2006). (b) Curves of four squirrel monkeys tested for discrimination between increasing dilutions of an androgen-based odorant versus an odorless solvent (Laska et al., 2006). (c) Percent response in pigeons reinforced for pecking at keys of wavelengths of 535 nm and greater (Boneau and Cole, 1967). (d) The relative operating characteristic (ROC) plot for the probability of responding to the 535-nm S+ versus the 534-nm S− (Boneau and Cole, 1967). All figures adapted with permission.

1000 Hz. The absolute threshold for detecting modulation was designated as the point at which the curve for each modulation rate crossed the 50% criterion line. For example, the threshold for detecting a 100-Hz modulation was a 17% depth.

Figure 8(b) shows the individual psychophysical curves of four squirrel monkeys in a choice discrimination task. Specifically, the monkeys were tested for their ability to detect an androgen-based odorant (Laska et al., 2006). On each trial, the monkeys sniffed two strips mounted on two closed food cups. One strip was impregnated with the odorant (S+), and the other with the odorless solvent (S−). The monkeys were then allowed to open one of the cups to discover whether or not it contained the reinforcer. After the initial discrimination was established, training was continued, in which the S+ odorant was progressively diluted until a monkey failed to discriminate it from the solvent. The left-hand point in each curve represents the dilution at which the monkey's choices failed to differ significantly from the 50% chance level.

1.08.3.1.2 Difference thresholds, sensitivity, and criterion

Figures 8(c) and **8(d)** show the results of an experiment aimed at identifying the difference threshold along the color dimension in a pigeon (Boneau and Cole, 1967). The procedure was a combination of discrimination training and generalization testing. A pigeon was reinforced for pecking at wavelengths of 535 nm and above, but not for shorter wavelengths. Two levels of hunger were used on different days. **Figure 8(c)** shows the resulting psychophysical curves, which indicate that the pigeon could detect a difference as small as 1 nm. The pigeon responded more when it was hungrier, displacing the function to the left. However, the slope of the function appeared the same, suggesting that the pigeon's sensitivity to stimulus differences was unaltered. Thus, the hunger is said to bias responding but not sensitivity.

These concepts of sensitivity and bias originate in signal detection theory (SDT) (Suboski, 1967; Blough, 2001b). According to SDT, observed responding results from the joint operation of the subject's ability to detect the stimulus (sensitivity) and their bias to respond (criterion). For a given sensitivity, a change in bias will cause the psychometric function to shift, as seen in **Figure 8(c)** with the effects of hunger. However, a clearer picture of the joint effect of sensitivity and criterion appears in a different type of plot, the relative operating characteristic (ROC). The ROC plots the probability of the target response to S+ against the probability of the response to S−. **Figure 8(d)** shows the ROC for the 535-nm S+ and the 534-nm S− under the two hunger conditions. The two points are plotted on axes scaled in z scores. The two points fall on a line that lies above the diagonal. The distance of the line above the diagonal is a measure of the sensitivity, while the position of the points along the line indicates the criterion. A slope of 1.00 indicates that the sensitivity is constant across the factors that influence the criterion. Conversely, deviations in the slope indicate that a manipulation influences sensitivity. In this case, a slope less than one suggests that, in fact, sensitivity declined as hunger increased.

1.08.3.2 Psychophysics of Memory

Discrimination training and generalization testing have been extended to the study of memory, often using a type of choice discrimination. In the basic version, called delayed matching to sample (DMTS), the subject is presented with one stimulus called the sample. Then, the subject is presented with pair of target stimuli. Choosing the stimulus that matches the sample results in reinforcement (S+), while choosing the other stimulus (S−) does not yield reinforcement. By manipulating the interval between the sample stimulus and target stimuli across trials, short-term memory for the sample stimulus can be mapped.

Figure 9 plots the results of two recent DMTS studies using rats and a single monkey, respectively. The rat study entailed a two-way spatial discrimination (Harper et al., 2006). On each trial, the sample stimulus was a presentation of a retractable bar on one side or the other of a wall in the test chamber. To ensure the sample bar was attended to, the rats were trained to press the bar three times before it was withdrawn. A delay interval of 0.1, 3.0, 9.0, or 18.0 s was then imposed. To prevent the rats from simply facing the location of the sample bar during this interval, they were trained to turn around and press another bar behind them. On completion of the delay, both the left and right bars were inserted into the chamber. As soon as either bar was pressed, the bars were retracted, and if the rat had pressed the previous sample bar, the reinforcer was delivered. As can be seen in **Figure 9**, accuracy in the choice response gradually declined when the delay interval exceeded 3 s, but even after 18 s, the level of performance still exceeded the chance level (50%).

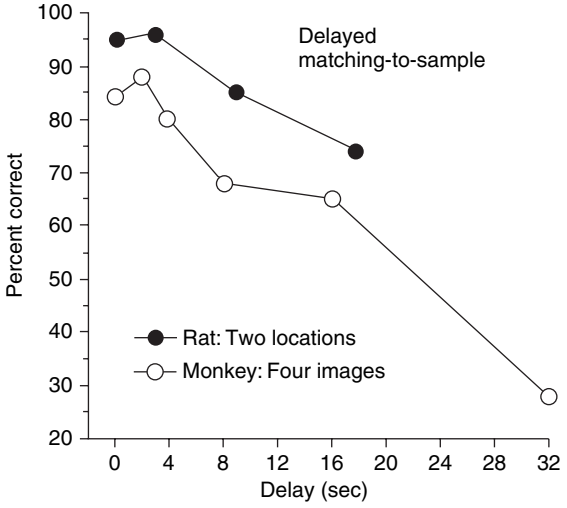

Figure 9 Percent correct choices in delayed-matching-to-sample tasks in rats (Harper et al., 2006) and a monkey (Hampton and Hampstead, 2006) as a function of delay interval between presentation of the sample and choice stimuli. All figures adapted with permission.

The other curve in Figure 9 shows the results obtained from a monkey in a four-way visual discrimination, for which the sample and test stimuli were images of 'clip art' (Hampton and Hampstead, 2006). On each trial, the sample stimulus appeared in the center of a touchscreen. After the monkey contacted this image, one of six delay intervals (0, 2, 4, 8, 16, or 32 s) was imposed. Then, four test stimuli appeared, one in each corner of the screen. Only one of the test stimuli matched the sample stimulus. A large set of images was used such that each image was seen only once in each session, which contained 48 trials. The monkey's performance showed a progressive decline but only sank to its chance level (25%) after a 32-s delay.

1.08.3.3 Psychophysics of Time

Timing is everything, and not just in comedy. Predators must pounce at just the right moment to catch their next meal, suitors must pick the right moment to make their advance, and prey must pick the right moment to dash for cover. Even a widespread, basic protective response like the eyeblink has demands on its timing. A blink that is too early or too late will not protect the eye from injury, and a blink that is too long may effectively blind an individual at a crucial moment.

Figure 10 shows a psychophysical function for stimulus duration (Church and Deluty, 1977). Rats were first trained in a choice discrimination. A press on one bar was reinforced after a 2-s light stimulus, and a press on another bar was reinforced after an 8-s light stimulus. After this training, the rats were tested with stimuli of intermediate durations. The curve in Figure 10 shows the mean percentage of tests in which the rats pressed the bar for the longer, 8-s signal. Under these conditions, the difference threshold was slightly greater than 4 s, a point approximately equal to the geometric mean of the 2-s and 8-s durations used in training.

A wide variety of studies have tracked the time course of responding based on the interval between a stimulus and a reinforcer. These studies have yielded two reliable results that are illustrated in Figure 11. Figure 11(a) shows the time course of an eyeblink CR in four groups of rabbits that were trained with four different intervals between CS onset and US onset, specifically, 125, 250, 500, and 1000 ms (Smith, 1968). The results are based on sporadic test trials in which the CS was presented without the US, and hence without any intrusion from the unconditioned

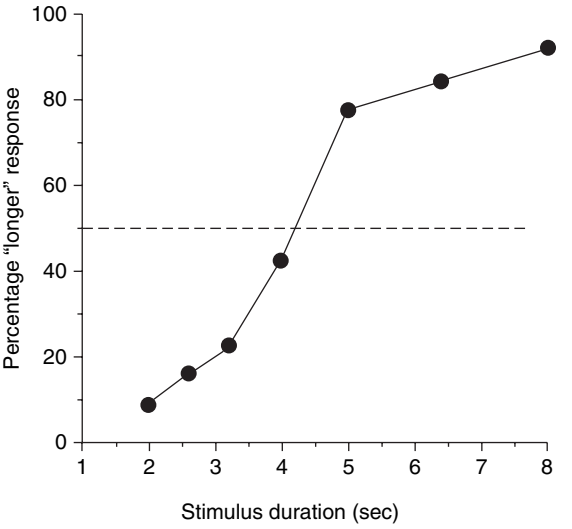

Figure 10 Psychophysical function in for stimulus duration after choice discrimination training in which rats were reinforced for pressing one lever when signaled by a 2-s stimulus and for pressing another lever when signaled by an 8-s stimulus (Church and Deluty, 1977). Figure adapted with permission.

response (UR). Similarly, Figure 11(b) shows the time course of barpress responding in a group of rats that had been trained in a temporal discrimination using a noise and a light (Roberts, 1981). For one stimulus, the first barpress after 20 s elapsed was reinforced by food. For the other stimulus, the first barpress after 40 s was reinforced. The results are based on test trials in which each stimulus was presented for 80 s without the reinforcer. Finally, Figure 11(c) shows the results of a study in which human participants were trained with stimuli of either 8, 12, or 21 s (Rakitin et al., 1998). After exposure to the target stimulus, the participants were asked to press a key when they thought that the appropriate time had passed.

Despite the large differences in the time scales, procedures, and species used in these three studies, responding showed similar temporal patterns. In each case, the peak of responding was well aligned to the interval used in training. Moreover, the variability in the placement of responding increased proportionally as the interval increased. Together, these proportional increases in the time and variability of peak placement are known as the 'scalar property' of timing. The theoretical and neural mechanisms responsible for the acquisition of response timing and its scalar property have been a matter of intensive research and theorizing in recent

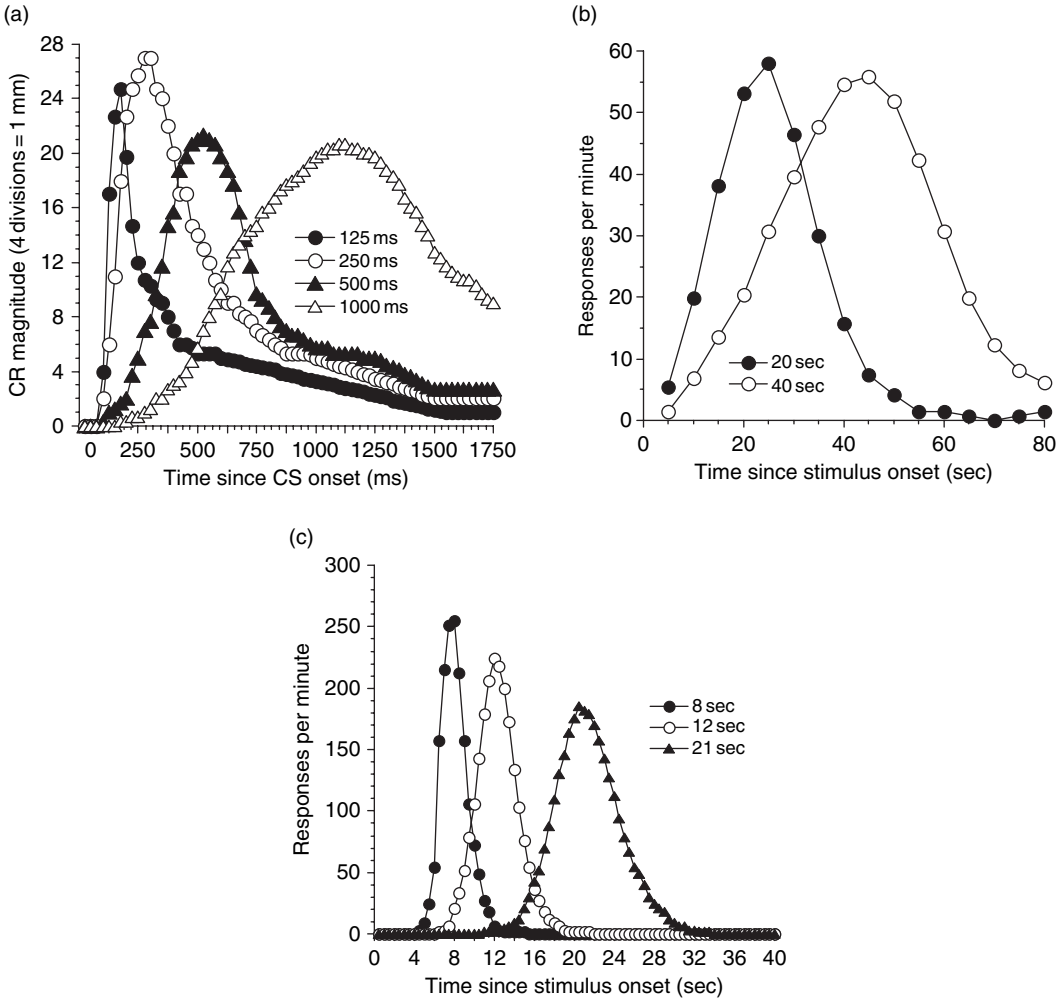

Figure 11 Examples of response timing in (a) rabbit eyeblink conditioning after training with different CS-US intervals (Smith, 1968), (b) barpressing by rats after training with two fixed intervals signaled by different discriminative stimuli (Roberts, 1981), and (c) reproduction of different stimulus intervals by humans (Rakitin et al., 1998). All figures adapted with permission. CS, conditioned stimulus; US, unconditioned stimulus.

years (e.g., Gallistel and Gibbon, 2000; McGann and Brown, 2000; Medina et al., 2000; Buhusi and Meck, 2005).

1.08.4 Excitatory and Inhibitory Learning Processes

Pavlov (1927) borrowed the terms of *excitation* and *inhibition* from neurophysiology to describe the processes underlying rises and falls in conditioned responding. Among other things, he proposed that discrimination learning could entail both excitatory learning for CS+ and inhibitory learning for CS−. Later, Spence (1936, 1937) extended these ideas to generalization testing after discrimination training. He proposed that responding to test stimuli would be influenced jointly by generalization from both S+ and S−. That is, the level of responding to each test stimulus would reflect an algebraic sum of generalized excitation from S+ and generalized inhibition from S−.

1.08.4.1 Transfer Tests of Inhibition

The measurement of inhibitory associative strength has not been a simple matter for two reasons. First, the absence of responding to a CS− may reflect a lack of excitatory learning rather than a negative association. Hence, the level of inhibitory learning

can only be inferred from the ability of the CS− to disrupt excitatory learning in a transfer test. Second, identifying transfer tests that isolate the effect of inhibitory learning from other possible disruptive factors has been difficult (Williams et al., 1992; Papini and Bitterman, 1993).

Two transfer tests have been used in tandem to determine whether a CS has acquired an inhibitory association (Brown and Jenkins, 1967; Rescorla, 1969; Cole et al., 1997). These two tests are known as the *summation* test and the *retardation* test. A candidate CS passes the summation test if it reduces CRs to another excitatory stimulus presented at the same time. Second, the candidate CS passes the retardation test if it shows a slow rate of CR acquisition when paired with the US.

Figure 12 illustrates the results of summation and retardation tests in fear conditioning in rats (Cole et al., 1997). The subjects were first given a discrimination learning task originated by Pavlov (1927), known as the *conditioned inhibition* procedure. Specifically, one stimulus was paired with an aversive US (A+), while a compound of two stimuli was presented alone (AX−). In addition, another stimulus was established as an excitatory stimulus by pairing it with the US (B+). Acquisition of excitatory fear conditioning was indexed by an appetitive response, specifically, licking water from a drinking tube. Thus, the greater the fear, the longer the time needed to complete a specified number of licks.

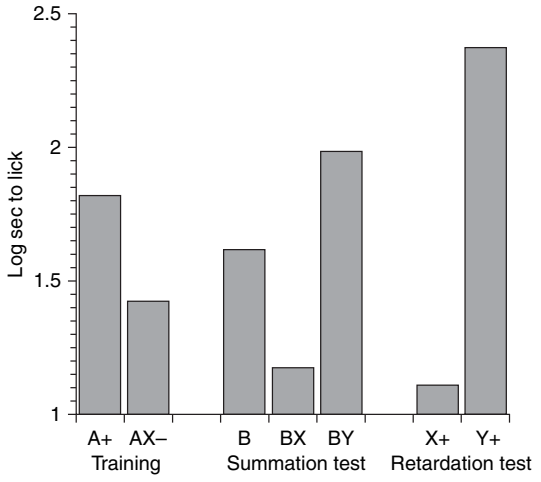

Figure 12 Results of summation and retardation tests after rats were given conditioned inhibition training, in which one stimulus was paired with an aversive US (A+), while a compound of two stimuli was presented alone (AX−). A third stimulus had also been paired with the US (B+), and a fourth stimulus was novel at the time of testing (Y) (Cole et al., 1997). Figure adapted with permission.

As can be seen in the left-hand portion of **Figure 12**, moderate discriminative responding to A+ versus AX− was achieved during initial training. Summation and retardation tests were conducted by splitting the subjects into five groups. For the summation test, one group was tested with the conditioned excitatory stimulus (B), another group was tested with a compound of the B stimulus plus the candidate inhibitor (BX), and a third group was tested with a compound of the B stimulus plus another stimulus (Y) that had not undergone any training (BY). This latter group was included to test whether compounding a neutral stimulus with B would disrupt the fear response. For the retardation test, the fourth group received pairings of the candidate inhibitor with the US (X+), and the fifth group received pairings of the untrained stimulus with the US (Y+).

Examination of **Figure 12** reveals that the candidate inhibitor (X) passed the summation test. That is, the BX compound yielded a lower level of responding than B stimulus alone. This reduction could not be attributed to unlearned effect of another stimulus, because the BY compound elicited a greater response than the B stimulus. Furthermore, the X stimulus also passed the retardation test. After X+ and Y+ pairings, the X stimulus produced a negligible response, while the Y stimulus produced a substantial response.

The two tests for associative inhibition are complementary (Rescorla, 1969). Together, they rule out different sources of response interference that do not reflect associative inhibition. The summation test reveals that the candidate CS has an antagonistic effect on responding to an excitatory stimulus. However, this antagonistic effect could have also occurred through either a division of attention between the two stimuli or a perceptual interaction between the two stimuli that would obscure the excitatory CS. The retardation test rules out these possibilities, because training with a single candidate CS is not subject to such influences from another stimulus. However, the retardation test by itself is not sufficient to demonstrate an inhibitory association, because slow CR acquisition may result from inattention to the CS (Lubow and Moore, 1959; Reiss and Wagner, 1972; Lubow, 1989; Schmajuk et al., 1996) In turn, the summation test guards against inattention, because attention to the candidate CS is needed for it to reduce responding to the excitatory CS.

The expense of conducting a thorough assay for conditioned inhibition like that of Cole et al. (1997) might seem prohibitive. However, more compact

designs are possible, albeit with some risk that multiple tests of the same subjects will alter the results. If four distinctive stimuli can be found, then a single group can be used. The subjects would first receive training identical to that used in Cole et al. (1997), specifically, A+, AX−, and B+. Subsequently, the summation test would be conducted using tests of BX versus B. If the testing, which is usually done without the US, reduces overall responding, refresher training can be conducted. Then, retardation can be assessed by pairing the candidate stimulus X with the US (X+) while a novel stimulus Y is also paired with the US (Y+). If there is mutual generalization between X+ and Y+ trials, this test will be conservative and reduce the differences in acquisition to the stimuli. If only three distinctive stimuli can be identified, then a rest control group or something like it would be needed to conduct the retardation test.

1.08.4.2 Generalization after Discrimination Training

Generalization testing has been used to infer whether or not S− has acquired inhibitory associative strength. Spence (1937) himself conducted experiments aimed at testing whether his theory could explain demonstrations of *transposition* in generalization tests after choice discrimination training. For example, chimpanzees were initially rewarded for selecting the larger of two squares, e.g., 160 cm^2 (S+) versus 100 cm^2 (S−). The subjects were then tested with other pairs of squares. Of particular interest was the pair that contained the S+ (160 cm^2) versus a larger square (256 cm^2). For this pair, the subjects selected the original S+ on only 22% of trials and, conversely, selected the larger square on 88% of the trials. Findings like this suggested that the subjects were learning a relational property of *larger than*.

Spence (1937) argued that the transposition results could be explained by the net amount of excitation and inhibition activated by each stimulus. **Figure 13** illustrates this hypothesis. In the figure, associative strength is plotted as a function of the value of stimuli along a dimension, e.g., size. There is a gradient of generalized excitation around S+ and a gradient of generalized inhibition around S−. The net amount of associative strength activated by any one stimulus is represented by the third gradient, which is the point-by-point algebraic sum of the excitatory and inhibitory strengths. As may be apparent, there is a region of stimulus values that have a larger net associative strength than the S+ (Alberts and Ehrenfreund, 1951; Ehrenfreund, 1952).

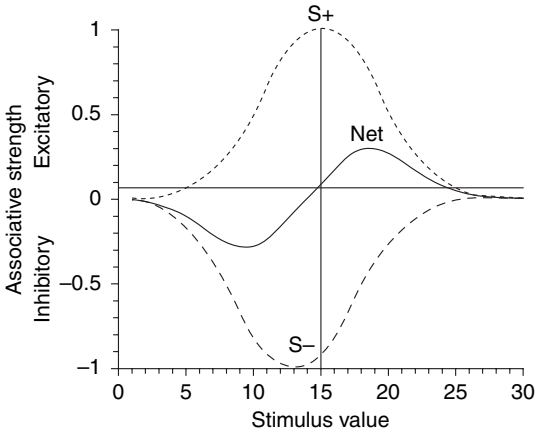

Figure 13 Theoretical net gradient based on hypothetical excitatory and inhibitory generalization gradients established during discrimination training with an S+ and S− along a stimulus dimension.

This hypothesis has also been used to explain the results of generalization testing after go/no-go discrimination training. After training with an S+ and S− along a stimulus dimension, generalization testing can produce asymmetric gradients (Ghirlanda and Enquist, 2003). In some cases, the peak of the gradient is shifted away from S+ (Hanson, 1959). In other cases, the peak of the gradient remains at S+, but the subjects respond more to test stimuli on the S+ side of the dimension than to stimuli on the S− side. This type of result is called an area shift.

Figure 14 shows an example of peak shift in a single horse (Dougherty and Lewis, 1991). Initially, the subject was reinforced with food for pressing a bar during a 60-s S+, which was a 2.5-in (63 mm) circle. After this single-stimulus training, generalization testing was conducted with a series of circles ranging in diameter from 0.5 in (13 mm) to 4.5 in (114 mm). As can be seen in **Figure 14**, the generalization gradient was more or less symmetric and centered on S+. Then, discrimination training was conducted, in which a 1.5-in (38 mm) circle was introduced as S−. After discriminative responding was established, further generalization testing occurred. The resulting gradient was shifted away from S+ and S−, and its peak was located at the 3.0-in (76 mm) circle.

The peak-shift and area-shift phenomena are consistent with the excitation-inhibition hypothesis (Spence, 1937). However, there are well-developed alternative theories that can explain these phenomena without resorting to associative inhibition (Blough,

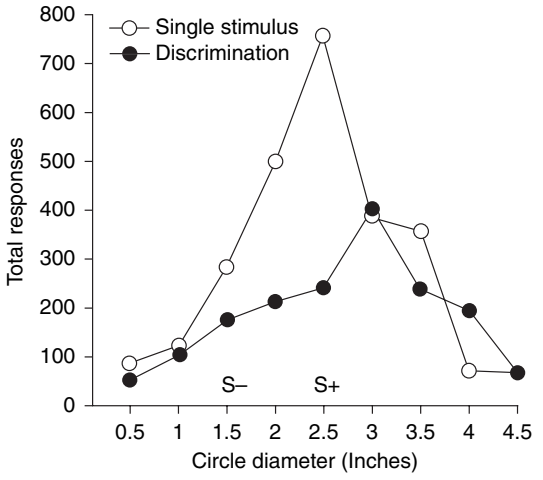

Figure 14 Peak shift after discrimination training. Generalization gradients of an operant response shown by a horse after single stimulus training and subsequent discrimination training along a size dimension (Dougherty and Lewis, 1991). Figure adapted with permission.

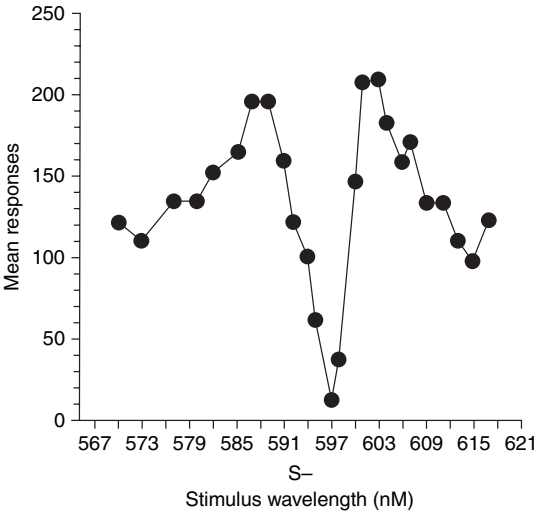

Figure 15 Generalization gradient obtained in pigeons during discrimination training in which keypecking to all stimuli along the wavelength dimension, except one (597 nm), was reinforced (Blough, 1975). Figure adapted with permission.

1975; Ghirlanda and Enquist, 2003). Furthermore, attempts to study generalization gradients during sustained operant training have yielded results contrary to the excitation-inhibition hypothesis (Blough, 1975; Hinson and Termison, 1997).

In these latter studies, discrimination training and generalization testing are conducted simultaneously, much like the psychophysical procedures described previously. Specifically, the subjects, often pigeons, are initially given reinforced training with multiple stimuli along a sensory dimension (e.g., visual wavelength). Once responding has been established to all the stimuli, discrimination training is begun. In positive discrimination training, responding to one stimulus (S+) continues to receive reinforcement, but responding to all the other stimuli along the dimension do not receive reinforcement. In the negative procedure, responding to all of the stimuli, bar one (S−), is reinforced.

Both procedures yield generalization gradients on a sustained basis. The positive discrimination yields a generalization gradient centered on S+. Conversely, the negative discrimination yields what has been described as an inhibitory gradient, in which responding is reduced at the S− value and also at nearby stimulus values (Jenkins and Harrison, 1962). An example of such an inhibitory gradient is shown in **Figure 15**.

The problem for the excitation-inhibition hypothesis arises from the shoulders that appear in the gradients at stimulus values that are at an intermediate distance from S+ or S−. In **Figure 15**, these shoulders appear for the stimulus values around 587 and 603 nm. According to the excitation-inhibition hypothesis, the negative impact of generalized inhibition from S− on responding to the excitatory stimuli should diminish in a smooth fashion. Instead, these contrast effects have been explained by models that do not use the construct of inhibition (Blough, 1975; Hinson and Termison, 1997).

1.08.4.3 Inhibition and Nonassociative Contributions to Responding

Revival of interest in learned inhibition has complicated the methodology of classical conditioning (Rescorla, 1967; Gormezano and Kehoe, 1975). In measuring excitatory conditioning, it would be ideal if each observed response were based entirely on the subject's history with the training manipulations, for example, the number of prior CS-US pairings. Not surprisingly, this ideal has never been achieved. The target response can and does occur during the CS in the absence of any CS-US pairings. The sources of this *nonassociative* responding include spontaneous occurrences of the target response, any innate tendency for the CS to evoke the target response, and pseudoconditioning, which is a sensitization-like effect arising from presentations of the US (Grant, 1943; Gormezano, 1966; Sheafor, 1975). Furthermore, in classical and also operant conditioning, performance of the learned response can be elevated or depressed

by a variety of third factors, e.g., fatigue, satiation, drugs, and individual differences in responsiveness.

In classical conditioning, a suite of control conditions has evolved for determining what proportion of responding during the CS arises from CS-US contiguity versus nonassociative sources. These control conditions traditionally include CS-alone presentations, US-alone presentations, and explicit unpairings of the CS and US. If one's goal is to obtain a pure measure of the excitatory associative strength of CS, then be prepared to be frustrated. None of these control groups provides an unbiased estimate of nonassociative responding. In particular, explicitly unpaired presentations of the CS and US, in which they are well separated in time, can foster inhibitory learning (Rescorla, 1967; Siegel and Domjan, 1971; Napier et al., 1992). Rescorla (1967) advocated a control in which the presentations of the CS and US were randomized in time. However, this truly random control itself can be biased. In particular, CS-US pairings can randomly occur. When they do, they produce excitatory conditioning and thus yield an overestimate of the nonassociative contributions (Ayres et al., 1975). Despite the possible biases, together these controls do guard against a gross overestimation of the excitatory associative effects of CS-US pairings (Kehoe and Macrae, 2002).

The implementation of the full suite of controls in separate groups of subjects dramatically increases the size of an experiment. Each subject, however, can serve as its own nonassociative control by using a discrimination procedure (Schneiderman, 1972; Schneiderman et al., 1987). Specifically, responding to CS+ reflects the total contribution of excitatory associative effects plus any nonassociative contributions. In contrast, responding to CS− would ideally reflect only nonassociative contributions. However, just as with the separate control conditions, this estimate is probably biased in two opposing ways. On the one hand, responding to CS− may be elevated by excitatory generalization from CS+. On the other hand, the explicit unpairing of CS− and the US may promote inhibitory learning that will reduce responding to CS−, and through generalization, it may also reduce responding to CS+. In summary, the difference in responding to CS+ versus CS− will be a conservative estimate of the net associative effect of excitatory and inhibitory associative learning.

1.08.4.4 Commentary

The concept of learned inhibition has been a powerful but elusive concept. Whether a form of negative association is needed to explain any or all of the phenomena remains an open question. Even the results of the conditioned inhibition procedure may be explained without assuming a negative association (Miller and Matzel, 1988). Regardless of the fate of inhibition as a theoretical construct, the empirical phenomena suggestive of inhibition provide a valuable means for investigating the ability of learning mechanisms to regulate responding downward as well upward.

1.08.5 Perception, Attention, and Cognition

Research using discrimination learning and generalization testing has progressively revealed a variety of phenomena that come under the headings of perception, attention, and cognition. There has been – and undoubtedly will continue to be – vigorous debate concerning the value of top-down versus bottom-up explanations. The transposition effect is an early example of a phenomenon that seems to require a top-down explanation, but as seen in excitation-inhibition theory (Spence, 1937), the effect may be explained by an imaginative extension of bottom-up, associative mechanisms. Other chapters in this volume describe in greater detail the theory and research surrounding the increasing number of higher-order phenomena that have been identified. The remainder of this chapter describes some key phenomena that illustrate the application of discrimination and generalization methods in these areas.

1.08.5.1 Compound Stimulus Paradigms

A compound stimulus in its simplest form consists of two elements, often a tone and a light, presented together. By varying the conditions of training for the compound and its elements in relatively small ways, a startling, diverse set of phenomena has appeared. In turn, these phenomena have driven key developments in conditioning theory since the late 1960s (Kamin, 1968; Wagner et al., 1968).

1.08.5.1.1 Compound versus element discriminations

There are four basic discrimination procedures entailing a compound and its elements, which are denoted the *feature-negative, feature-positive, negative patterning,* and *positive patterning* procedures. With the exception of the feature-positive procedure (Jenkins and Sainsbury 1969; Jenkins, 1973), they

originated with Pavlov, who used them to demonstrate both conditioned inhibition (Pavlov, 1927, pp. 68–87) and the perceptual synthesis of stimuli (Pavlov, 1927, p. 144). **Figure 16** depicts examples of the outcomes from these four procedures as seen in rabbit eyeblink conditioning, using a compound of tone and light elements (Kehoe, 1988).

1.08.5.1.1.(i) Feature-negative and feature-positive discriminations **Figures 16(a) and 16(b)** show the acquisition of feature-negative and feature-positive discriminations between a compound versus one of its elements. The feature-negative discrimination is, in fact, the same as used in the conditioned inhibition task. That is, the compound is presented alone (AX−), while one element is paired with the US (A+). Conversely, in the feature-positive procedure, the compound is paired with the US (AX+), and one element is presented alone (A−). The A stimulus is labeled as the *feature cue*, because it is the distinguishing element on AX versus X trials. The X stimulus is labeled as the *target stimulus*. In the experiments described here, the X stimulus was presented sporadically (X test) to determine the level of responding it alone would elicit.

As can be seen, discriminative responding was acquired in both tasks. The feature-negative task yielded a high level of responding on A+ trials, a low level of responding on AX− trials, and virtually no responding on X tests (Marchant et al., 1972; Solomon, 1977). In the feature-positive task, CRs were quickly acquired on AX+ trials, while responding on A− trials grew only slightly (Kehoe and Schreurs, 1986). Tests with the X stimulus revealed that it elicited nearly as much responding as did the AX+ trials.

Both these results have suggested that the level of responding to the compound reflects a summation of the separate associative strengths of the separate elements. Thus, the low level of responding on AX− trials in the feature-negative task can be attributed to the algebraic sum of A's positive strength and

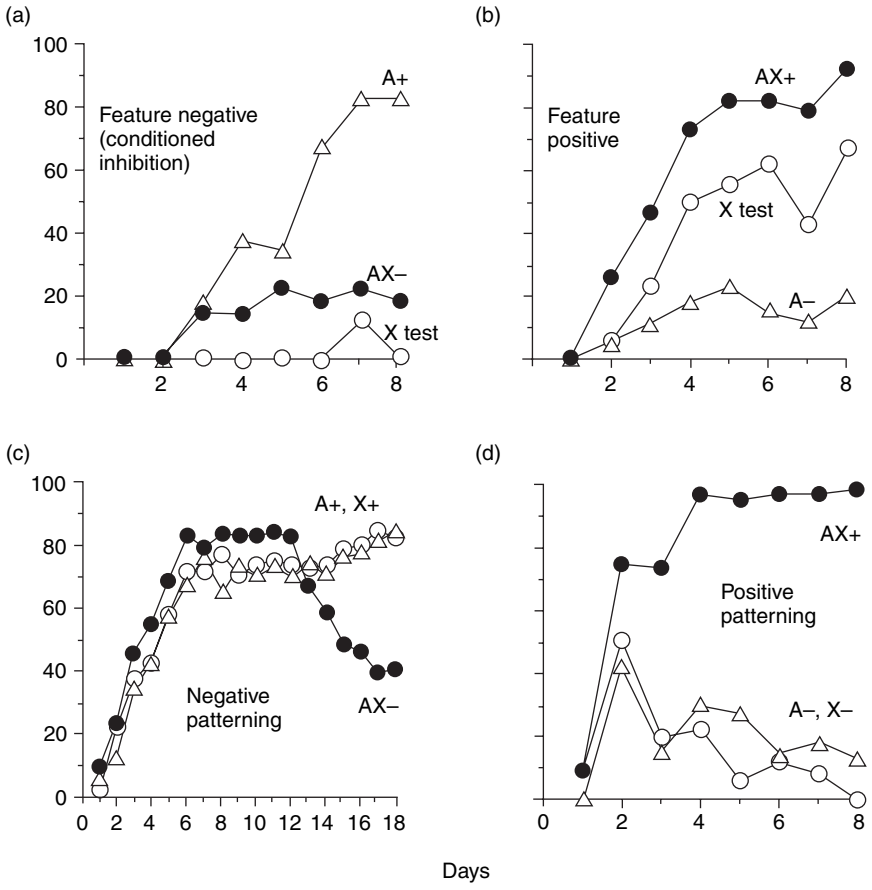

Figure 16 Compound-versus-element discrimination learning in rabbit eyeblink conditioning using tone and light elements (Kehoe, 1988). Figure adapted with permission.

X's unseen negative strength. In the feature-positive case, the high-level responding on AX+ trials can be explained as the sum of the high positive strength of the X stimulus and the low positive strength of the A stimulus. However, this elemental summation seems at most to be true only for cases like these. As will be described below, different processes appear to be engaged when these circumstances are varied (Kehoe and Gormezano, 1980).

1.08.5.1.1.(ii) Negative and positive patterning **Figures 16(c)** and **16(d)** show the results of discrimination training using a compound and both its elements. In these patterning tasks, no element is strictly a feature cue or target stimulus, but for the sake of consistency in exposition, the elements remain labeled as A and X. **Figure 16(c)** shows the results of negative patterning. The early training sessions contained a mixture of trials in which the individual elements were each repeatedly paired with the US (A+, X+). The compound without the US (AX−) was presented only occasionally. Once the CR was established on A+ and X+ trials, more AX− trials were added. By the end of the experiment, each session contained 40 AX− trials, 10 A+ trials, and 10 X+ trials. Responding on AX− trials gradually declined, while responding on A+ and X+ trials was maintained. In contrast to the slow acquisition of negative patterning, discriminative responding (**Figure 16(c)**) emerged rapidly in the positive patterning procedure, in which the compound was paired with the US (AX+), and the elements were not (A−, X−).

Patterning has attracted considerable theoretical interest. In particular, the low level of responding on AX− trials in negative patterning cannot be explained by the summation of the elements' positive associative strengths. Since the first demonstrations of patterning (Pavlov, 1927, p. 144), it has been widely supposed that there is a perceptual synthesis of the elements to form an additional configural stimulus that can acquire its own associative strength, either alongside the elemental associations (Rescorla, 1973; Kehoe, 1988) or in place of them (Bellingham et al., 1985; Pearce, 1987, 1994). As an alternative to configural theories, other theories postulate that elements and compounds have distinctive and shared features. By the appropriate assignment of excitatory and inhibitory strengths to these features, patterning can be explained (Estes and Burke, 1953; Kehoe and Gormezano, 1980; Harris, 2006). Apart from these theoretical debates, patterning procedures have been used in distinguishing the neural substrates for "simple" conditioning for single CSs from the substrates of more complex processes engaged by compound stimuli (Sutherland and Rudy, 1989; Rudy and Sutherland, 1995; O'Reilly and Rudy, 2001).

1.08.5.1.1.(iii) Serial conditional discriminations The discriminations described above all entailed compounds in which the elements were presented simultaneously. There are corresponding tasks that use stimuli presented in a serial fashion to form conditional discriminations. The delayed matching-to-sample task, previously described, is one form of a serial conditional discrimination. **Figure 17** shows the acquisition of discriminative behavior to a target stimulus (X) in three serial procedures, which are denoted, respectively, the *serial feature positive*, the *serial*

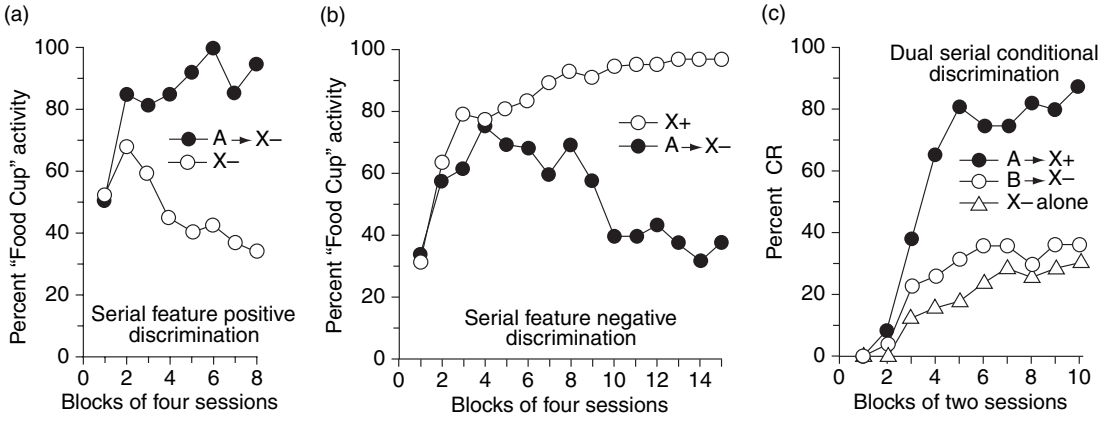

Figure 17 Acquisition of discriminative behavior to a target stimulus (X) in serial conditional discriminations, specifically a feature-positive procedure (a) and a feature-negative procedure (b) in appetitive conditioning of rats (Holland et al., 1999), plus a dual-feature procedure in rabbit eyeblink conditioning (Kehoe et al., 1987). All figures adapted with permission.

feature negative, and the *dual serial conditional* procedures. In the first two cases, the appetitive behaviors of rats for a food reinforcer were measured during the target stimulus (Holland et al., 1999). In the third case, conditioned eyeblinks in rabbits were measured during the target stimulus (Kehoe et al., 1987).

In all three cases, the feature cues (A, B) were presented before the target stimulus (X). This sequencing permits responding during the target stimulus to be measured under the influence of the prior feature cues. To denote this arrangement, the serial feature positive procedure is described as A→X+ versus X−, and the serial feature negative procedure is denoted as A→X− versus X+. For the discriminations shown here, the feature cue was a 5-s light (A) followed by a 5-s gap before the target stimulus (X), which was a 5-s tone. In the third case, both the reinforced and nonreinforced presentations of the X stimulus are preceded by a different feature cue (A→X+ vs. B→X−). In the example shown here, the feature cues were an 800-ms tone and an 800-ms noise. Each feature cue was followed by a gap of 3400 ms, and the target stimulus was a 100-ms light. On reinforced trials, the US was presented 300 ms after the light.

The discriminations shown in **Figure 17** were based on serial compounds in which there was a gap between the feature cue and target stimulus. However, similar discriminations have been established when the feature cues were extended to overlap and even extend past the target stimulus. In rabbit eyeblink conditioning, serial conditional discriminations have been reliably obtained with feature cues up to a minute in length (e.g., Brandon and Wagner, 1991; Macrae and Kehoe, 1995; Weidemann and Kehoe, 1997; Rogers and Steinmetz, 1998).

Serial conditional discriminations have been of interest in addressing several theoretical questions. The control of the feature cue over responding during the target stimulus has been thought to reveal a special type of learning. The feature cues may act indirectly on the ability of the X stimulus to elicit the CR by either (1) exercising superordinate control over memory retrieval, so-called *occasion-setting* (Holland, 1992; Schmajuk and Holland, 1998), (2) evoking an appropriate motivational state for responding (Konorski, 1967; Brandon and Wagner, 1991), or (3) perceptually fusing with the target stimulus in working memory to form a configural stimulus (Kehoe et al., 1987; Brandon and Wagner, 1998; Schmajuk et al., 1998). Finally, like delayed matching to sample, manipulations of the interval between the feature cue and target stimulus have been used to investigate working memory (Holland et al., 1997; Holland, 1998; Weidemann, 1999; Kehoe et al., 2000).

1.08.5.1.2 Compound and element testing

In investigations using compound stimuli, there are two counterparts to generalization testing after single-stimulus training. First, in *compound conditioning*, training is conducted with a compound of stimuli, and these elements are then tested separately. Second, in *stimulus compounding*, two stimuli receive separate training and are then tested by presenting them simultaneously. Since the late 1960s, investigations using compound conditioning have played a key role in the development of associative theories in which the stimuli in a compound compete for attention and/or associative strength (Kamin, 1968; Rescorla and Wagner, 1972; Mackintosh, 1975). Since then, both procedures have been used in a now-massive body of research stimulated by these contending theories, as well as newer ones (Kehoe and Gormezano, 1980; Miller et al., 1995; Wasserman and Miller, 1997; Kehoe, 1998; Blaisdell and Miller, 2001; Pearce and Bouton, 2001; Pearce, 2002).

Compound conditioning and stimulus compounding can be viewed as the endpoints of a continuum in which AX+ trials are intermixed with element trials (A+, X+) in varying proportions. For example, **Figure 18** shows conditioned eyeblink responding in

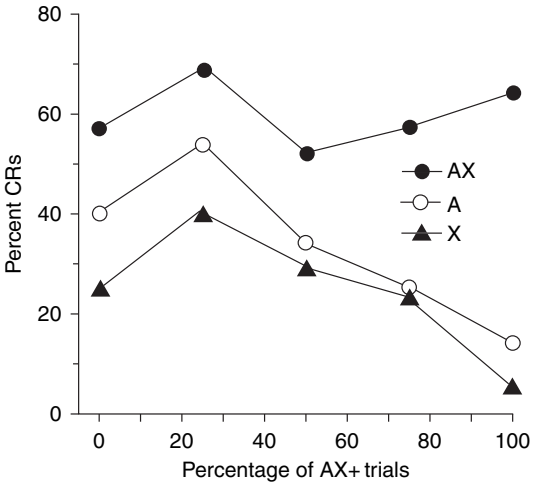

Figure 18 Conditioned eyeblink responding in rabbits to a tone+light compound (AX+) and its elements (A+, X+) as a function of the proportion of AX+ trials relative to A+ and X+ trials (Kehoe, 1986). All figures adapted with permission.

five groups of rabbits, in which the proportion of AX+ trials relative to A+ and X+ trials was varied from 0% (stimulus compounding) to 100% (compound conditioning). The A and X elements were a tone and a light. As shown in **Figure 18**, responding on AX test trials was at a high level across groups. In contrast, responding on A and X test trials was generally lower and progressively declined to negligible levels as the proportion of AX+ trials increased. These results suggest that there was summation of the associative strengths of the elements on AX trials when A+ and X+ pairs predominated. However, as the proportion of AX+ trials increased, a configural stimulus appeared to capture most of the associative strength, thus reducing the level of associative strength possessed by the A and X elements (Kehoe, 1986).

1.08.5.2 Multiple Discrimination Procedures

Multiple discrimination tasks, often presented in succession, have been used to illuminate the perceptual, memorial, navigational, and cognitive abilities of rats and pigeons in the laboratory, as well as other species in more natural environments (Roitblat et al., 1984; Bekoff et al., 2002; Spetch et al., 2003; Blaisdell et al., 2006; Hurley and Nudds, 2006). In the section on basic methods, two examples of multiple discriminations were described. One is the discrimination reversal procedure, in which two stimuli are repeatedly switched in their assignment as S+ and S−. The other is the learning set procedure, in which different pairs of stimuli are successively used as S+ and S−. This section will describe two relatively simple extensions of these procedures used to investigate higher-order processes in learning and memory in animals.

1.08.5.2.1 Overtraining reversal effect

Animals given extended discrimination training can, under many circumstances, acquire reverse discrimination more rapidly than animals given only moderate training (Reid, 1953; Sutherland and Mackintosh, 1971; Orona et al., 1982; Weiner et al., 1986; Van Golf Racht-Delatour and Massioui, 2000). This effect has seemed paradoxical, because basic learning rules predict that extra training should make the original discriminative responding more resistant, not less resistant, to reversal. This paradox has stimulated diverse theoretical accounts (e.g., Lovejoy, 1966; Siegel, 1967; Denny, 1970; Hall, 1974; Mackintosh, 1974). Among them, attentional accounts have been prominent. For example, the additional training may more firmly fix the subject's attention on the relevant stimulus dimension, which would make the reversal a relatively easy matter of switching the specific stimulus-response assignments (Sutherland and Mackintosh, 1971).

1.08.5.2.2 Oddity learning sets

Harlow (1949) argues that learning to learn "transforms the organism from a creature that adapts to a changing environment by trial and error to one that adapts by seeming hypothesis and in-sight." In this respect, learning set research foreshadows more recent investigations of the cognitive abilities of animals (Kamil, 1987). Research using the learning set procedure has, among other things, produced evidence that animals can acquire what appear to be abstract concepts (Delius, 1994; Thomas, 1996).

One example of such concept acquisition is found in oddity learning. In oddity learning, each problem involves a choice between three stimuli, two alike and one different. Selecting the different stimulus is reinforced. As is the case in the more familiar two-stimulus problems, the subjects initially show gradual improvement over trials in their ability to select the correct stimulus. The subject is said to have acquired an oddity concept when it selects the correct stimulus on the first trial of each problem, prior to any reward or nonreward for that set of stimuli. In fact, after extensive experience with oddity problems, correct choices of the odd stimulus on the first encounter with a new set of stimuli do emerge in primates (e.g., Thomas and Frost, 1983). Among nonprimate species, there has been a recent demonstration of above-chance performance on the first trial of visual oddity problems in a seal (Hille et al., 2006). However, for rats, first-trial selections of the odd stimulus have not as yet proved reliable using either visual or olfactory stimuli (Thomas and Noble, 1988; Bailey and Thomas, 1998).

1.08.5.3 Reinforcer-Related Discriminations

1.08.5.3.1 Sequential effects

Reinforcers are sensory events and thus can serve as cues in learning tasks just as well as tones and lights. In operant fixed-interval training, for example, the delivery of a reinforcer is often the only external cue for timing the next interval. Similarly, in other forms of conditioning, food has been used to signal food (Goddard, 1997), shock has been used to signal shock

(Schreurs and Alkon, 1990), water has been used to signal shock (Gormezano and Tait, 1976), and shock has been used to signal water (Gormezano and Tait, 1976).

Reinforcers have also been used extensively as feature cues in serial conditional discriminations (Capaldi, 1994). The most well-developed examples of this use may be found in investigations of the sequential features of reinforcement schedules in instrumental runway tasks using rats. These studies have revealed that the episodic memory of a reinforcer on one trial can control responding on succeeding trials. The simplest sequential effect is seen in the single alternation schedule, in which reinforced trials (R) are strictly alternated with nonreinforced trials (N). From trial to trial, the external events remain the same. If the apparatus is considered the target stimulus (X), then the single alternation schedule can be viewed as a serial conditional discrimination involving N→X+ versus R→X− trials. Through studies using variations on this basic discrimination task, the qualitative and quantitative features of reinforcers on one or more trials have been found to be effective conditional cues (Capaldi, 1994; Fountain and Benson, 2006).

1.08.5.3.2 Differential outcomes effect

The use of different reinforcers can aid discrimination learning. In the original demonstration of this effect (Trapold, 1970), two groups of rats were trained using a conditional choice discrimination. On each trial, both groups were presented with two bars to press. On half the trials, a tone (A) was presented, and presses on the right bar were reinforced. On the other half of the trials, a clicking sound (B) was presented, and presses on the left bar were reinforced. In the experimental group, different reinforcers – a food pellet and sucrose solution – were used on the A and B trials. For half the rats in this group, the two reinforced sequences were A→Right→Food and B→Left→Sucrose. The other half of the rats received sucrose on A trials, and food on B trials. In contrast, the control group received the same reinforcer on both A and B trials. Thus, half the rats in this group received the reinforced sequences of A→Right→Food and B→Left→Food. The other half of the control group received sucrose as the reinforcer.

As can be seen in **Figure 19**, the experimental group showed both faster acquisition of the correct responses and a higher asymptote of correct responding than the control group. This facilitation of discrimination learning and its terminal accuracy by using differential outcomes has been widely replicated in birds (Jones and White, 1994; Poling et al., 1996), horses (Miyashita et al., 2000), and humans (Overmier et al., 1999; Estevez et al., 2001). As well as using qualitatively different reinforcers, the effect has been obtained using different probabilities of food presentation, durations of food presentation, and locations of the food dispenser (see Jones and White, 1994, for a brief review).

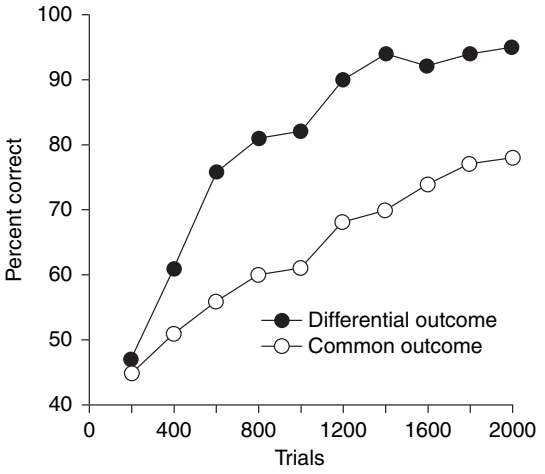

Figure 19 Acquisition of a choice discrimination in rats trained with different reinforcers (differential outcome) or the same reinforcer (common outcome) for the two responses (Trapold and Overmier, 1972). Figure adapted with permission.

The differential outcome effect and similar results have been variously attributed to 'expectancy learning,' 'prospective memory,' and 'response-outcome associations' (Rescorla, 1992; Overmier et al., 1999; Donahoe and Burgos, 2000). To objectify these notions, it has been noted that, during the reinforced sequences, the feature cue is effectively paired with the reinforcer just as in classical conditioning (Trapold and Overmier, 1972). Subsequently, like CR acquisition, the feature cue could elicit a central state describable as an expectancy or prospective memory of the reinforcer. If these central states are at all salient, they could act as additional cues that aid discriminative responding in the experimental group but interfere with discriminative responding in the control group. For example, a food-related state can be denoted X, and a sucrose-related state can be denoted Y. In subjects receiving differential outcomes, these central cues would be distinctive for each reinforced sequence, specifically, AX→Right→Food versus BY→Left→Sucrose. In contrast, for the control

group, the reinforced sequences have a common element, for example, AX→Right→Food and BX→Left→Food.

In one demonstration that expectancies acquired through classical conditioning may be responsible for the differential outcome effect, rats were first trained in a differential outcomes procedure using, once again, tone and clicker cues (A, B), plus food and sucrose as the reinforcers (Kruse et al., 1983). Second, in a different box without the operant bars, the same rats were given pairings of a white noise stimulus (C) with either food or sucrose. Third, the rats were returned to the choice discrimination task, but on test trials, the C stimulus was substituted for the A and B cues. In line with expectancy theory (Trapold and Overmier, 1972), a C stimulus that had been paired with the food caused the rats to press the bar that had been reinforced with food. Likewise, the C stimulus that had been paired with sucrose caused the rats to press the bar that had been reinforced with sucrose.

1.08.6 Conclusion

The uses of discrimination learning and generalization testing are limited only by the imagination of the investigator. This article is only a sampler of the methods that have been used and their major results. Although this article was intended to be atheoretical, it was necessary to delve into some theoretical issues in order to place particular methods in their wider context. The reader should not make any inferences about the relative merits of any particular theory and should consult wider literature cited here to understand the fully range of research and theory surrounding a specific topic. In conclusion, this article should serve as a point of departure for investigators who wish to adapt these methods to address their interests.

1.09 Extinction: Behavioral Mechanisms and Their Implications

M. E. Bouton and A. M. Woods, University of Vermont, Burlington, VT, USA

Extinction is one of the best-known phenomena in all of learning theory. In Pavlovian learning, extinction occurs when the conditioned stimulus (CS) that has been associated with a biologically significant event (unconditioned stimulus, US) is now presented repeatedly without the US. In operant or instrumental learning, extinction occurs when an action or behavior that has been associated with a reinforcer is no longer reinforced. In either case, the learned performance declines. Extinction is important because it allows behavior to change and adapt as the environment also changes. Despite its fame and importance, however, it is not necessarily obvious how extinction works. One surprisingly common idea is that extinction involves the destruction of what was originally learned. Although this idea is built into several models of learning and memory (e.g., Rescorla and Wagner, 1972; McClelland and Rumelhart, 1985; see also McCloskey and Cohen, 1989), there is ample evidence that much of the original learning survives extinction (e.g., see Rescorla, 2001; Bouton, 2002, 2004; Myers and Davis, 2002; Delamater, 2004). This chapter selectively reviews results and theory from the behavioral literature in an effort to understand what is learned in extinction, what causes extinction, and how we can use our understanding of extinction to address certain clinical issues outside the laboratory.

There has been renewed interest in extinction in recent years. One reason is that as neuroscientists have made progress in understanding the brain mechanisms behind acquisition processes in learning (e.g., *See* Chapters 1.36, 3.23, 4.11), they have naturally turned their attention to extinction and inhibition too. A detailed review of the biological work is beyond the scope of this chapter, although we consider some of its implications in the final sections. Another reason for renewed interest in extinction is that it is now clearly understood to be part of cognitive behavioral therapy. That is, in clinical settings, extinction is often the basis of treatment that is used to effectively eliminate maladaptive behaviors, thoughts, or emotions (e.g., Bouton, 1988; Conklin and Tiffany, 2002). However, as this chapter highlights, extinction does not result in a permanent removal of the behavior but instead leaves

the organism vulnerable to relapse. This conclusion provides one illustration of how basic research on extinction provides information that is practically important.

The first part of this chapter introduces several extinction phenomena that any adequate theory of extinction will need to explain and accommodate. These phenomena suggest that extinction does not destroy the original learning, but instead involves new learning that is at least partly modulated by the context. They also potentially contribute to lapse and relapse effects that may occur after extinction therapies. The second part of the chapter then asks: if extinction is an example of new learning, what events reinforce or cause it? We come to the conclusion that extinction is mainly caused by generalization decrement and by new learning caused by the violation of an expectancy of reinforcement. The third part of the chapter takes knowledge from the first two sections and asks what can be done to optimize extinction learning in a way that eliminates the possibility of relapse. Our discussion in the first two sections expands and updates discussions in Bouton (2004); the last section updates a discussion in Bouton et al. (2006b).

1.09.1 Six Recovery Effects after Extinction

A number of experimental manipulations can be conducted after extinction that cause the extinguished response to return to performance. All of them are consistent with the idea that extinction involves new learning, and it therefore leaves the CS with two available meanings or associations with the US. As is true for an ambiguous word, the context is crucial in selecting between them.

1.09.1.1 Renewal

The renewal effect is perhaps the most fundamental postextinction phenomenon. In this effect (e.g., Bouton and Bolles, 1979a; Bouton and King, 1983), a change of context after extinction can cause a robust return of conditioned responding. Several versions of the renewal effect have been studied, but all cases of it support the idea that (1) extinction does not destroy the original learning and (2) the response triggered by the extinguished CS depends on the current context. In the most widely studied version, ABA renewal, conditioning is conducted in one context (Context A) and extinction is then conducted in a second one (Context B). (The contexts are typically separate and counterbalanced apparatuses housed in different rooms of the laboratory that differ in their tactile, olfactory, and visual respects.) When the CS is returned to the original conditioning context (Context A), responding to the CS returns (e.g., Bouton and Bolles, 1979a; Bouton and King, 1983; Bouton and Peck, 1989). In a second version, ABC renewal, conditioning is conducted in Context A, extinction is conducted in Context B, and then testing is conducted in a third, "neutral" context – Context C. Here again, a renewal of responding is observed (e.g., Bouton and Bolles, 1979a; Bouton and Brooks, 1993; Harris et al., 2000; Duvarci and Nader, 2004). In a final version, AAB renewal, conditioning and extinction are both conducted in the same context (Context A) and then the CS is tested in a second context (Context B). Here again, conditioned responding returns (e.g., Bouton and Ricker, 1994; Tamai and Nakajima, 2000), although there is currently less evidence of this type of renewal in operant than in Pavlovian conditioning (e.g., Nakajima et al., 2000; Crombag and Shaham, 2002).

Research on the renewal effect has helped us understand how contexts control behavior—in addition to understanding extinction itself. Several facts about the renewal effect are worth noting. First, it has been observed in virtually every conditioning preparation in which it has been investigated (see, e.g., Bouton, 2002, for a review). Second, it can occur after very extensive extinction training. In fear conditioning (conditioned suppression) in rats, Bouton and Swartzentruber (1989) observed it when 84 extinction trials followed eight conditioning trials. Other evidence suggests that it can occur after as many as 160 extinction trials (Gunther et al., 1998; Rauhut et al., 2001; Denniston et al., 2003), although at least one report suggests that it might not survive an especially massive extinction treatment (800 extinction trials after eight conditioning trials; Denniston et al., 2003). Third, the role of the context is different from the one anticipated by standard models of classical conditioning (e.g., Rescorla and Wagner, 1972; Pearce and Hall, 1980; Wagner, 1981; Wagner and Brandon, 1989, 2001). Those models accept the view that the context is merely another CS that is presented in compound with the target CS during reinforcement or nonreinforcement. It therefore enters into simple excitatory or inhibitory associations with the US. In the ABA renewal effect, for example, Context A might acquire excitatory associations with the US, and Context B might acquire

inhibitory associations. Either kind of association would summate with the CS to produce the renewal effect (inhibition in B would reduce responding to the CS, whereas excitation in A would enhance it). However, a number of experiments have shown that the renewal effect can occur in the absence of demonstrable excitation in Context A or inhibition in Context B (e.g., Bouton and King, 1983; Bouton and Swartzentruber, 1986, 1989). These findings, coupled with others showing that strong excitation in a context does not influence performance to a CS unless the CS is under the influence of extinction (described later; Bouton, 1984; Bouton and King, 1986), suggest that direct associations in a context are neither necessary nor sufficient for a context to influence responding to a CS. The implication (e.g., Bouton, 1991b; Bouton and Swartzentruber, 1986) is that the contexts modulate or set the occasion for the current CS–US or CS–no US association (e.g., Holland, 1992; Swartzentruber, 1995; Schmajuk and Holland, 1998). Put another way, they activate or retrieve the CS's current relation with the US (*See* Chapter 1.05).

Another fact about renewal is that it appears to be supported by many kinds of contexts, including physical, temporal, emotional, and physiological ones (e.g., Bouton, 2000). For example, when fear extinction is conducted in the interoceptive context provided by benzodiazepine tranquilizers chlordiazepoxide and diazepam, renewed fear was observed when the rat was tested in the original nondrug state (Bouton et al., 1990). Cunningham (1979) had reported compatible evidence with alcohol, and we have recently collected similar observations with the benzodiazepine midazolam. State-dependent learning or retention can be conceptualized as the drug playing the role of context (e.g., Overton, 1985).

A further important characteristic of the renewal effect is that it implies that extinction learning is more context specific than original conditioning. This asymmetry in context dependence between conditioning and extinction must be true if one observes ABC and AAB renewal; in either case, conditioning transfers better to the final test context than extinction does. There is typically no measurable effect of switching the context after conditioning on responding to the CS in either fear or appetitive conditioning paradigms (e.g., Bouton and King, 1983; Bouton and Peck, 1989). This is also true of taste aversion learning (e.g., Rosas and Bouton, 1998) and human causal learning, in which humans are asked to judge the causal relationship between cues and outcomes presented over a series of trials (e.g., Rosas et al., 2001). The presence of the renewal effect indicates that extinction, on the other hand, is especially context specific. Some research suggests that both conditioning and extinction become somewhat context specific after extinction has occurred (Harris et al., 2000). However, there is little question that extinction comes under relatively more contextual control than original conditioning.

The reason for the difference in the context dependence of conditioning and extinction has been the subject of recent research. Given the similarities between extinction and inhibition, Bouton and Nelson (1994) and Nelson and Bouton (1997) asked whether pure inhibition (as acquired in the feature-negative paradigm, in which a CS is paired with the US when it is presented alone, but not when it is combined with an inhibitory CS) was context specific. Inhibition acquired by the inhibitory CS transferred without disruption to a new context; thus, extinction is not context specific merely because it is a form of inhibition. A second reason why extinction might be context specific is that it is the second thing the organism learns about the CS. Nelson (2002) confirmed that excitatory conditioning (tone–food pairings) transferred undisturbed across contexts, unless the tone had first been trained as a conditioned inhibitor, as discussed earlier, in the feature-negative paradigm. Conversely, inhibition to a conditioned inhibitor also transferred across contexts unless the CS had first been trained as a conditioned excitor (through tone–food pairings). Thus, regardless of whether the association was excitatory or inhibitory, the second thing learned was more context specific than the first (cf. Rescorla, 2005). Compatible data had been shown by Swartzentruber and Bouton (1992), who found that excitatory conditioning was context specific if it had been preceded by nonreinforced preexposure to the CS.

The evidence therefore suggests that the learning and memory system treats the first association as context free, but the second association as a kind of context-specific exception to the rule. (The main exception to the second-association rule is latent inhibition, in which the first phase can be shown to exert a context-dependent influence on the second phase (e.g., Hall and Channell, 1985), despite the fact that it is arguably the first thing learned. Latent inhibition is unique, however, in that the CS is not paired with anything significant in the first phase. One possibility, therefore, is that the CS is in part encoded as a feature of the context, making it difficult to extract it from that context when it is paired with the US in Phase 2 (cf. Gluck and Myers, 1993).)

There may be functional reasons for this (Bouton, 1994). A conditioning trial provides a sample from which an animal may make inferences about the state of the world (e.g., Staddon, 1988). Statistically, if the world is composed of two types of trials (CS–US and CS–no US), then the probability of sampling a particular type of trial will reflect its true prevalence in the world. Therefore, an early run of conditioning trials would reflect its high incidence in the population; a subsequent trial of another type might reflect an exception to the rule. Learning and memory may thus be designed to treat second-learned information as conditional and context-specific. At a more mechanistic level, recent research in human predictive learning (Rosas and Callejas-Aguilera, 2006) and in taste-aversion learning with rats (Rosas and Callejas-Aguilera, 2007) suggests that ambiguity introduced by conflicting information in Phase 2 leads the participants to pay attention to the context. The key finding is that after conflicting information about one CS or predictor is introduced, other subsequently learned associations are context dependent, even if they are entirely new or learned in a separate context. Thus, the introduction of a competing, conflicting association appears to encourage the participant to pay attention to all contexts.

It is worth concluding this section by noting the direct relevance of the renewal effect to exposure therapy in humans. Several studies have now shown that an exposure treatment that diminishes fear of spiders in one context (a room or a patio outdoors) can still allow a renewal of the fear when exposure to the spider was tested in the other context (Mystkowski et al., 2002; see also, e.g., Mineka et al., 1999; Vansteenwegen et al., 2005). Similar renewal has also been reported in the study of cue exposure therapy with both alcohol (Collins and Brandon, 2002) and cigarette users (Thewissen et al., 2006). Both types of participants reported a renewed urge to use the drug when tested in a context that was different from the one in which exposure to drug-related cues (e.g., visual and/or olfactory cues associated with the drug) had taken place; the alcohol participants also demonstrated renewal of a salivation response. All such results suggest limits to the effectiveness of cue exposure therapy (see also Conklin, 2006). However, renewal effects can be attenuated if the participant is reminded of extinction just prior to the renewal test. Collins and Brandon (2002) found that presenting explicit cues (a unique pencil, eraser, and clipboard) that had been a feature of the extinction context reduced renewal of the aforementioned reactivity to alcohol cues. Mystkowski et al. (2006) reported that renewal of spider fear could be decreased if human participants mentally reinstated (imagined) stimuli from the treatment context before being tested in a different context. Both studies extended earlier findings that the renewal effect can be reduced in rats if cues that were part of the extinction context were later presented before the test (Brooks and Bouton, 1994). Renewal can be viewed as due to a failure to retrieve extinction outside the extinction context (*See* Chapter 1.05). Retrieval cues can provide a "bridge" between the extinction context and possible relapse contexts which allows for the generalization of extinction learning between the contexts (see Bouton et al., 2006b).

1.09.1.2 Spontaneous Recovery

Pavlov (1927) first observed spontaneous recovery, another well-known postextinction effect that involves recovery of the conditioned response as time passes following extinction. There are several available explanations of spontaneous recovery (for a discussion, see Brooks and Bouton, 1993; Devenport et al., 1997; Robbins, 1990; Rescorla, 2004a), and it seems likely to be multiply determined. However, we have argued (e.g., Bouton, 1988, 1993) that just as extinction is relatively specific to its physical context, it may also be specific to its temporal context. The passage of time might also bring about changes in internal and external stimulation that provide a gradually changing context. Spontaneous recovery can be seen as the renewal effect that occurs when the CS is tested outside its temporal context. Both are due to a failure to retrieve memories of extinction outside the extinction context. Consistent with this perspective, a cue that is presented intermittently during the extinction session and again just before the final test (an 'extinction cue') can attenuate both spontaneous recovery and renewal by reminding the subjects of extinction (Brooks and Bouton, 1993, 1994; Brooks, 2000). Interestingly, changing the physical and temporal contexts together can have a bigger effect than changing either context alone, as if their combination creates an even larger context change (Rosas and Bouton, 1997, 1998).

A series of experiments in appetitive conditioning with rats further suggests that temporal context can include the intertrial interval (ITI), the time between successive extinction trials (Bouton and García-Gutiérrez, 2006). Previous experiments had shown

that rats that received extinction trials spaced by either 4-min or 16-min ITIs showed equivalent spontaneous recovery when tested 72 h later (Moody et al., 2006). However, when the retention interval was 16 min rather than 72 h (Bouton and García-Guiterrez, 2006), rats that had received extinction trials separated by the 4-min interval showed spontaneous recovery, whereas rats that had received the extinction trials separated by the 16-min interval did not. These results are consistent with the possibility that the ITI was coded as part of the extinction context. Thus, analogous to a renewal effect, conditioned responding returned when the animals were tested after an interval between trials that differed from the ITI that was used in extinction. However, a mismatch between the extinction ITI and the retention interval is not always sufficient to produce renewal; rats that received extinction trials spaced by 16 min and then received a short retention interval of 4 min failed to show spontaneous recovery. This anomaly is consistent with results that emerged in discrimination experiments in which the different ITIs were used as signals about whether or not the next CS presentation would be reinforced (see Bouton and García-Gutiérrez, 2006). Specifically, rats readily learned that a 16-min ITI signaled reinforcement of a CS, whereas a 4-min ITI did not. In contrast, they had considerably more difficulty learning that a 4-min ITI signaled reinforcement and a 16-min ITI did not. The results suggest that there are interesting constraints on how the interval between trials may be coded and/or used as a context.

1.09.1.3 Rapid Reacquisition

A third effect further indicates that conditioning is not destroyed in extinction. In rapid reacquisition, when CS–US pairings are reintroduced after extinction, the reacquisition of responding can be more rapid than initial acquisition with a novel CS (e.g., Napier et al., 1992; Ricker and Bouton, 1996; Weidemann and Kehoe, 2003). Although such an effect again suggests that the original learning has been 'saved' through extinction, the early literature was often difficult to interpret because many early designs were not equipped to rule out less interesting explanations (see Bouton, 1986, for a review). To add to the complexity, studies of fear conditioning (conditioned suppression) (Bouton, 1986; Bouton and Swartzentruber, 1989) and flavor aversion learning (Danguir and Nicolaidis, 1977; Hart et al., 1995) have shown that reacquisition can be slower than acquisition with a new CS. (It is more rapid than initial acquisition with a CS that has received the same number of nonreinforced trials without conditioning (Bouton and Swartzentruber, 1989).) In fear conditioning, slow reacquisition requires extensive extinction training; more limited extinction training yields reacquisition that is neither fast nor slow (Bouton, 1986). At least part of the reason these preparations support slow reacquisition is that both typically involve very few initial conditioning trials. In contrast, procedures in which rapid reacquisition has been shown (conditioning of the rabbit nictitating membrane response (NMR) and rat appetitive conditioning) have usually involved a relatively large number of initial conditioning trials. Consistent with a role for number of trials, Ricker and Bouton (1996) demonstrated that slow reacquisition occurred in an appetitive conditioning preparation when the procedure used the number of conditioning and extinction trials that had been used in previous fear conditioning experiments. In rabbit NMR and heart rate conditioning, extensive extinction training has abolished rapid reacquisition, although slow reacquisition has yet to be observed (Weidemann and Kehoe, 2003).

Ricker and Bouton (1996) suggested that rapid reacquisition may partly be an ABA renewal effect that occurs when the animal has learned that previous USs or conditioning trials are part of the original context of conditioning. That is, when CS–US pairings are resumed after extinction (a series of CS–no US trials), they return the animal to the original conditioning context. The hypothesis is compatible with Capaldi's (1967, 1994) sequential analysis of extinction, which has made excellent use of the idea that responding on a particular trial is determined by how the animal has learned to respond in the presence of similar memories of previous trials. Presumably, conditioning preparations that employ a relatively large number of conditioning trials (e.g., rabbit NMR) allow many opportunities for the animal to learn that previous reinforced trials are part of the context of conditioning. Furthermore, Ricker and Bouton (1996) reported evidence that high responding during the reacquisition phase was more likely after a reinforced than a nonreinforced trial, which had signaled conditioning and extinction, respectively.

Bouton et al. (2004) reasoned that if rapid reacquisition is caused by recent reinforced trials generating ABA renewal, then an extinction procedure that includes occasional reinforced trials among many nonreinforced trials should slow down rapid

reacquisition by making recent reinforced trials part of the context of both conditioning and extinction. Consistent with this hypothesis, a very sparse partial reinforcement procedure in extinction slowed reacquisition compared to a group that had received simple extinction. Evidence of a similar slowed reacquisition effect has also been obtained in instrumental conditioning (Woods and Bouton, 2007) when a lever-press response was sparsely reinforced during extinction and then paired again more consistently with the reinforcer. Such a result is consistent with the idea that rapid reacquisition is at least partly an ABA renewal effect. Because the partial reinforcement treatment involved many more CS–US (or response–reinforcer) pairings than simple extinction, it is difficult to reconcile with the view that rapid reacquisition is a simple function of the strength of an association that remains after extinction (e.g., Kehoe, 1988; Kehoe and Macrae, 1997). Slowing rapid reacquisition of an instrumental response may be especially relevant from a clinical perspective, because instrumental learning is often involved in maladaptive behaviors such as substance abuse (e.g., Bouton, 2000). The evidence suggests that extinction (i.e., strict abstinence) might not be the most effective treatment to prevent relapse in all situations (cf. Alessi et al., 2004). A more successful technique might be one that permits occasional reinforcers during treatment (e.g., see Sobell and Sobell, 1973; Marlatt and Gordon, 1985) and therefore provides a bridge between the extinction and testing contexts (see also Bouton et al., 2006b).

1.09.1.4 Reinstatement

A fourth context-dependent postextinction phenomenon is reinstatement. In this effect, the extinguished response returns after extinction if the animal is merely reexposed to the US alone (e.g., Pavlov, 1927; Rescorla and Heth, 1975; Bouton and Bolles, 1979b). If testing of the CS is contemporaneous with US delivery, then the USs may cause a return of responding because they were encoded as part of the conditioning context (as earlier; see Reid, 1958; Baker et al., 1991; Bouton et al., 1993). On the other hand, in many studies of reinstatement, testing is conducted at an interval of at least 24 h after US reexposure; here one still observes reinstatement compared to controls that were not reexposed to the US (e.g., Rescorla and Heth, 1975; Bouton and Bolles, 1979b). In this case, evidence strongly suggests that the effect is due to conditioning of the context. When the US is presented after extinction, the organism associates it with the context; this contextual conditioning then creates reinstatement. For example, if the reinstating USs are presented in an irrelevant context, there is no reinstatement when the CS is tested again (e.g., Bouton and Bolles, 1979b; Bouton and King, 1983; Bouton, 1984; Baker et al., 1991; Wilson et al., 1995; Frohardt et al., 2000). Independent measures of contextual conditioning also correlate with the strength of reinstatement (Bouton and King, 1983; Bouton, 1984). Recent evidence that the effect in fear conditioning is abolished by excitotoxic lesions of the bed nucleus of the stria terminalis (Waddell et al., 2006), a brain area thought to control anxiety (e.g., Walker et al., 2003), suggests that in the fear-conditioning situation, at least, the effect may be mediated by anxiety conditioned in the context. Also, if the animal receives extensive extinction exposure to the context after the reinstatement shocks are presented, reinstatement is not observed (Bouton and Bolles, 1979b; Baker et al., 1991). These results indicate that mere reexposure to the US is not sufficient to generate reinstatement. It is necessary to test the CS in the context in which the US has been reexposed.

This effect of context conditioning is especially potent with an extinguished CS. For example, Bouton (1984) compared the effects of US exposure in the same or a different context on fear of a partially extinguished CS or another CS that had reached the same low level of fear through simple CS–US pairings (and no extinction). Although contextual conditioning enhanced fear of the extinguished CS, it had no impact on the nonextinguished CS (see also Bouton and King, 1986). This result is consistent with the effects of context switches mentioned earlier: An extinguished CS is especially sensitive to manipulations of the context. One reason is that contextual conditioning may be another feature of the conditioning context; its presence during a test may cause a return of responding after extinction because of another ABA renewal effect (Bouton et al., 1993).

1.09.1.5 Resurgence

Another recovery phenomenon has been studied exclusively in operant conditioning. In resurgence, a new behavior is reinforced at the same time the target behavior is extinguished. When reinforcement of the new behavior is discontinued, the original response can resurge. Resurgence can occur in two different forms. In one, a response (R1) is first trained and

then extinguished. After R1 is extinguished, a new response (R2) is trained and subsequently extinguished. Recovery, or resurgence, of R1 happens during the extinction of R2 (Epstein, 1983; Lieving and Lattal, 2003, Experiment 1). The other version of the procedure, which can be called the ALT-R procedure (for reinforcement of an alternative response), involves first training R1 and then reinforcing R2 during the extinction of R1. When R2 then undergoes extinction, recovery of R1 occurs (Leitenberg et al., 1970, 1975; Rawson et al., 1977; Epstein, 1985; Lieving and Lattal, 2003). Like the other recovery phenomena described earlier, both forms of resurgence support the idea that extinction does not produce unlearning.

There has been little research designed to uncover the actual mechanisms behind resurgence. One possibility is that extinction of R2 could cause an increase in behavioral variability, or frustration, that might result in an increase in any alternative behavior, not just R1 (e.g., Neuringer et al., 2001). Few studies have included a control response to show that resurgence is unique to an extinguished response. The sole exception is a study by Epstein (1983), who reported that pigeons rarely pecked an alternative, previously nonreinforced response key. An explanation with specific regard to the ALT-R procedure is that reinforcement of R2 during extinction of R1 physically prevents the animal from emitting R1 and thus prevents exposure to the R1–no reinforcer contingency (Leitenberg et al., 1975; Rawson et al., 1977). It is also possible, however, that resurgence follows from the mechanisms implicated in the other recovery effects described earlier. In particular, resurgence observed in the ALT-R procedure could be due to the fact that extinction of R1 occurs in the context of R2 responding. Then, given that extinction is context-specific, R1 would return when extinction of R2 occurs and the frequency of R2 decreases. That is, little R2 responding would return the animal to the context in which R1 had been reinforced, and thus recovery of R1 in the ALT-R procedure would be analogous to an ABA renewal effect.

A somewhat different explanation would be required to explain the form of resurgence in which R1 is extinguished before R2 training begins. In this case, testing of R1 occurs after extinction of R2, and thus responding on R2 would be minimal in both the extinction and testing conditions and thus no renewal effect should result. For this scenario, we might suggest the following explanation. The reinforcer is consistently presented during training of R2, which occurs simultaneously with extinction of R1, and thus this would continuously reinstate responding to R1 (e.g., Rescorla and Skucy, 1969; Baker et al., 1991). Reinstatement of R1 is possible due to conditioning of background context or due to the fact that the reinforcer is a discriminative stimulus signaling to make the response (e.g., Baker et al., 1991). While R2 is being reinforced, the response will interfere with the reinstated performance of R1. However, when R2 then undergoes extinction, the reinstated R1 responding (i.e., resurgence) can then be revealed. In this case, then, resurgence may be an example of the basic reinstatement effect.

1.09.1.6 Concurrent Recovery

Concurrent recovery is another effect indicating that extinction does not destroy original learning. To date, the phenomenon has been studied exclusively in rabbit NMR conditioning: In that preparation, extinguished responding to a target CS can return if a completely different CS is separately paired with the US (e.g., Weidemann and Kehoe, 2004, 2005). One interesting fact about concurrent recovery is that the effect does not necessarily depend on extinction. Rather, similar to a "learning to learn" effect in which conditioning with one CS increases the subsequent rate of conditioning with other CSs (e.g., Kehoe and Holt, 1984), responding to a weakly conditioned target CS can be increased as a result of conditioning with a different CS (Schreurs and Kehoe, 1987). Kehoe (1988) has interpreted these phenomena from a connectionist perspective. He has suggested that the effects occur because inputs from different CSs might converge on a common hidden unit. When a nontarget CS is paired with the US, it strengthens the association of the common hidden unit with the US and thereby allows more responding when the target CS is again presented. This account suggests that extinction plays no special role in enabling concurrent recovery, although the effects that reinforcing one CS has on responding to extinguished and nonextinguished target CSs have not been compared.

A different account of concurrent recovery is that it might merely be a reinstatement effect that occurs due to presentation of the US (with another CS) after extinction of the target CS. Thus, rather than depending on new CS–US pairings, the mere presence of the US alone might be enough to produce concurrent recovery and would suggest that it is similar to a basic reinstatement effect. This possibility appears unlikely in the case of NMR conditioning, because exposure to the US on its own after extinction does

not cause much reinstatement in that preparation (e.g., Napier et al., 1992). However, in the many other preparations where reinstatement does occur (e.g., fear conditioning or appetitive conditioning), a demonstration of concurrent recovery might merely be a reinstatement effect – exposure to CS–US pairings simply involves reexposure to the US (see Rescorla and Heth, 1975; Bouton and Bolles, 1979b, for evidence of reinstatement when the US is presented with or without a CS). Additional work on concurrent recovery is required to determine whether it differentially influences an extinguished CS and, importantly, whether it (like reinstatement) is context specific. Perhaps reinforcing a CS in the same context where a target CS was previously extinguished could remove the contextual inhibition that had accrued there or allow excitation to generalize to the target CS via common associations between the CSs and the context (cf. Honey and Hall, 1989).

1.09.1.7 Summary

A great deal of research thus indicates that responding to an extinguished CS is susceptible to any of a number of recovery effects, suggesting that extinction is not unlearning. Indeed, based on the results of a number of tests that allow a specific comparison of the strength of the CS–US association before and after extinction (e.g., Delamater, 1996; Rescorla, 1996a), Rescorla (2001) has suggested that extinction involves no unlearning whatsoever; the original CS–US association seems to survive essentially intact. Extinction must thus depend on other mechanisms. The renewal effect, and the fact that extinction leaves the CS so especially sensitive to manipulations of context, is consistent with the idea that extinction involves new learning that is especially context-dependent. We have therefore suggested that extinction leaves the CS under a contextually modulated form of inhibition (e.g., Bouton, 1993): The presence of the extinction context retrieves or sets the occasion for a CS–no US association.

1.09.2 What Causes Extinction?

A theoretically and clinically significant question in the field of learning and memory is what event or behavioral process actually causes the loss of responding during extinction? Several ideas have been examined and are discussed next.

1.09.2.1 Discrimination of Reinforcement Rate

One possibility is that the animal eventually learns that the rate of reinforcement in the CS is lower in extinction than it was during conditioning. Gallistel and Gibbon (2000) have argued that the animal continually decides whether or not to respond in extinction by comparing the current rate of reinforcement in the CS with its memory of the rate that prevailed in conditioning. Because rate is the reciprocal of time, the animal computes a ratio between the amount of time accumulated in the CS during extinction and the amount of time accumulated in the CS between USs during conditioning. When the ratio exceeds a threshold, the animal stops responding.

This approach has been tested in several experiments. Haselgrove and Pearce (2003) examined the impact of varying the duration of the CS during extinction; when longer CSs are used in extinction, time in the CS accumulates more quickly, and the animal should stop responding after fewer trials. In some experiments, rats were given appetitive conditioning with a 10-s CS and then given extinction exposures to a series of 10-s or 270-s presentations of the CS. When responding was examined at the start of each CS, there was an occasionally significant, but surprisingly small, effect of increasing the duration of the CS during extinction. For instance, by the 12th two-trial block, the 10-s and 270-s CS groups had similar nonzero levels of responding, even though they had accumulated a total of 4 and 108 min of exposure in the CS, respectively. On the other hand, responding did decline as a function of time within a single presentation of the 270-s CS, perhaps reflecting generalization decrement resulting from the increasing difference between the current CS and the 10-s CS employed in conditioning. Consistent with that view, when conditioning first occurred with a 60-s CS, extinction of responding occurred more rapidly with a 10-s CS than with a 60-s CS. Thus, either an increase or a decrease in the duration of the CS relative to conditioning accelerated the loss of responding. This effect of time was not anticipated by the rate-discrimination view (Gallistel and Gibbon, 2000).

Drew et al. (2004) reported compatible results in experiments on autoshaping in ring doves. Doubling or halving the duration of the CS from the 8-s value used in conditioning did not affect the number of trials required to stop responding. The fact that extinction was thus largely controlled by the number

of CS presentations is consistent with experiments that have examined the effects of the number and duration of nonreinforced trials added to conditioning schedules (Bouton and Sunsay, 2003). On the other hand, Drew et al. found that a more extreme increase in CS duration (from 8 to 32 s) increased the rate of extinction. This was attributed to the animal learning to discriminate the longer nonreinforced CS presentations from the shorter reinforced CS presentations: When 8-s CSs were presented again after extinction, birds extinguished with 4-s and 32-s CSs responded again. Animals are sensitive to time in the CS, but the number of extinction trials appears to be an important factor.

As noted by Gallistel and Gibbon (2000), the rate discrimination theory seems especially consistent with a well-known extinction phenomenon, the partial reinforcement effect (PRE; see Mackintosh, 1974, for a review). In this phenomenon, conditioning with partial reinforcement schedules (in which nonreinforced trials are intermixed with reinforced trials) creates a slower loss of responding in extinction than does conditioning with a continuous reinforcement schedule (in which every trial is reinforced). According to a rate-discrimination hypothesis (Gallistel and Gibbon, 2000), the partially reinforced subjects have learned to expect the US after more accumulated time in the CS, and it thus takes more CS time in extinction to exceed the threshold of accumulated extinction time/expected time to each US. The more traditional approach, in contrast, has been to think that partially reinforced subjects have learned to expect the US after more trials than continuously reinforced subjects have. It therefore takes more trials to stop generalizing from conditioning to extinction (e.g., Mowrer and Jones, 1945; Capaldi, 1967, 1994).

Contrary to the rate discrimination hypothesis, Haselgrove et al. (2004) and Bouton and Woods (2004) have shown that a PRE still occurs when partially and continuously reinforced subjects expect the reinforcer after the same amount of CS time. For example, both sets of investigators showed that a group that received a 10-s CS reinforced on half its presentations (accumulated CS time of 20 s) extinguished more slowly than a continuously reinforced group that received every 20-s CS presentation reinforced. Bouton and Woods (2004) further distinguished the time-discrimination account from the traditional trial-discrimination account (e.g., Mowrer and Jones, 1945; Capaldi, 1967, 1994). Rats that had every fourth 10-s CS reinforced extinguished more slowly over a series of alternating 10-s and 30-s extinction trials than rats that had received every 10-s CS reinforced. This PRE was still observed when extinction responding was plotted as a function of time units over which the US should have been expected (every 40 s for the partially reinforced group but every 10 s for the continuously reinforced group). In contrast, the PRE disappeared when extinction responding was plotted as a function of the trials over which the US should have been expected (every fourth trial for the partially reinforced group and every trial for the continuously reinforced group). Ultimately, the PRE is better captured by trial-based theories (e.g., Capaldi, 1967, 1994; see Mackintosh, 1974, for a review of the older literature).

We have already seen that responding on a particular trial occurs in the context of memories of the outcomes of previous trials – that was the explanation provided earlier of rapid reacquisition as an ABA renewal effect (Ricker and Bouton, 1996; Bouton et al., 2004). Interestingly, the recent finding that occasional reinforced trials in extinction (partial reinforcement) can slow down the rate of reacquisition (Bouton et al., 2004; Woods and Bouton, 2007) is really just the inverse of the PRE: In the PRE, nonreinforced trials in conditioning allow more generalization from conditioning to extinction, whereas Bouton et al.'s finding suggests that reinforced trials in extinction allowed for more generalization of extinction to reconditioning. Either finding suggests the importance of considering recent trials as part of the context that controls performance in extinction.

In summary, there is little support for the idea that responding extinguishes when the US is omitted because the organism detects a lower rate of reinforcement in the CS. The number of extinction trials, rather than merely the accumulating time in the CS across trials, appears to be important to the extinction process. Time in the CS can have an effect: It appears to be another dimension over which animals generalize and discriminate (Drew et al., 2004; Haselgrove and Pearce, 2003). Explanation of the PRE, however, appears to be most consistent with a view that animals utilize their memories of the outcomes of preceding trials as a dimension over which they generalize and respond (see also Mackintosh, 1974, for an extended review).

1.09.2.2 Generalization Decrement

It is possible that the animal stops responding in extinction from the point at which it stops generalizing between the stimuli that prevailed in conditioning and

those that prevail in extinction (e.g., Capaldi, 1967, 1994). This idea has had a long history in research on extinction, especially in research on the PRE. It is interesting to note that a generalization decrement theory of extinction does not imply destruction of the original learning in extinction, or indeed any new learning at all. However, there is still good reason to think that extinction also involves new learning. For instance, nonreinforcement of a food CS elicits measurable frustration, and this can be associated with stimuli present in the environment (Daly, 1974). Nonreinforcement of the CS in the related conditioned inhibition paradigm (in which a CS is nonreinforced in the presence of a second stimulus and that second stimulus acquires purely inhibitory properties) also generates measurable new learning in the form of conditioned inhibition. There is also evidence for new learning in the renewal effect. For example, either ABC renewal or AAB renewal (see earlier discussion) implies that the extinction context acquires an ability to modulate (suppress) performance to the CS. Such observations suggest that the animal has not merely stopped responding in extinction because of a failure to generalize. Instead, it appears to have learned that the CS means no US in the extinction context (see earlier).

1.09.2.3 Inhibition of the Response

Rescorla (2001) suggested that extinction might involve learning to inhibit the conditioned response. He summarized evidence from instrumental (operant) conditioning experiments indicating that the effects of extinction can be specific to the response that undergoes extinction. For example, Rescorla (1993) reinforced two operant behaviors (lever pressing and chain pulling) with food pellets and then extinguished each response in combination with a new stimulus (a light or a noise). Subsequent tests of the two responses with both light and noise indicated that each response was more depressed when it was tested in combination with the cue in which it had been extinguished (see also Rescorla, 1997a). There is thus good reason to think that the animal learns something specific about the response itself during operant extinction: It learns not to perform a particular response in a particular stimulus. One possibility is that the animal learns a simple inhibitory S–R association (Colwill, 1991). Another possibility, perhaps more consistent with the context-modulation account of extinction emphasized earlier, is that the animal learns that S sets the occasion for a response – no reinforcer relationship. Rescorla (1993: 335; 1997a: 249) has observed that the experiments do not separate the two possibilities. To our knowledge, no analogous experiments have been performed in the Pavlovian conditioning situation.

The main implication examined in Pavlovian conditioning is that extinction procedures should be especially successful at causing inhibitory S–R learning if they generate high levels of responding in extinction. This prediction may provide a reasonable rule of thumb (Rescorla, 2001). For example, when a CS is compounded with another excitatory CS and the compound is extinguished, there may be especially strong responding in extinction (due to summation between the CSs), and especially effective extinction as evidenced when the CS is tested alone (Wagner, 1969; Rescorla, 2000; Thomas and Ayres, 2004). Conversely, when the target CS is compounded with an inhibitory CS, there is relatively little responding to the compound (excitation and inhibition negatively summate), and there is also less evidence of extinction when the target is tested alone (Soltysik et al., 1983; Rescorla, 2003; Thomas and Ayres, 2004). However, although these findings are consistent with the hypothesis that the effectiveness of extinction correlates with the degree of responding, either treatment also affects the degree to which the animal's expectation of the reinforcer is violated: The stimulus compound influences the size of the error term in the Rescorla-Wagner model, and in more cognitive terms the extent to which the expectation of the US created by the compound is violated when the US does not occur. The results do not separate the response-inhibition hypothesis from an expectancy-violation hypothesis, which will be covered in the next section.

An eyeblink experiment by Krupa and Thompson (2003) manipulated the level of responding another way. During extinction, rabbits were given microinjections of the gamma-aminobutyric acid (GABA) agonist muscimol adjacent to the motor nuclei that control the conditioned response (the facial nucleus and the accessory abducens). The injection therefore eliminated the CR during extinction. However, when the subjects were then tested without muscimol, the CS evoked considerable responding, suggesting that evocation of the CR was necessary for extinction learning. Unfortunately, the muscimol microinjections also had robust stimulus effects. They caused complete inactivation of the ipsilateral facial musculature: "the external eyelids were flaccid, the left ear hung down unsupported, and no vibrissae movements

were observed on the side of the infusion" (Krupa and Thompson, 2003: 10579). In effect, the rabbits received extinction in a context that was different from the one in which conditioning and testing occurred (the ordinary state without partial facial paralysis). There are thus strong grounds for expecting a renewal effect. The hypothesis that elicitation of the CR is necessary for extinction must await further tests.

There are also data suggesting that the number of responses or level of responding in extinction does not correlate with effective extinction learning. For example, Drew et al. (2004) noted that although animals given long CSs in extinction responded many more times in extinction than animals given shorter CSs, extinction was mainly a function of the number of extinction trials. In fear conditioning experiments with mice, Cain et al. (2003) reported that extinction trials that were spaced in time produced a slower loss of freezing than extinction trials that were massed in time. Nevertheless, there was less spontaneous recovery after the massed treatment, suggesting that extinction was more effective when the treatment involved less overall responding. Experiments in our own laboratory with rat appetitive conditioning (Moody et al., 2006) suggest a similar conclusion, even though the results were different. Spaced extinction trials again yielded more responding in extinction than massed trials, but the treatments caused indistinguishable amounts of extinction learning as assessed in spontaneous recovery and reinstatement tests.

In related conditioned suppression experiments, Bouton et al. (2006a) compared the effects of extinction in multiple contexts on the strength of ABA and ABC renewal effects (discussed more in the section titled 'Other behavioral techniques to optimize extinction learning'). Rats received fear conditioning with a tone CS in Context A, and then extinction of the tone for three sessions in Context B, or a session in B, then C, and then D, before final renewal tests in the original context (Context A) or a neutral fifth context (Context E). Although the successive context switches in the BCD group caused more fear responding during extinction (due to renewal effects with each context switch), the groups showed strikingly similar renewal in either Context A or Context E. Thus, higher responding in extinction does not indicate better extinction learning; in fact, the level of responding on extinction trials was positively, rather than negatively, correlated with the level of renewal (see also Moody et al., 2006). The results seem inconsistent with a response-inhibition hypothesis. Their impact on the expectancy violation hypothesis is perhaps less clear.

Rescorla (2006, Experiment 5) provided perhaps the most direct test of whether enhanced responding or enhanced associative strength is responsible for the increased extinction (loss of responding) that typically follows compound presentation of two extinguished stimuli (see also Reberg, 1972; Hendry, 1982). He studied the effects of a diffuse excitor (e.g., a noise paired with food) and a diffuse positive occasion setter (e.g., a houselight that signaled the reinforcement of a keylight CS) on extinction of autoshaped key pecking in pigeons. When combined with a target keylight CS that was undergoing extinction, the diffuse excitor failed to increase the amount of pecking at the keylight, although it theoretically increased the animal's expectation of the US. In contrast, when combined with the target keylight CS, the diffuse occasion setter increased the amount of pecking at the CS without theoretically increasing the direct expectancy of the US. Contrary to Rescorla's (2001) rule of thumb about more responding resulting in more extinction, extinction in combination with the excitor caused a more durable extinction effect (assessed in reacquisition) than did extinction in combination with the occasion setter. The occasion setter caused no more effective extinction than extinction of the target alone. This finding suggests that the actual level of responding in extinction is not as important in determining the success of extinction as the extent to which the US is predicted and thus nonreinforcement is surprising.

In summary, although animals that receive extinction after operant conditioning may in fact learn to refrain from performing a particular response in a particular context (e.g., Rescorla, 1993, 1997a), the importance of response inhibition in Pavlovian extinction is not unequivocally supported at the present time. High responding in extinction does not guarantee more effective extinction learning, and a better explanation of the results of stimulus-compounding experiments (where the level of responding does appear to predict the success of extinction) may be the violation-of-expectation hypothesis, to which we now turn.

1.09.2.4 Violation of Reinforcer Expectation

It is commonly thought that each CS presentation arouses a sort of expectation of the US that is disconfirmed on each extinction trial. For example, in

the error-correction rule provided by Rescorla and Wagner (1972), the degree of unlearning (which we have seen can create inhibition) is provided by the difference in the overall associative strength present on a trial and the actual US that occurs on the trial. In the Pearce-Hall model (Pearce and Hall, 1980), the discrepancy was conceptualized as an event that reinforced new inhibitory learning that is overlaid on the original excitatory learning (see also Daly and Daly, 1982). Wagner's SOP ("sometimes opponent process") model (1981) accepts a similar idea. One piece of evidence that seems especially consistent with the expectation-violation view is the "overexpectation experiment," in which two CSs are separately associated with the US and then presented together in a compound that is then paired with the US. Despite the fact that the compound is paired with a US that can clearly generate excitatory learning, the two CSs undergo some extinction (e.g., Kremer, 1978; Lattal and Nakajima, 1998). The idea is that summation of the strengths of the two CSs causes a discrepancy between what the animal expects and what actually occurs, and some extinction is therefore observed. As mentioned earlier, the expectation-violation view is also consistent with the effects of compounding excitors and inhibitors with the target CS during no-US (extinction) trials (Wagner, 1969; Soltysik et al., 1983; Rescorla, 2000, 2003, 2006; Thomas and Ayres, 2004).

One theoretical challenge has been to capture the expectancy violation in real time. Gallistel and Gibbon (2000) have emphasized the fact that traditional trial-based models like the Rescorla–Wagner model have been vague about the precise point in time in a trial when the violation of expectation actually occurs. The issue is especially clear when trial-based models explain the extinction that occurs with a single extended presentation of the CS, as is the case for the context or background in conditioning protocols with very widely spaced conditioning trials. (Spaced trials are held to facilitate conditioning of the CS because long intertrial intervals allow more context extinction and thus less blocking by context.) There is good evidence that widely spaced trials do create less contextual conditioning than massed trials (e.g., Barela, 1999). To account for contextual extinction over long intertrial intervals, many trial-based models arbitrarily assume that the single long-context exposure is carved into many imaginary trials, and that more imaginary trials occur and create more extinction in longer-context exposures.

It is worth noting, however, that Wagner's SOP model (e.g., Wagner, 1981; Wagner and Brandon, 1989, 2001) is relatively specific about where in time the process that generates extinction occurs. According to that model, CS and US are represented as memory nodes that can become associated during conditioning. For the association between them to be strengthened, both nodes must be activated from inactivity to an active state, "A1," at the same time. Once the association has been formed, the presentation of the CS activates the US node to a secondarily active state, "A2." This in turn generates the CR. An inhibitory connection is formed between a CS and a US when the CS is activated to the A1 state and the US is activated to A2 rather than A1. This happens in simple extinction because the CS activates the US into A2. This process occurs in real time; thus, during any nonreinforced trial, inhibition will accrue to the CS from the point in time at which the US node is first activated to A2 until the CS leaves the A1 state, which may not occur until the CS is turned off at the end of the trial. Thus, extinction learning will proceed continuously as long as the CS is on and no US occurs on any extinction trial. A limiting factor, however, is the extent to which the CS itself is in the A2 state: The longer it remains on, the more likely the elements in the CS node will be in A2 rather than A1, making new learning about the CS more difficult. Nonetheless, extensions of the CS in extinction will have an effect, because elements in A2 eventually return to the inactive state, from where they will return to A1 because of the continued presence of the CS. SOP thus accounts for extinction in extended CSs without recourse to imaginary trials, and a recent extension of the model (Vogel et al., 2003) may also account for generalization decrement as a function of CS time (Haselgrove and Pearce, 2003; Drew et al., 2004). Although a complete analysis of SOP requires computer simulations that are beyond the scope of the present chapter, the principles contained in the model are consistent with many of the facts of extinction reviewed here. From the current point of view, its most significant problem is that it underestimates the role of context in extinction, and might not account for the negative occasion-setting function of context (e.g., Bouton and King, 1983; Bouton and Swartzentruber, 1986, 1989; Bouton and Nelson, 1998) that arguably provides the key to understanding the renewal, spontaneous recovery, rapid reacquisition, and reinstatement phenomena (for a start at addressing occasion-setting phenomena in terms of SOP, see Brandon and Wagner, 1998; Wagner and Brandon, 2001).

In fear extinction, at the physiological level, expectation violation may be mediated by activation of opioid receptors (see McNally and Westbrook, 2003). Fear conditioning is typically impaired by opioid receptor agonists (e.g., Fanselow, 1998) but facilitated by antagonists, such as naloxone. Extinction, in contrast, is facilitated by opioid receptor agonists and impaired by antagonists (McNally and Westbrook, 2003). According to McNally and Westbrook, opioid receptors may be involved in fear extinction because the omission of the expected US leads to a feeling of relief (Konorski, 1967; Dickinson and Dearing, 1978) that is mediated by opioid peptides; the relief associated with the absence of the US might countercondition fear responses. The idea is also captured in SOP theory's sometimes opponent process, A2. That is, activation of the US node in A2 reduces the effectiveness of the US and also constitutes the crucial event that leads to extinction. Activation of opioid receptors may thus play the physiological role of A2 in fear conditioning. A similar physiological mechanism has not yet been specified for appetitive conditioning, although the underlying basis of frustration is an obvious candidate.

1.09.3 Can Extinction Be Made More Permanent?

Recent research on extinction has explored several methods that might enhance extinction learning. These methods are discussed here because they provide further insight into the causes of extinction and how extinction therapies might be enhanced.

1.09.3.1 Counterconditioning

One way to optimize extinction learning might be to actually pair the CS with another US that evokes a qualitatively different (or opposite) response. In counterconditioning, a CS that has been associated with one US is associated with a second US, often incompatible with the first, in a second phase. Not surprisingly, performance corresponding to the second association replaces performance corresponding to the first. Clinical psychologists have incorporated this idea into therapies, such as in systematic desensitization, which involves the training of relaxation responses in the presence of a CS while fear to that CS extinguishes (e.g., Wolpe, 1958). Although counterconditioning may result in a quicker loss of phase-1 performance than simple extinction does (e.g., Scavio, 1974), it is another paradigm that, like extinction, involves a form of retroactive interference. Similar principles may therefore apply (Bouton, 1993). As with extinction, the original association remains intact despite training with a second outcome. This is true in both Pavlovian (Delamater, 1996; Rescorla, 1996a) and instrumental conditioning (Rescorla, 1991, 1995).

Equally important, counterconditioning procedures do not necessarily guarantee protection against relapse effects (the postextinction phenomena discussed earlier) (see also Rosas et al., 2001; García-Gutiérrez and Rosas, 2003, for compatible results in human causal learning). Renewal of fear occurs when rats receive CS–shock pairings in one context, then CS–food pairings in another, and are finally returned to the original context (Peck and Bouton, 1990). Complementary results were obtained when CS–food preceded CS–shock pairings. Spontaneous recovery occurs if time elapses between phase 2 and testing (Bouton and Peck, 1992; Rescorla, 1996b, 1997b). Finally, reinstatement has also been observed (Brooks et al., 1995): When CS–food follows CS–shock, noncontingent shocks delivered in the same context (but not in a different context) can reinstate the original fear performance. Counterconditioning thus supports at least three of the recovery effects suggesting that extinction involves context-dependent new learning.

1.09.3.2 Other Behavioral Techniques to Optimize Extinction Learning

If extinction involves new learning, then procedures that generally promote learning might also facilitate extinction. This idea has motivated recent research in several laboratories. For example, one idea is that conducting extinction in multiple contexts might connect extinction with a wider array of contextual elements and thereby increase the transfer of extinction learning to other contexts and potentially reduce the renewal effect (e.g., Bouton, 1991a). The results, however, have been mixed. Experiments in conditioned lick suppression (Gunther et al., 1998) and flavor-aversion learning with rats (Chelonis et al., 1999) have shown that extinction in multiple contexts can attenuate (but not abolish) instances of both ABC and ABA renewal relative to that observed after extinction in a single context (see also Vansteenwegen et al., 2006, for a related

example). In contrast, as discussed earlier, our own experiments using a fear conditioning method (conditioned lever-press suppression) with rats found that extinction in multiple contexts had no discernible influence on either ABA or ABC renewal (Bouton et al., 2006a). Null results (in ABA renewal) have also been reported with a fear conditioning (shock expectancy) procedure in humans (Neumann et al., 2007). All results together suggest that there are important variables that modulate the positive impact of extinction in multiple contexts on the renewal effect (see Bouton et al., 2006a, for a discussion).

Another approach to optimizing extinction learning is to space extinction trials in time. This idea has been inspired by the fact that spaced trials often yield better excitatory learning than massed trials (e.g., Spence and Norris, 1950). It is worth noting, though, that the behavioral mechanisms behind trial-spacing effects on conditioning are multiple and complex (e.g., see Bouton et al., 2006b), and that many of them focus on the facilitating effects of spacing US presentations, which obviously are not involved in extinction. Nonetheless, there are still some grounds for expecting trial spacing effects in extinction, and these have been tested in several experiments. Spaced trials often cause a slower loss of responding in extinction (e.g., Cain et al., 2003; Morris et al., 2005; Moody et al., 2006), as one might expect, for example, if long intervals between successive CS presentations allow some spontaneous recovery. However, the long-term effects of spacing extinction trials have been variable and much less clear. When responding is tested after a long retention interval, spaced extinction trials have been shown to reduce responding (e.g., Westbrook et al., 1985; Morris et al., 2005), have no effect on responding (Moody et al., 2006), and create more responding than massed extinction trials (Cain et al., 2003; Rescorla and Durlach, 1987). Another complication is the results mentioned earlier, which suggest that extinction ITI can also be part of the context that controls extinction performance (Bouton and García-Gutierrez, 2006). More work will be necessary to untangle these various effects.

Another temporal manipulation has attracted recent interest. In the fear-potentiated startle paradigm in rats, extinction conducted immediately after fear acquisition leads to seemingly more durable extinction (Myers et al., 2006). In particular, rats that received extinction 10 min or 1 h (and in some cases 24 h) after a single acquisition session later failed to exhibit reinstatement, renewal, or spontaneous recovery, whereas rats tested after a longer 72-h acquisition-to-extinction interval showed all these postextinction recovery effects. Immediate extinction thus seemed to produce a more permanent form of extinction that potentially corresponds to biological depotentiation (i.e., reversal) of potentiated synapses (e.g., see Lin et al., 2003). However, once again there are complications and boundary conditions. For example, humans that have received extinction within a few minutes of fear acquisition still show reinstatement (LaBar and Phelps, 2005) and renewal (Milad et al., 2005) when these phenomena are tested later. In rat experiments that measured freezing rather than potentiated startle, Maren and Chang (2006) found that immediate fear extinction may be less effective than delayed extinction under some conditions; immediate extinction never produced a more durable loss of freezing after delayed extinction. And in several appetitive conditioning preparations, Rescorla (2004b) independently found more spontaneous recovery (less-effective extinction) in rats when extinction occurred 1 day, rather than 8 days, after acquisition. Rescorla's methods differed substantially from those in the aforementioned studies, and it is worth noting that his extinction after a 1-day interval might already be outside the temporal window in which depotentiation is possible (e.g., see Staubli and Chun, 1996; Huang et al., 2001). But it seems clear that additional research will be required to fully understand the effects of the interval between conditioning and extinction on the long-term effects of extinction.

1.09.3.3 Chemical Adjuncts

Research on the neurobiology of conditioning and extinction suggests that certain pharmacological agents may also be used to optimize extinction learning. For example, there has been a great deal of recent interest in D-cycloserine (DCS), a compound that is a partial agonist of the *N*-methyl-D-aspartate (NMDA) glutamate receptor. The NMDA receptor is involved in long-term potentiation, a synaptic model of learning (e.g., Fanselow, 1993), and has now been shown to be involved in several examples of learning including fear conditioning (e.g., Miserendino et al., 1990; Campeau et al., 1992, see Davis and Myers, 2002; Walker and Davis, 2002). The discovery that NMDA receptor antagonists interfere with fear extinction (e.g., Falls et al., 1992; Cox and Westbrook, 1994; Baker and Azorlosa, 1996; Lee and Kim, 1998; Santini et al., 2001) supported the idea that the NMDA receptor was also involved in extinction learning. The next step was to ask whether an NMDA agonist like DCS

might correspondingly facilitate extinction. And it does; there is now evidence that administration of DCS facilitates extinction of conditioned fear in rats (Walker et al., 2002; Ledgerwood et al., 2003). And importantly, it also enhances exposure therapy in humans with acrophobia (Ressler et al., 2004) and social phobia (Hofmann et al., 2006). In each of these cases, when DCS was combined with a number of extinction trials that only partially reduced fear in a control group, it yielded more complete fear extinction as revealed during tests that were conducted without the drug.

The fact that DCS can facilitate extinction needs to be interpreted cautiously. For example, there is little in the description of how DCS works to suggest that it would do more than merely strengthen ordinary extinction learning, which, as we have shown, is relatively context specific and subject to relapse. Consistent with this possibility, although DCS facilitates the rate of fear extinction, it does not decrease the strength of the ABA renewal effect (Woods and Bouton, 2006). That is, rats for whom DCS had facilitated extinction still showed a robust return of fear when they were tested with the CS in the original conditioning context. This result indicates that DCS combined with extinction does not abolish the original learning. Woods and Bouton (2006) actually suggested that DCS might facilitate inhibitory conditioning of the context in which extinction occurs. Such a possibility is consistent with rapid extinction (enhanced contextual inhibition would decrease fear of the CS presented in it) and intact renewal (context inhibition would be gone when the CS is tested in another context). It is also consistent with other DCS effects reported in the literature. For example, DCS given during extinction can later reduce reinstatement (Ledgerwood et al., 2004); enhanced inhibition in the context would interfere with reinstatement by disrupting the development of context conditioning during US-alone presentations. DCS combined with extinction of one CS also causes less fear of a second CS tested in the same context (Ledgerwood et al., 2005); if the context were an inhibitor, it would inhibit fear of any CS tested in that context. Although DCS can have positive effects on fear extinction, it does not create unlearning.

Another compound that has been of interest is yohimbine, an alpha-2 adrenergic antagonist. This substance may cause paniclike responding when it is injected in animals or panic patients (Davis et al., 1979; Pellow et al., 1985; Johnston and File, 1989; see Stanford, 1995, for review). For that reason, it might increase the level of fear during extinction, and by thus enabling either increased response inhibition or a higher violation of reinforcer expectation (see earlier discussion), allow for better extinction learning. Consistent with this possibility, yohimbine administered before a fear extinction session can lead to better extinction learning in mice (i.e., less freezing in a subsequent test session conducted 24 hours later; Cain et al., 2003). We have replicated this effect in rats (Morris and Bouton, 2007). However, the facilitated extinction was highly context specific; rats tested in a new context or back in the original conditioning context after extinction with yohimbine still showed a strong renewal of fear. Thus, as we saw with DCS, yohimbine facilitates the rate of extinction learning without necessarily abolishing relapse. Further results suggested that presenting yohimbine on its own in a context allows that context to suppress subsequent extinguished fear performance – as if it was conditioning a form of context-specific fear inhibition. Although the exact mechanism is unclear, it seems apparent that as an adjunct to extinction, yohimbine once again may not prevent the occurrence of future relapse.

Behavioral neuroscientists have recently also become interested in memory "reconsolidation" effects (*See* Chapter 1.24) that might suggest a new way to modify previously learned memories. It has long been known that freshly learned memories may be labile and easily disrupted before they are consolidated into a stable long-term form (e.g., McGaugh, 2000; Dudai, 2004). The consolidation process requires synthesis of new proteins in the brain (e.g., Davis and Squire, 1984; Goelet et al., 1986) and can therefore be blocked by administration of a protein synthesis inhibitor, such as anisomycin (e.g., Schafe and LeDoux, 2000). In the case of fear memories, whose consolidation can be modulated by stress hormones, consolidation can also be hindered by administration of a β-adrenergic receptor blocker such as propranolol (Pitman et al., 2002; Vaiva et al., 2003; McGaugh, 2004; see also Pitman, 1989). Recent research suggests that an older memory that has recently been reactivated (for example) by a single exposure to the CS likewise temporarily returns to a labile state from which it needs to be reconsolidated (e.g., Nader et al., 2000; Sara, 2000; Walker et al., 2003; Lee et al., 2004; Suzuki et al., 2004; Alberini, 2005). Like consolidation, reconsolidation can be blocked by anisomycin (e.g., Nader et al., 2000), and in the case of a fear memory, by administration of propranolol (Przybyslawski et al., 1999; Debiec and LeDoux, 2004). In these experiments, memory is returned to a labile state by presenting the CS on a very small

number of occasions that are insufficient to produce extinction on their own (e.g., Suzuki et al., 2004). The crucial new result is that administration of anisomycin or propranolol while the memory is in this state can reduce evidence of conditioned responding when the CS is tested later. A therapeutic implication may be that one of these drugs in combination with one or two presentations of a CS may weaken an aversive fear memory. However, more basic research is needed. For example, it is not necessarily clear that a behavioral reconsolidation result involves actual modification of the original memory or mere difficulty in retrieving it (see Duvarci and Nader, 2004, for a critical analysis of these possibilities as induced by anisomycin). It seems clear that caution is necessary in interpreting the results of any effect of a drug or chemical on learning, extinction, and therapy.

1.09.3.4 Summary

A variety of manipulations have been thought to hold promise in optimizing extinction learning, but their effects have been mixed and (at this point in time) are not well understood. When investigators have specifically tested their effects on the relapse effects we reviewed in the first part of this chapter, they have often provided surprisingly little protection (see Bouton et al., 2006b, for a review). In contrast, one of the most effective and durable ways to optimize extinction learning and protect against relapse seems to be with the use of techniques that bridge the extinction and testing contexts, such as retrieval cues and presentation of occasional reinforced trials during extinction (discussed earlier). Bridging treatments accept the inherent context-specificity of extinction and work by increasing the similarity between the extinction context and test contexts where lapse and relapse may be a problem.

1.09.4 Conclusions

Extinction is a highly complex phenomenon, even when analyzed at a purely behavioral level. It is probably multiply determined. But, according to the results reviewed here, it usually does not involve destruction of the original learning. Instead, the main behavioral factors that cause the loss of responding appear to be generalization decrement and new learning that may be initiated by the violation of an expectation of the US. In SOP (e.g., Wagner, 1981; Wagner and Brandon, 2001), perhaps the most powerful and comprehensive model of associative learning that is currently available, that expectation violation takes the form of the CS activating the US node into a secondarily active (A2) state that potentially enables new inhibitory learning as long as the CS remains on and no US is presented. Importantly, this new inhibitory learning leaves the original CS–US association intact.

Bouton (1993) has argued that the fact that extinction might leave the original learning intact means that the CS emerges from extinction with two available associations with the US. It therefore has properties analogous to those of an ambiguous word, and the current performance depends on which of two associations is retrieved. Consistent with this idea, another fact that emerges from behavioral research on extinction is that it is relatively context dependent. Given this, the CS's second (inhibitory) association is especially dependent on the context for its activation or retrieval. The role of the context is usually modulatory; it activates or retrieves the CS's second (inhibitory) association, much as a negative occasion setter might (e.g., Holland, 1992). This hypothesis begins to integrate several facts about extinction and brings relapse effects like the renewal effect, spontaneous recovery, rapid reacquisition, reinstatement, and perhaps resurgence to center stage.

The major implication of behavioral research on extinction is thus that lapse and relapse are always possibilities after exposure therapy. As just reviewed, there is substantial interest among basic researchers in discovering new ways to make extinction more permanent. To date, behavioral and pharmacological methods of enhancing or optimizing extinction learning have produced lawful effects on the rate of extinction, but their effectiveness in the long term is less clear. Treatments that increase the rate at which fear is lost in therapy may not change extinction learning's inherent context specificity. At the current time, the best way to combat the various relapse phenomena reviewed here may be to consider their behavioral causes and develop techniques that might defeat them. This perspective has led to certain bridging treatments, such as the use of reminder cues or strategies or conducting extinction in the presence of the contextual cues that can lead to particular examples of relapse, which do appear to hold some promise in maintaining extinction performance in the presence of conditions that might otherwise initiate relapse.

1.10 Cognitive Dimension of Operant Learning

A. P. Blaisdell, University of California at Los Angeles, Los Angeles, CA, USA

1.10.1 Introduction

1.10.1.1 Thorndike and the Law of Effect

A rat presses a lever and quickly scurries to the feeding niche to collect its meal. A crow picks up a piece of newspaper – uncovering a morsel of food dropped by a passerby. A child lifts the lid off of a cookie jar and takes a cookie. These are the types of acquired behaviors that a theory of instrumental learning seeks to explain. Instrumental learning is the acquisition of a new response through reinforcing feedback. Thorndike (1898, 1911) provided the first general theory of instrumental learning with his Law of Effect. The Law of Effect is a simple trial-and-error learning model in which the actions an individual makes in the presence of a particular stimulus or context are strengthened or weakened depending on the consequences of those actions. Actions followed by desirable consequences – such as attainment of food rewards or escape from aversive situations – become strengthened in that stimulus context, while actions followed by undesirable consequences – such as a loss of food or attainment of an aversive stimulus – become weakened in that context. His theory grew out of experiments on escape learning in animals – most famously cats. In these experiments he studied the acquisition of a new behavior in a controlled manner. A cat was placed in a cage that Thorndike called a puzzle box (**Figure 1**), with food located in view just outside. The cat could escape the box by manipulating a device.

Various puzzle boxes were rigged so that each one required a different manner of escape, such as pushing the door aside, pressing a lever, pulling a string, or a series of these behaviors. Thorndike repeatedly placed the cat inside a puzzle box and observed the latency to escape. As the cat learned which responses led to its release from the box, the latency to escape would diminish (**Figure 2**).

What struck Thorndike was that the cat initially tried all manners of escape – trying to squeeze through the bars, pawing at the door, clawing and biting and things in the box. The cat would

> strive instinctively to escape from confinement. The vigor with which it struggles is extraordinary. For eight or ten minutes it will claw and bite and squeeze incessantly. (Thorndike, 1898: 13)

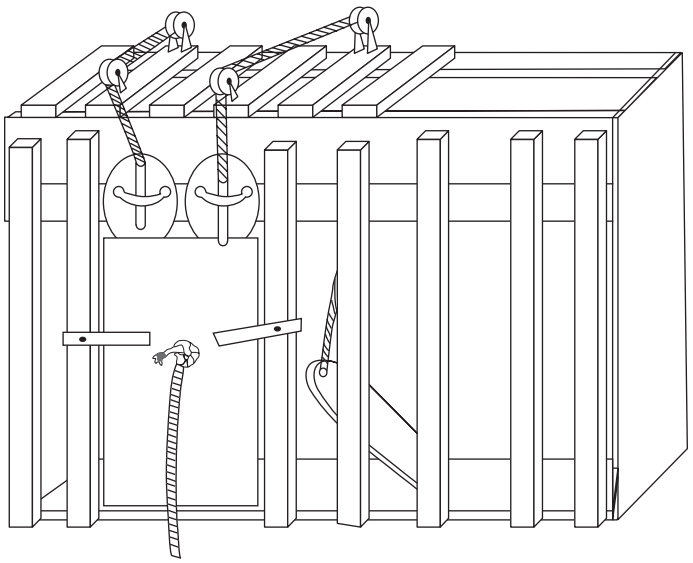

Figure 1 One of the puzzle boxes used by Thorndike to study the acquisition of new behaviors in cats. From Thorndike EL (1911) *Animal Intelligence: Experimental Studies.* New York: Macmillan.

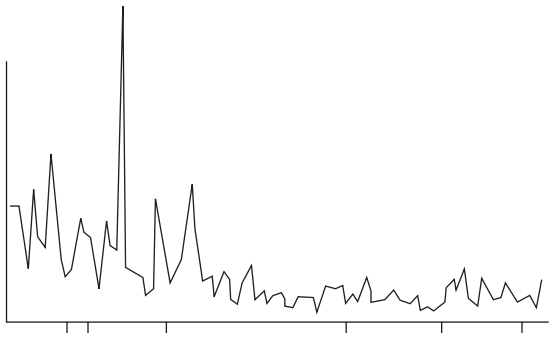

Figure 2 Escape times as a function of trials for one cat in a puzzle box experiment. From Thorndike EL (1911) *Animal Intelligence: Experimental Studies.* New York: Macmillan.

These strivings, however, diminished upon repeated exposures to the box as the cat learned which actions led to escape and which did not. The cat become more successful over repeated trials – successful escape responses that at first had been unleashed fortuitously in the random fury of its strivings became more systematically employed, while those behaviors that led to no release died away. It was this transformation from seemingly random behaviors to successfully organized ones that led Thorndike to formulate the Law of Effect.

Importantly, observations of the behavior of the cat during and after learning an escape response led Thorndike to conclude that the cat did not understand the relationship between its behavior and the consequence. Rather, the cat appeared to blindly engage in the trained action whenever it was placed in the box. Thus, in Thorndike's framework the consequences of action play an important role in the strengthening or weakening of behavior, but those consequences do not themselves enter into an association with the action or with the prevailing stimulus conditions. Rather, the subject only learns an association between the stimulus context (S) and the response (R) (**Figure 3**).

Many other behaviorists, perhaps Watson being the most famous, had their own take on S-R psychology. The behaviorist ideology eschewed references to mental terms, such as expectations, wants, and desires, and attempted to describe all acquired behavior through the objective lens of stimulus input and response output, with outcomes and consequences of behavior serving only to solidify S-R

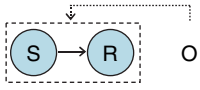

Figure 3 Theoretical associative structure underlying instrumental conditioning. S = stimulus representation, R = response representation, O = outcome. Solid arrow indicates hypothetical unidirectional excitatory association between the S and R representations. The dashed-line box envelopes the content of learning. The dotted arrow indicates that O only plays a role in reinforcing the strength of the S-R association but does not enter into an association with either S or R.

relationships (*See also* Chapters 1.03, 1.06, 1.07). Thus, to characterize the learning of a cat in a puzzle box or of a rat in a maze, the cat (or rat) is said to engage in a series of conditioned responses (muscle twitches) when they are in a certain context. The fact that these muscle twitches typically bring about a consequence is irrelevant from the cat's (or rat's) point of view. That is, the behavior of the cat or the rat is not goal directed. If one were to ask the behaviorists, "Why did the chicken cross the road?" their reply would be "Because the chicken had crossed the road a number of times in the past, and each time the crossing was followed by a satisfying outcome; whereas each failure to cross the road was followed by an unsatisfying outcome. Thus, when in the presence of the road, the experienced chicken will cross to the other side." Likewise, a child learns to lift the lid off of a cookie jar because doing so in the past has repeatedly been followed by a satisfying outcome. If the child were to be asked why they are lifting the lid off of the cookie jar, the behaviorist would expect a reply of "I dunno."

1.10.1.2 Tolman's Purposive Psychology

But doesn't it strike us as being exceedingly odd to interpret the child's act of lifting the lid off the cookie jar as NOT being due to the child's desire for a cookie – as the behaviorist would have it? Tolman agreed, and suggested that actions are performed for some purpose, that is, they are driven by expectations of an outcome (Tolman, 1932). Experiments conducted in Tolman's lab led to this conclusion. In one example, rats were given nine trials on which they learned to run down a maze and collect a desirable food reward – bran mash – in the goal box. On the tenth trial, the rats found a less desirable sunflower seed in the goal box rather than the bran mash. On the eleventh trial, the rats ran down the maze more slowly than they had on the preceding ten trials. In contrast with behaviorist theory, the rats appeared to have learned during the first nine trials to expect bran mash when they reached the goal box. The violation of this expectation on the tenth trial caused a dramatic and immediate shift in their behavior. Tolman used the behaviorist's controlled methodology and strict adherence to empirical validation to support cognitive processes as variables that intervene between stimulus and response. As a result, cognitive theories of animal learning and behavior have again become fashionable.

1.10.2 Operant Behavior: Goal Directed versus Habitual

In the past few decades, there has been a resurgence in the analysis of goal-directed behavior in psychology according to which an individual's actions are motivated by the outcome representation with which they are associated. Beyond being merely a catalyst for learning, the consequence of a response can become part of what is learned. The response–outcome (R-O) association allows the outcome to motivate the response. That is, the subject *expects* to receive O if it engages in R. A more contemporary view holds that all three elements of an instrumental learning association, S, R, and O, can be bound by associations (**Figure 4**; see also Balleine and Ostlund, 2007, for a review).

The claim that instrumental behavior can be goal-directed should not be taken to deny the existence of non-goal-directed, habitual behavior. Much of our behavior is clearly produced without the aid of any explicit representation, such as when we walk from our car to our doorstep. We may carry out such a task almost perfectly in complete darkness, or if we are otherwise distracted – such as when we are engaged in conversation with a visitor. Likewise, it is said that one way to catch a sleepwalker in the act is by rearranging the furniture in their dwelling. Presumably they will wake up when they bump into furniture that is now blocking a previously unobstructed pathway. Even when we are aware that we have rearranged the furniture in a room, it usually takes time to stop going to the corner where the easy chair used to be to have a seat. Discovering the empty corner quickly reminds us of our error. Old habits die hard, as the saying goes.

To be theoretically useful, there must be a way to empirically distinguish habitual (S-R) from goal-directed (R-O) behavior. According to several theorists (Colwill and Rescorla, 1986; Dickinson and Balleine, 1994), behavior is said to be goal directed

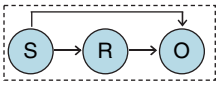

Figure 4 Theoretical associative structure underlying instrumental conditioning. S = stimulus representation, R = response representation, O = outcome representation. Arrows indicate hypothetical unidirectional excitatory associations between representations. The dashed-line box envelopes the contents of learning. Associations are hypothesized to form between S and R, between S and O, and between R and O.

if it is mediated by the instrumental contingency between the action and the outcome and by the value of the outcome (*See also* Chapters 1.03, 1.06). This operational definition is consistent with the two lines of evidence in support of R-O associations: posttraining changes in the value of the outcome and manipulations of the response–outcome contingency.

1.10.2.1 Behavioral Dissociations

1.10.2.1.1 Outcome devaluation

Perhaps the simplest way to demonstrate that the instrumental response is motivated by the expectation of the outcome is to change the value of the outcome after instrumental learning. The logic is straightforward: If desire for the outcome is motivating the instrumental response, then rendering the outcome less desirable should reduce the motivation to acquire it. Thus, reducing the value of the instrumental reinforcer after training should render it less desirable and weaken the instrumental response that had previously earned that reinforcer. Likewise, increasing the value of a reinforcer should increase the motivation to work toward obtaining that reinforcer.

Tolman and Honzik (1930) provided early empirical support for the role of the outcome expectancy in motivating the instrumental response (see also Tinklepaugh, 1928). Their study involved three groups of rats placed in a complex alley maze (**Figure 5**).

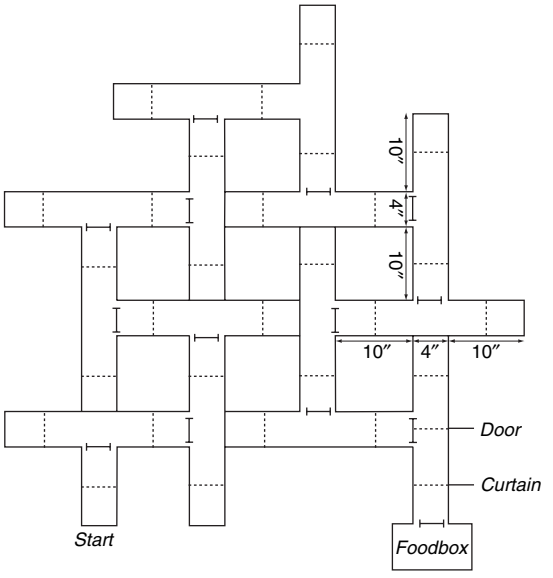

Figure 5 Maze used by Tolman and Honzik (1930) to study latent learning in rats. From Tolman EC (1948) Cognitive maps in rats and men. *Psychol. Rev.* 55: 189–208.

Each rat was placed into a start box at one end of the maze and removed from a goal box at the other end. Only one sequence of arms of the maze led from the start box to the goal box, and a number of other arms led to dead ends. Tolman and Honzik scored the number of dead-end arms rats entered ('errors') during each trip from start to goal box. One group of rats was rewarded with food when they reached the goal box, and the number of errors decreased dramatically as a function of the number of trips they made (**Figure 6**).

The second and third groups of rats received no food in the goal box for the first 10 trials in the maze. One of these groups, however, did find food in the goal box on the eleventh and subsequent trials. **Figure 6** reveals that after finding food in the goal box for the first time on the eleventh trial, the number of errors this group of rats made dramatically decreased on the twelfth and subsequent trials. This result is perhaps the most famous demonstration of latent learning in the literature, showing that rats had learned to traverse the maze efficiently (i.e., with few turns into dead ends) even in the absence of explicit food reinforcement. In fact, this learning was just as strong in the group that was not rewarded during the first 10 trials as it was for the group for which food was available from the very beginning of training. More important for our purposes, this study also demonstrates that an increase in the motivational significance of a goal (in this case the contents of the goal box) has a dramatic and immediate effect on performance. The rats in the latent group must have changed their representation of the outcome on the eleventh trial, which motivated their performance on the twelfth trial. More recent

Figure 6 Acquisition performance from Tolman and Honzik (1930). From Tolman EC (1948) Cognitive maps in rats and men. *Psychol. Rev.* 55: 189–208.

demonstrations of positive behavioral contrast effects like this provide further support for the role of outcome representations in mediating the strength of instrumental behavior (for a review see Flaherty, 1996).

Tolman and Gleitman (1949) also showed that a downshift in the cues surrounding the reinforcer can affect instrumental performance. Rats first learned to find food at either end of a T-maze. The goal box at the end of one arm was always dark, and that at the end of the other arm was always lit. Both goal boxes, however, always contained the same amount of food, and thus had equal value. Following training, the rats were taken to a separate room that was dark, in which they received foot shocks. After this experience, the rats were returned to the T-maze. Not surprisingly, the rats avoided the dark goal box in favor of the lit goal box, despite both boxes containing the same amount of food and having no shocks. This preference suggests that the rats had encoded the illumination properties of the two goal boxes and avoided the dark box in which they expected the possibility of receiving another shock.

One problem with the above studies is that they involve a change in the quality of the reinforcer, such as from no food to food in the goal box, or from food to food + shock in the dark part of the box. Perhaps the new outcome itself caused rapid changes in the instrumental response through the normal S-R mechanisms, rather than affecting the representation of the outcome mediating the response. That is, the added or altered outcome reinforces a new S-R association. This problem can be avoided by directly manipulating the value of the reinforcer itself without affecting its qualities or attributes. Adams and Dickinson (1981) demonstrated in an operant lever-pressing preparation that a downward shift in the value of the reinforcer immediately affects instrumental performance (but see Adams, 1980, 1982). Rats first learned to press a lever by reinforcing lever pressing with a food reward. After subjects had acquired the task, the reinforcer was devalued through pairings with a mild toxin that produced gastric malaise. After being paired with the toxin, rats were highly reluctant to consume the food, showing that they had acquired an aversion to it. When placed back into the conditioning chamber with the lever available that had earned the food during initial training, rats were now reluctant to press the lever as well. Importantly, the devaluation procedure was conducted away from the conditioning situation, which rules out effects of the manipulation on learning of the response and on context-illness associations. Moreover, the devaluation procedure had an immediate effect on instrumental responding when the rat was returned to the operant chamber.

More compelling evidence for the role of outcome representations in the mediation of an instrumental response comes from work by Colwill and Rescorla (1985). They demonstrated the specificity of the devaluation manipulation to the instrumental response that had earned that outcome using a choice procedure. In their study, rats were trained on two action–outcome contingencies involving two actions (lever pressing and chain pulling) and two outcomes (a sugar solution and food pellets). For each subject, one of the actions was always reinforced with one of the outcomes (e.g., lever press → sugar solution), and the other action was always reinforced with the other outcome (e.g., chain pull → food pellet). Following instrumental training of the two action → outcome sequences, one of the outcomes was devalued through pairings with a mild toxin. The effect of this devaluation procedure was to depress instrumental responding of the action that had previously earned that outcome, but not of the action that had earned the other outcome (**Figure 7**).

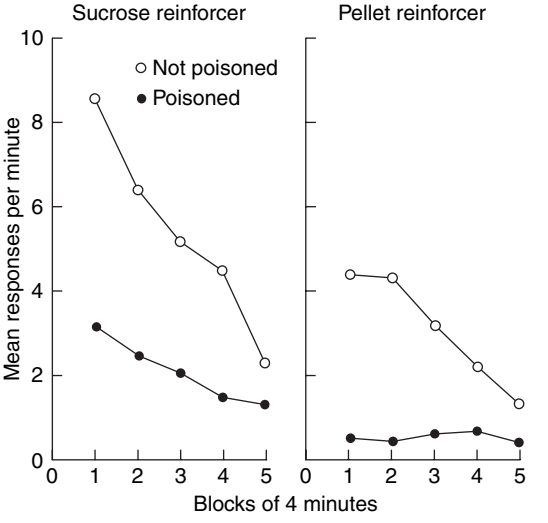

Figure 7 Experiment 1 of Colwill and Rescorla (1985). Mean response rate on the levers that had earned the poisoned (filled symbols) and nonpoisoned (open symbols) actions, for both sucrose reinforcer (left panel) and pellet reinforcer (right panel). Reprinted from Colwill RM and Rescorla RA (1985) Postconditioning devaluation of a reinforcer affects instrumental responding. *J. Exp. Psychol. Anim. Behav. Process.* 11: 120–132, with permission from the authors.

Similar results are obtained if the animal is satiated on one of the outcomes prior to the choice test session. Balleine and Dickinson (1998b) trained rats to make two instrumental responses (right and left lever presses), one for a salt-flavored and one for a lemon-flavored polycose solution. Following instrumental training, rats were given one hour to feed freely on one of the foods immediately prior to an extinction choice test in which both responses were available (but no reinforcement was delivered during the test session). Response rates were significantly lower on the lever that had earned the food reward to which they had been sated than on the lever that had earned the nonsated reward. The results of these experiments reveal the selective nature of the devaluation procedure and provide strong evidence that two separate R-O associations motivated instrumental responding. The selective nature of the devaluation treatments further show that the qualitative features of each outcome were specifically associated with the instrumental response that earned that outcome. One important caveat needs to be mentioned. In most cases, the suppressive effects of outcome devaluation on instrumental responding require the subject to reexperience the devalued food during the extinction choice test (i.e., incentive learning; Balleine, 1992; Balleine and Dickinson, 1998a,b). Initial failures to find outcome devaluation effects on instrumental responding stemmed from failures to expose the subject to the devalued outcome after devaluation treatment (Adams, 1980, 1982).

1.10.2.1.2 Manipulations of the R-O contingency

A second line of evidence for R-O associations comes from manipulations of the R-O contingency. If an instrumental response is goal directed, then by definition it should be sensitive to the relation between the action and the outcome. If the outcome is made freely available, for example, then there is no need for the individual to go through the extra effort involved in making the instrumental response to earn that outcome. Evidence showing the necessity of the R-O contingency on instrumental behavior comes from experiments using the omission procedure. In an omission procedure, a behavior is initially conditioned through pairings with reinforcement. After conditioning is established, the reinforcer is scheduled to be omitted if the subject makes a response. The reinforcer will be delivered, however, if the subject withholds responding. This procedure was developed for the purpose of dissociating instrumental from Pavlovian conditioned responding. The logic of the procedure is that Pavlovian conditioned responses (CRs) are not sensitive to the response–reinforcer contingency, and thus should not be affected by the omission of the reinforcer, whereas while instrumental responses, which by definition are sensitive to their own consequences, should be affected by the omission of the reinforcer. This procedure has been useful in discriminating acquired responses that are Pavlovian or instrumental in nature. For example, Holland (1979) showed that the acquisition of magazine approach during a tone that was paired with food developed despite the fact that food was withheld if the animal approached the food magazine during the tone. Although magazine approach appeared goal directed, it was actually shown to be insensitive to the negative response–reinforcer contingency. Rather, magazine approach appears to be a Pavlovian response (see Dickinson, 1988, for a fuller discussion of the omission procedure).

More recently, demonstrations that animals are sensitive to the response–outcome contingency have been pursued for the explicit aim of showing the goal-directedness of instrumental behavior. A simple method that demonstrates the goal-directed nature of instrumental responding is to deliver free (i.e., noncontingent) reinforcers during an instrumental session. Delivery of noncontingent food pellets during a session in which a rat is engaged in pressing a lever for food suppresses instrumental lever pressing. Moreover, if a rat has two manipulanda available, each delivering a different outcome, the suppressive effects of noncontingent delivery of one outcome is selective to the manipulandum that earns that outcome (Hammond, 1980; Dickinson and Charnock, 1985; Colwill and Rescorla, 1986; Dickinson and Mulatero, 1989). For example, Colwill and Rescorla trained rats on two instrumental responses (lever press and chain pull), each for a particular outcome (sucrose solution and food pellet). After response rates had stabilized, one of the outcomes was freely delivered in addition to being earned by the response. The rate of responding on the manipulandum that earned the noncontingent outcome decreased, while the rate of responding on the other manipulandum was unaffected. In some cases, noncontingent presentations of one outcome can depress both responses that earn that outcome and those that earn a different outcome, but the response that earns the same outcome that is made freely available shows significantly greater suppression (**Figure 8**; Balleine and Dickinson, 1998a).

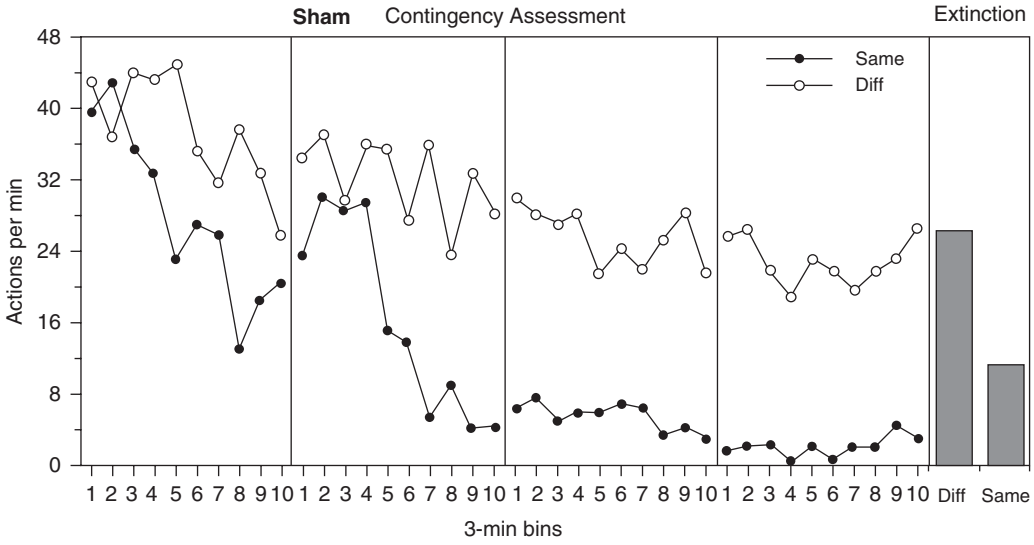

Figure 8 Figure 1 from Balleine and Dickinson (1998a). The mean number of actions (lever pressing and chain pulling) per minute during the four sessions of training under the noncontingent training and during the final extinction test (right-hand panel). The response rates are shown separately for the actions paired with the reward that was same as and different from the unpaired reward. Reprinted from Balleine BW and Dickinson A (1998) Goal-directed instrumental action: Contingency and incentive learning and their cortical substrates. *Neuropharmacology* 37: 407–419, copyright (1998), with permission from Elsevier.

1.10.2.2 Neurobiological Dissociations

The distinction between habitual and goal-directed behavior can also be made at the level of neural circuitry. Vertebrates and invertebrates both show parallel circuitry for reflexive behavior – including unconditional reflexes and species-typical fixed-action patterns on the one hand, and conditioned reflexes on the other – and voluntary behavior. For example, there are two circuits that mediate tail-flick escape behavior in the crayfish (*Procambarus clarkii*): one that mediates rapid and automatic escape responses and one that mediates slower and more flexibly controlled responses (Wine and Krasne, 1972; Edwards et al., 1999; see **Figure 9**).

The rapid escape reflex in response to abrupt stimulation, such as a sharp tap to the side of the abdomen, is a fixed-action pattern that is mediated by medial giant (MG) command neurons. Intracellular recordings from the MGs detect electrical responses in as little as 10 ms after the tap stimulus is applied. The nongiant system, which is excited by gentle prodding and pinching, mediates longer-latency responses that are under a much greater degree of control by the animal than are the immediate escape behaviors. The nongiant neural circuitry innervates and controls the same muscle systems as do the MGs, but it is much more complex (**Figure 9**) in both the interconnections and the number of layers between the sensory and motor neurons. Although much less is known about the functional control by the nongiant system, presumably it allows for a finer degree of control over the timing and direction of the movement and may even monitor actions as they are planned to allow for corrective feedback prior to execution of the action (see Section 1.10.4.1).

The distinction between the neural basis of the habit system and the voluntary or goal-directed action system can be made in vertebrates as well. There is not sufficient space here to adequately review the extensive literature on this dissociation, but it appears that, in mammals at least, S-R habit learning can be mediated at many locations within the nervous system, including the spinal cord (Chen and Wolpaw, 1995), the basal ganglia (White, 1989), and the striatum (Yin et al., 2004), whereas goal-directed R-O learning is mediated by cortical structures, such as the prelimbic area and the insular cortex (Balleine and Dickinson, 1998a).

1.10.3 Agency

1.10.3.1 Intentional Psychology: Beliefs and Desires

Now that we have established the veracity of the goal-directedness of some acquired behaviors, we can speak with some assurance about the role of

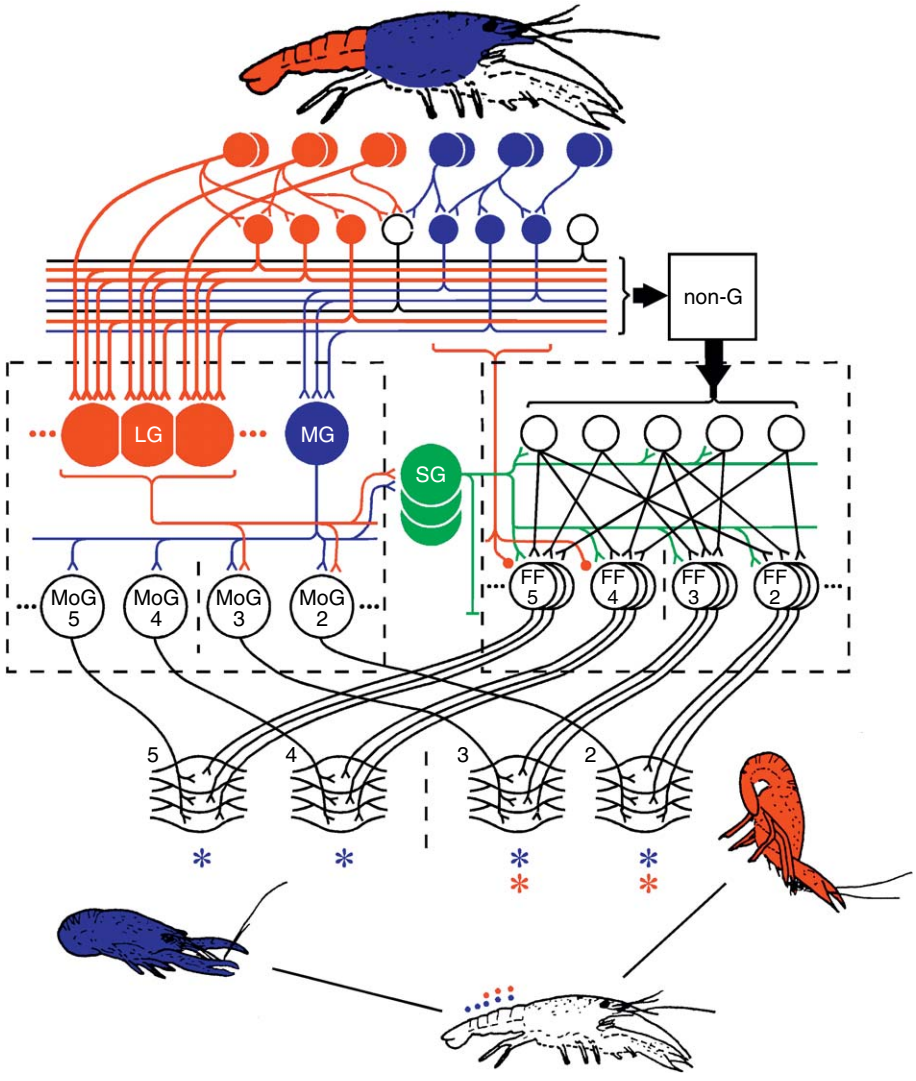

Figure 9 Neural circuitry mediating the escape reflex and volitional tail flipping in the crayfish. Giant-fiber (GF)-mediated reactions are portrayed in the drawings at the bottom of the left side of the figure: the red crayfish represents a lateral giant-axon (LG)-mediated response, and the blue crayfish represents a medial giant-axon (MG)-mediated response. The segmental joints at which bending occurs to produce these reactions are indicated by small colored circles above the white crayfish. LG-associated elements and MG-associated elements are colored in red and blue, respectively. The sensory fields (mechanosensory for LG and mechanosensory and visual for MG) for the two types of GF-mediated reactions are indicated at the top of the figure. Circuitry for GF-mediated responses is shown on the left with primary afferents, sensory interneurons, LG and MG, and giant motor neurons (MoGs) arranged from top to bottom. The multisegmental nature of the LG, which is an electrically well-coupled chain of segmental neurons, each with its own dendrites, is indicated. Colored asterisks mark phasic flexor muscles of segments 2–5 that are used in each type of GF reaction. Circuitry for responses that do not use giant neurons (non-G responses) is shown on the right. A separate population of fast flexor (FF) motor neurons generates non-G responses; uncharted circuitry (box marked non-G) and a set of partially identified premotor interneurons (open circles) mediate between sensory neurons and FF motor neurons. The segmental giant neuron (SG; green), with its blind-ending axon, allows the LG and MG to recruit non-G motor and premotor units. Lateral giant-neuron-associated sensory circuitry provides inhibitory input to caudal FFs (red) so that the SG will not cause bending at caudal joints during LG-type tail flips. Curly brackets show that multiple neurons of the population innervate the indicated target. Reprinted from Edwards DH, Heitler WJ, and Krasne FB (1999) Fifty years of a command neuron: The neurobiology of escape behavior in the crayfish. *Trends Neurosci.* 22: 153–161, copyright (1999), with permission from Elsevier.

beliefs and desires in an intentional psychology (Dickinson, 1988). Intentionality is notoriously difficult to establish in a system because so much behavior can be described using intentional language. We readily slip into intentional language to describe the behavior of our pets (Rover is barking to warn the stranger at the doorstep), computers (My laptop is searching its memory for the file), and the weather (Political leaders escaped Katrina's wrath). The language of intentional folk psychology provides a convenient shorthand to describe and explain behavior, even when we fully recognize that the behavior itself is not intentional at all (Dennett, 1987). Learning theorists themselves find it difficult not to slip into intentional language when describing the behavior of their subjects. In fact, we frequently apologize to our peers for slipping into teleological or anthropomorphic language when we catch ourselves doing so or diffuse the affront by placing the offending material in scare quotes. The rampant misuse of intentional language, however, is for the most part benign and should not devalue the scientific investigation of behavior that is truly intentional in nature. In fact, describing nonintentional behavior using intentional language may assist humankind's ability to predict and control nonintentional systems.

Given the evidence for goal-directed, intentional behavior in the animal kingdom, what is its function? That is, why would it have evolved? Couldn't a creature that lacked goal-directed behavior function just as well in its world as one that had it? Perhaps not. Explicit representation of a goal may serve to motivate behavior to bring the animal into contact with the goal. Furthermore, an animal that believes that an action produces (or prevents) a goal, and that desires (or dislikes) that goal, can be more flexible in when and how it goes about seeking and obtaining (or avoiding) the goal. For example, an omnivorous species – such as a rat, a pig, or a human – must learn which foods are good to eat and which should be avoided. A food previously discovered to be safe for consumption, however, may become spoiled or otherwise unpalatable. The animal that is capable of learning about the devalued food should be able to refrain from seeking out and consuming that food more rapidly than an animal that depended on trial-and-error learning alone. A rat is much more likely to live after one poisoning event than after many. Likewise, an animal that learns of another source where food can be obtained with much reduced effort should be able to immediately curtail exertions to acquire that food from its previous source. Such an animal can plan for the future. So far, these suppositions are no better than Kipling's (1912) *Just So Stories*. There may, however, be a more important and defensible role for intentional behavior that led to its evolution. This has to do with the concept of agency – a term that often arises in discussions of goal-directed action and intentional behavior.

1.10.3.2 Animals as Free Agents

Leslie (1995) defines an agent as an object that has three properties that distinguish it from other physical objects: mechanical, actional, and cognitive properties. The mechanical property that distinguishes agents from other types of objects is that they have an internal and renewable source of energy (or FORCE in Leslie's terminology) that allows them to *cause* things to happen in the world without themselves having to rely on external sources of energy and force (although we must acknowledge the fact that even agents must refuel). Premack (1990) has made the same distinction, invoking the term 'self-propelledness.' This property allows the agent to be a source of causation (though perhaps not the ultimate source according to adherents of philosophical determinism). To be classified as agents, objects also need to exhibit actional properties, which consist of the object's ability to act and react to events or circumstances in the world that are spatially and/or temporally distant. This property is what characterizes the agent's behavior as goal directed or intentional – at least by appearance. Note, this property of agenthood can be ascribed to an object that only appears to have intentional, purposeful, goal-directed behavior, even if the internal control mechanism itself is not goal directed. For example, a moth's suicidal plunge into a burning flame appears goal directed (the moth sought the flame) even though the control mechanism is a simple, innate (i.e., 'blind') phototaxic reflex. The third property of agency is the cognitive property. An agent's behavior is determined by its beliefs about the world (propositional knowledge). Beliefs are not only about static, coherent states of the world (semantic knowledge) but, more important, are about the causal texture of the world. To believe that A causes B asserts the belief that certain values of A (a1, a2, a3...) are determinants of certain values of B (b1, b2, b3...), and that changes in the state of A (e.g., a1 → a2) should bring about a complimentary change in the state of B (i.e., b1 → b2) (see Woodward, 2003, for a discussion of causal explanation).

1.10.4 Interventions and Causal Reasoning

1.10.4.1 Making Things Happen

What advantages does an agent gain with its ability to represent causal relationships in this manner and hold desires for particular outcomes? One obvious advantage is that such an agent could test its belief system – that is, to fact check. More important, an agent could check facts systematically (cf. Dennett's [1995] Popperian creatures) rather than through blind or random trial and error (cf. Dennett's Skinnerian creatures). The intersection of causal beliefs with desires for goals provides a creature with the ability to manipulate its environment to achieve its goals. This feature of agency provides a creature with a powerful tool – instrumental manipulation of its world. A purely Pavlovian creature can merely passively learn about the causal texture of the world through observation; such a creature is stuck in its world and can merely predict effects based on their cues and respond in anticipation. A creature with both Pavlovian and instrumental learning processes available to it could both passively learn about the causal texture of the world through observation and actively manipulate the world to directly discover its causal texture. Goal-directed instrumental learning allows the agent to actively explore its world through direct intervention. This exploration will uncover many cause–effect relationships that would have remained hidden to a purely passive observer.

Another important feature of agency is that goal-directed behaviors impart a sense of agency to the individual's intentional behaviors. That is, in contrast to reflexive habits, goal-directed behavior is accompanied by unique sensory feedback that is responsible for the sense that 'I' (the agent) control events in the outside world (Haggard, 2005). This distinction is supported by experimental (Libet, 1985) and neurobiological (Sirigu et al., 2004) evidence. These internal sensory markers of intentional behavior should be important, if not critical, to the ability to reason from causal interventions (see discussion below). That is, without the ability to distinguish effects resulting from self-generated, intentional actions from effects resulting from other causal sources (including the agent's nonvoluntary or reflexive behavior), the agent would be incapable of interventional reasoning. This suggestion is supported by imaging studies that use transcranial magnetic stimulation to temporarily inactivate a particular brain area. These studies suggest that the presupplementary motor area – which tracks the neural pathways responsible for intentional action – acts as an internal monitor of intentional action (Haggard et al., 2002; Haggard and Clark, 2003). This predicting signal allows the agent to correct errors in the execution of the action before the action itself occurs. Moreover, this predictive signal can be used to enhance the perception of non-self-generated sensations. For example, the tactile sensation that results from one finger touching the adjacent one is perceived as weaker than the same stimulus imposed from an external source. Attenuated self-generated sensations can more readily be ignored, freeing up attentional resources to focus on the external world. This attenuation of self-generated sensory experience may result from a predictive process that anticipates self-generated sensations, or a postdictive process that judges the source of the perception to be self-generated or externally generated after the sensation has been experienced.

A recent study suggests that the process is predictive (Bays et al., 2006). Participants were required to judge whether a second (comparison) tap was stronger or weaker than a first (sample) tap to their left index finger. The first tap was always the same magnitude, while the strength of the second tap was varied across trials. On most trials, the second tap followed the first by a short interval and was produced by the subject tapping with their right hand onto a button positioned above the left-hand index finger (Contact Trials, **Figure 10(a)**, top panel). This produced a sensation of tapping on one's finger through a solid object. Occasionally, subjects would receive a trial on which the second tap was artificially delayed by 500 ms after they tapped the button with their right hand. On Delay trials, the second tap was perceived as being much stronger than a tap of the same magnitude on Contact trials (**Figure 10(b)**, Group A). The increased magnitude of the perceived tap on Delay trials was not, however, a result of the absence of a right-index finger press at the time the tap was felt. Of primary importance, however, were the occasional No-Contact trials that were conducted to test whether subjects were predicting a self-generated sensation when they attempted to press the button. On No-Contact trials, the button was removed so that when the subject attempted to make a button press they failed to actually press the button (**Figure 10(a)**, bottom panel). Despite the absence of a button press, the subjects reported these No-Contact taps to be much weaker than the

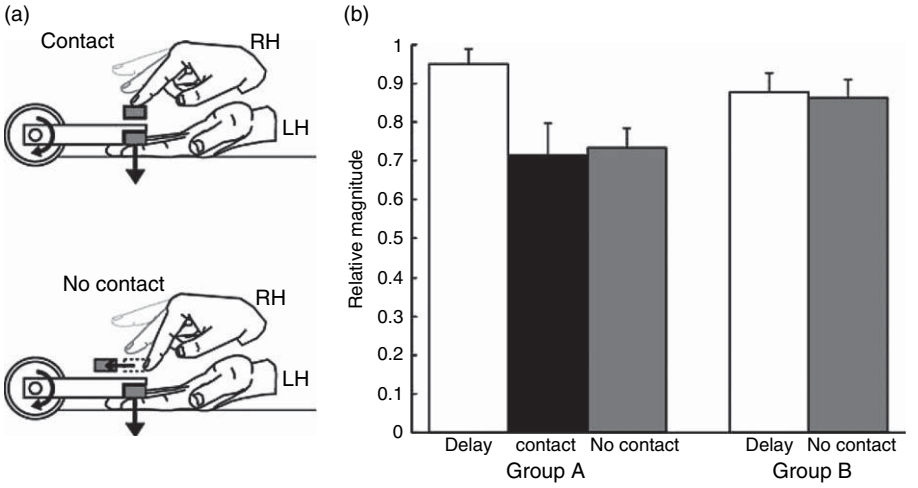

Figure 10 (a) Schematic of the apparatus and task used by Bays et al. (2006). On contact trials (top), in response to an auditory go signal, participants produced a brief force pulse with their right index finger on a force sensor fixed above their left index finger. A similar force pulse was delivered to the left index finger by a torque motor. On no-contact trials (bottom), the force sensor was moved at the start of the trial so that participants made a tapping movement with their right index finger but did not make contact. (b) Mean relative magnitude of the comparison tap to the test tap at the point of perceptual equality as a function of trial type and participant group. Error bars represent ±1 SE. Reprinted from Bays PM, Flanagan JR, and Wolpert DM (2006) Attenuation of self-generated tactile sensations is predictive, not postdictive. *PLoS Biol.* 4: e28.

taps felt on Delay trials. In fact, No-Contact taps were perceived as being the same magnitude as Contact taps (**Figure 10(b)**, Group A). These results show that the subjects anticipated the sensation of a self-generated tap, even when they were prevented from physically engaging the tap. It therefore appears that the process that monitors intentional actions is predictive and attempts to attenuate sensations arising from self-generated actions. This in turn can enhance the perception of sensations caused by an external source.

1.10.4.2 Seeing versus Doing

A burgeoning literature exploring the theoretical mechanisms of causal interventions is developing in the fields of computer science, statistical theory, philosophy, and psychology (Spirtes et al., 1993; Pearl, 2000; Steyvers et al., 2003; Woodward, 2003; Sloman, 2005; Waldmann and Hagmayer, 2005; Waldmann et al., 2006). A resulting achievement is a clear and precise language, taxonomy, and formalization of the difference between observing the cause–effect relationships among a set of variables (Seeing) and intervening on one variable to determine its causal status in relation to the other variables (Doing). These analyses describe the special status interventions have on our (human) ability to determine cause–effect relationships in the world. "If I flick this switch, the light turns on. If I don't flick the switch, the light remains dark." Such a simple cause–effect relationship can only be determined through intervention. (Note that the agent does not have to actively intervene; the agent can merely observe another agent intervening or observe a fortuitous intervention, such as a book that falls off the shelf and accidentally flicks the switch on its journey to the floor. Theoretical treatment of causal interventions does not treat these scenarios as being different in any significant way.) The ability to reason about cause–effect relationships through the intervention on a single variable is the basis for the scientific method, which gives humankind an incredible analytical power over the world. "If I put reagent X into a beaker filled with reagent Y, the mixture ignites, otherwise the mixture remains inert." "If I look at a blue-filled circle for 60 seconds, I then see a yellow, circular afterimage when I look at a white wall."

A simple example will serve to clarify the fundamental difference between Seeing and Doing and the powerful role interventions (Doing) play in causal reasoning processes. Consider the workings of a barometer (**Figure 11**).

The barometer's reading may vary upward or downward, and this variation correlates strongly with changes in the weather. If we observe an

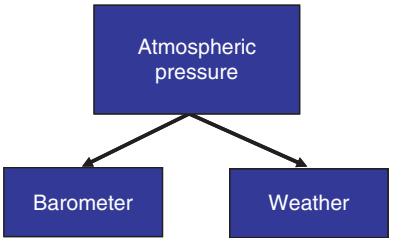

Figure 11 Causal model for how a barometer and the weather are both effects of a common cause, atmospheric pressure. Arrows indicate causal relationship directed from the cause to the effect.

increase in the barometer's reading, we can expect to see sunny skies when we look out the window. If we observe a decrease in the barometer's reading, however, we can expect to see rain clouds gathering. This tight correlation between the barometer and the weather is not the result of a direct causal relationship between the two events. Rather, changes in both the reading of the barometer and the weather are caused by a third event – changes in atmospheric pressure. If we understand the actual causal relationship among these three variables, then we would predict that tampering with the barometer (an intervention) should not affect the weather (or air pressure for that matter; Waldmann and Hagmayer, 2005). Imagine a child observing a barometer for the first time. Without prior schooling on its operation, she might at first entertain the notion – because of temporal priority – that changes in the barometer's reading cause changes in the weather. If she set the barometer to a higher reading, however, she would soon discover that she did not bring about sunny skies. Through intervention on the barometer she was able to test her hypothesis and discover a more accurate underlying causal structure. She would never have been able to discover the underlying causal relationship without access to interventional knowledge (her own or someone else's). Gopnik et al. (2004) provide another telling example:

> smoking is correlated both with having yellow fingers and with getting cancer, so having yellow fingers is correlated with getting cancer, but cleaning your hands will not keep you from getting cancer, and quitting smoking will. Knowing the right causal structure may not be essential for predicting one thing from another, but it is essential for predicting the effects of interventions that deliberately manipulate events. (Gopnik et al., 2004: 8)

Goal-directed behavior provides an important foundation for interventional reasoning. The ability to use interventions to examine causal relationships within a system is predicated on three assumptions (adapted from Gopnik and Schulz, 2004): (1) that interventions are exogenous to the system being studied and not caused by other variables within the system, (2) the intervention directly fixes one variable within the system to a specific value (e.g., a switch is moved from OFF to ON), and (3) the intervention does not affect the values of other variables within the system except through its influence on the variable that is the target of the intervention. The second and third assumptions necessarily depend on goal-directed behavior. If an individual can not represent the contingent relationship between their actions and goals, then they would not profitably use their actions – via the effects their actions have on the world – to investigate cause–effect relationships.

1.10.4.2.1 Seeing versus doing in children

Children, it turns out, do appreciate the special role of interventions in diagnosing cause–effect relationships from an early age (Gopnik et al., 2004). In one experiment, 4-year-old children were shown two or three colored rubber balls attached to sticks (hereafter referred to as 'puppets') and placed on top of a box. The children observed the puppets move up and down simultaneously. The puppets could be attached to each other – though the children could not see the attaching mechanisms – so that the experimenter could arrange for the simultaneous movement of the puppets (**Figure 12**). This enabled the children to observe the correlation of movement without observing the intervention by the experimenter. In other conditions, the experimenter could move one puppet at a time, independently of the others. In the pretraining phase of the experiment, the children watched the puppets move together simultaneously. They were then told that one of the puppets was 'special' in that it always made the other puppet(s) move.

The children were then presented with two types of tasks. In the common-effects task, the children observed two puppets (X and Y) move and then stop together simultaneously a number of times, followed by a demonstration that one of the puppets (Y) could be moved without affecting the movement of the other puppet (X). This was accomplished by the experimenter visibly moving puppet Y by moving the top of the stick to which it was attached. Finally, the children watched both puppets move

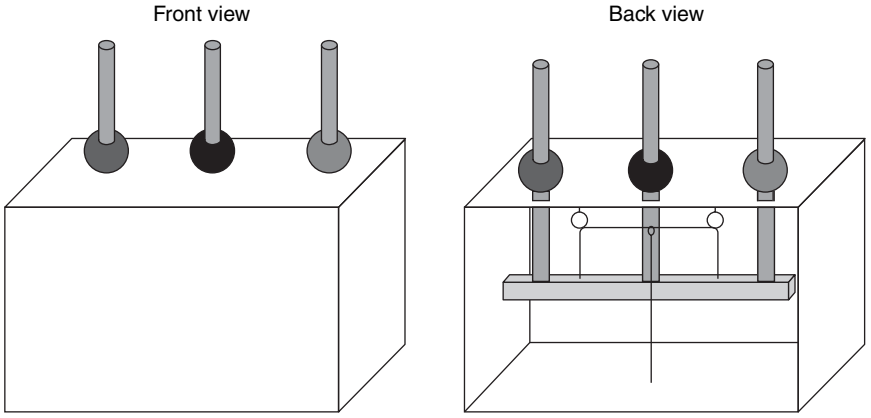

Figure 12 The puppet machine used by Gopnik et al. (2004). Reprinted from Gopnik A, Glymour C, Sobel DM, Schulz LE, Kushnir T, and Danks D (2004) A theory of causal learning in children: Causal maps and Bayes nets. *Psychol. Rev.* 111: 3–32, with permission from A. Gopnik.

together again by the experimenter invisibly moving the connecting mechanism behind the box. The children were asked "Which is the special puppet?" The children chose puppet X a majority (78%) of the time. This suggest that they drew the 'correct' causal interpretation of the relationship between the puppets; that is, that movement of Y is a common effect of both the experimenter's intervention (I) and of the movement of X. I use quotes because the movement of puppet Y was always the result of intervention by the experimenter; however, the children could not see this intervention when it was hidden by the box. Thus, given their sensory data, they observed two conditions: puppets X and Y moving without an apparent intervention by the experimenter, and puppet Y moving in the absence of the movement of puppet X when the experimenter intervened on it. The children's selection of puppet X as special indicates that they represented the causal relationships in the following way: $I \rightarrow Y \leftarrow X$, where the letters represent the events (I = intervention, Y and X = puppets) and the arrows indicate causal directionality. In causal graphs, arrows always point from the cause to the effect. Thus, in the causal graph the children inferred, Y was a common effect of both intervention by the experimenter (I) and of the movement of puppet X.

The second task involved a common-cause relationship among events. In this task, children observed three new colored puppets (X, Y, and Z) move and stop together a number of times. Then they observed the experimenter intervene to move Y independently of the other two puppets and then intervene to move Z independently of the other two puppets. The causal relationships the children should have drawn from this pattern of observations can be graphed as follows: $I \rightarrow Z \leftarrow X \rightarrow Y \leftarrow I$. This causal graph follows from the observations that puppets Z and Y could be moved independently through intervention (I) or moved simultaneously with puppet X. Thus, the children should have inferred that X was a common cause (i.e., a special puppet) of the movements of the other two puppets. This is exactly what the children reported, choosing X as the special puppet 84% of the time.

These experiments reveal how important information from interventions is for young children to reason about the causal texture of their world. If the children only had access to observations of the puppets moving together, then it would have been completely ambiguous which puppet or puppets caused the others to move, if indeed any of them were causally related to the others. It would also have been just as likely that some other, hidden force caused all of the puppets to move together (cf. changes in a barometer and the weather being driven by the unobservable air pressure). Observing that direct interventions on some of the puppets caused only those puppets to move allowed the children to select out the unlikely causal relationships among them and zero in on the most likely interpretation. That is, interventions allowed them to test their hypotheses.

1.10.4.2.2 Seeing versus doing in rats

If children can reason about cause–effect relationships from interventions, what about other animals? What is the evidence that nonhuman animals can reason about

their causal interventions? Blaisdell et al. (2006) recently investigated this question in rats using conventional conditioning procedures. In a training phase, rats observed a light followed by a tone (L → T) in one session and a light followed by food (L → F) in a second session (Blaisdell et al., 2006, Experiment 2).

One possible causal representation the rats could derive from this observational learning is that the light was a common cause of both the tone and food. No levers were present during the training phase, but during the test phase a lever was inserted into the conditioning chamber for the first time. Note that the rats had never seen this lever before and had certainly not received any training to press the lever. Nevertheless, the following contingency was put in place for half of the rats in the study: if the rat pressed the lever, the tone would come on. In contrast to this Intervention condition, the remaining rats were allocated to an Observation condition. Rats in the Observation condition also had the lever available, but pressing the lever had no effect. That is, the rats in the Observation condition had an inactive lever. The Intervention condition allowed Blaisdell et al. to assess what the rat inferred when it intervened via the lever press to turn on the tone. The Observation condition measured whether the rats expected food when they heard the tone. If rats had formed the causal model T ← L → F, then by observing the tone (Group Observe) they should diagnostically predict the light and thus also predict that food should be available (**Figure 13**, top panel, left-hand graph). By intervening on the tone, however, the rats should infer that they – and not the light – had caused the tone. Therefore, they should neither predict the light nor the food (**Figure 13**, top panel, right-hand graph). This pattern of data was exactly what Blaisdell et al. observed (**Figure 14**, left-hand bars).

If the rats were reasoning correctly about their interventions, then lever-pressing should not invariably disrupt all causal relationships between the tone and other events but only between other causes of the tone. For example, interventions on the tone should not disrupt expectations of the tone's effects. To show this, Blaisdell et al. (2006) tested another group of rats that had similar training as described above but for one key difference. Rather than receiving Light → Tone pairings in the first phase of training, they received Tone → Light pairings. This treatment, when combined with the following phase of Light → Food pairings should have taught the rats a Tone → Light → Food causal chain (**Figure 13**, bottom panels). Again the rats were divided into two test groups after receiving causal-chain training, with half the rats receiving the Intervention condition (lever pressing turned on the tone) and the remaining rats receiving the Observation condition (tones were presented independent of lever pressing). If rats had learned to treat the light as an effect of the tone, then interventions on the tone at test should still activate an expectation of the light that should then generate the expectation of food (**Figure 13**, bottom panel, right-hand graph). Thus, equivalent amounts of magazine entries should be observed in both the Intervention and Observation conditions. This is exactly what was observed (**Figure 14** central

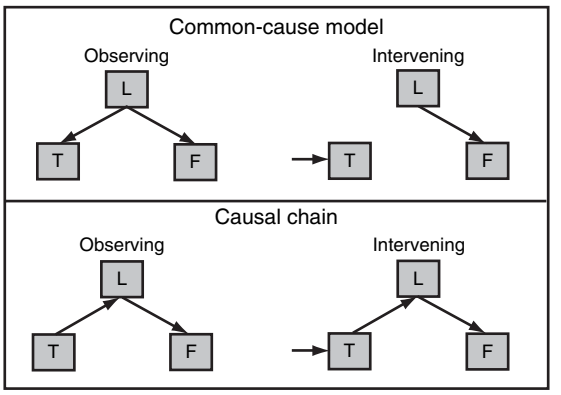

Figure 13 Causal models of the relationships among events in Experiment 2 of Blaisdell et al. (2006). Reprinted from Blaisdell AP, Sawa K, Leising KJ, and Waldmann MR (2006) Causal reasoning in rats. *Science* 311(5763): 1020–1022, with permission.

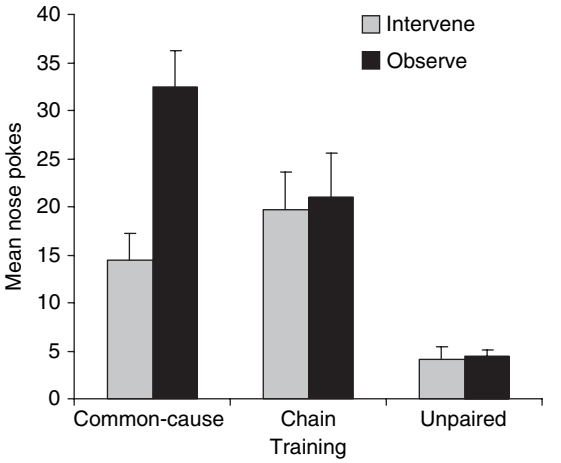

Figure 14 Data from Blaisdell et al (2006) Experiments 2a and 2b. Adapted from Blaisdell AP, Sawa K, Leising KJ, and Waldmann MR (2006) Causal reasoning in rats. *Science* 311(5763): 1020–1022, with permission. See text.

bars). It was furthermore established that magazine entries evoked by the tone depended on the tone having an indirect causal relationship to the food. This was shown through the inclusion of a third group of rats that had received unpaired presentations of the tone and light, so that the two could not enter into any kind of causal relationship, which prevented the tone from eliciting magazine entries at test (**Figure 14**, right-hand bars).

These results show that even rats can reason in a sophisticated manner about their goal-directed interventions by using them to infer the causal structure of the world. I am pitching this description of reasoning processes in rats at the computational level of analysis (Marr, 1982), which is described in terms of representations. The distinction should be made between a causal representation and the learning process though which the representation is acquired (Dickinson, 1980; Heyes and Dickinson, 1990). The learning process might take the form of an entirely algorithmic level associative process. The rats for which a lever press produced a tone did not expect food as strongly as did rats that received tones unconnected to their lever pressing behavior. A plausible explanation for this difference at the algorithmic level of description lies in the rat's knowledge about what instrumental actions do. That is, the rats in our study (and rats in general) have had lots of experience learning about the effects of their actions on the world. This learning starts in infancy (if not earlier) and continues throughout the lifetime of the rat. In fact, both 1-day-old rat pups (Johanson and Hall, 1979) and newborn human infants (DeCasper and Fifer, 1980) can learn instrumental responses. Thus, throughout their lifetimes, rats acquire a large number of action–outcome associations. This learning is typically accompanied by unique feedback cues associated with self-generated, volitional behavior (see Section 1.10.4.1). These feedback cues are presumably present while the rat is engaged in lever pressing in the study phase of the test by Blaisdell et al. (2006). If the associations between these feedback cues and prior outcomes of self-generated, goal-directed action generalize to the current test situation, then the rats that experience the tone following their lever press should discriminate the tone as being the outcome of a self-generated cause rather than the outcome of a non-self-generated cause. Therefore, the tone in the intervention condition should be treated as being caused by the rat itself, and not by the light. The light should not be expected (at a higher rate than its baseline rate of occurrence), and hence neither should the food. In other words, there are strong grounds for believing that rats can distinguish between self-generated and non-self-generated events, allowing them to learn that they can produce effects through their actions. Rats that received a tone when they pressed the lever may have generalized from their vast instrumental experience and treated the tone as the effect of their own action. This is a likely psychological mechanism candidate for reasoning about causal interventions in both nonhuman and human animals.

The analysis above suggests that, while the rats in the study by Blaisdell et al. (2006) used causal beliefs or models to reason about the source cause of the tone at test, these beliefs or models could have been acquired through conventional associative learning processes (Dickinson, 1980). Dickinson has argued that, in both animals and humans, associative learning processes can support the acquisition of causal beliefs (as distinct from associations) that then control performance through a process of practical inference (see also Heyes and Dickinson, 1990). Of course, humans also have other routes to causal knowledge available, such as verbal and instructional, but the associative (statistical) process is clearly of great importance to humans, as it is to other species.

1.10.5 Tool Use: From Crow to Cro-Magnon

The intentional, goal-directed dissection of cause–effect relationships in the world depends on two abilities: (1) the ability to discriminate self-generated intentional acts from those elicited reflexively by the environment and (2) the ability to discriminate changes in the environment resulting from one's own actions from those changes produced by other means (e.g., environmentally caused). Hence, it is only through the intentional and systematic probing and manipulation of an object that one can build a representation of its causal features. Our knowledge of everyday folk physics – that unsupported objects fall toward the ground, that pushing or pulling on an object usually moves it in the direction of the push or pull, and so on – derives from our vast lifetime experience of manipulating objects and observing the dynamic world (Gopnik et al., 2004). The ability to construct causal maps of the world through observation and planned intervention (what Gopnik et al. refer to as egocentric causal navigation) is not confined only to the human animal but is likely present in many other species as well. I already presented above

evidence that rats in a conventional laboratory setting are capable of deriving causal inferences from observational and interventional data. Below I review some of the recent literature investigating what type of causal understanding underlies tool use in nonhuman primates and in Corvids – a family of birds.

1.10.5.1 Tool Use in Primates

Tool use provides an interesting case in which to study causal knowledge and reasoning. Tools are objects with properties and affordances that convey functional value to achieving a particular goal. For example, chimpanzees (*Pan troglodytes*) in West Africa learn to use hammer-anvil stone tools to crack open palm nuts and extract the meat inside (**Figure 15**).

This behavior is transmitted culturally from one generation to the next. The full act, which takes many years to master, involves placing a round palm nut on a large, flat anvil stone and striking it hard enough with a hammer stone without causing the nut to fly off of the anvil. The learning process is motivated by many hours spent observing a proficient adult perform the act and is shaped during many hours of practice of the individual steps involved (Matsuzawa, 1994; Inoue-Nakamura and Matsuzawa, 1997; Hayashi et al., 2005). The final functional sequence eventually develops, and the skill can be usefully employed to extract the rich and nutritious meat inside the nuts.

For a tool to be functional, the user must learn about its properties and about how the user can manipulate the tool to achieve a goal. This learning might involve only a superficial understanding of the tool. For example, the animal might learn how to use the tool through procedural or habit learning without representing the underlying causal structure of the tool. The tool user may, however, acquire a deeper understanding of how the tool works. They may represent both the tool's physical properties, the rules by which those properties can be put to use (i.e., functional properties and affordances), the goal motivating the use of the tool, and the interrelationships among these domains of knowledge. This is a more complex set of relationships than what the rat was faced with in the experiment by Blaisdell et al. (2006). Perhaps this is why it has been difficult to empirically demonstrate that a tool-using animal understands the causal properties of tools and their effects.

The trap-tube task was first developed to study causal reasoning processes involved in tool use in capuchin monkeys and chimpanzees and has become a standard test for assessing causal understanding involved in tool use in nonhuman animals (Visalberghi and Limongelli, 1994; Limongelli et al., 1995; Povinelli, 2000). The trap-tube task involves the placement of a piece of food inside of a clear tube with two open ends (**Figure 16**). The subject is provided with a stick that can be used to retrieve

Figure 15 Chimpanzee using hammer and anvil stones as tools to crack open palm nuts. (Photo courtesy of Etsuko Nogami.)

Reprinted from Visalberghi E and Limongelli L (1994) Lack of comprehension of cause–effect relations in tool-using capuchin monkeys (*Cebus apella*). *J. Comp. Psychol.* 108: 15–22, with permission from E. Visalberghi.

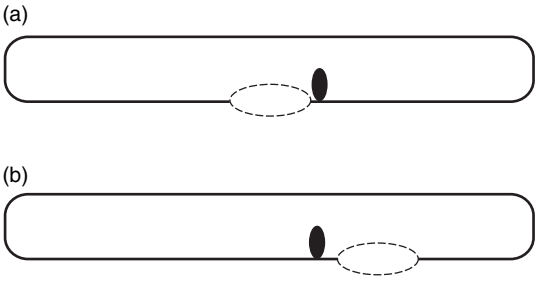

Figure 18 Trap-tube task for capuchin monkeys (Visalberghi and Limongelli, 1994) and chimpanzees (Limongelli et al., 1995). Trap Tube A is the training configuration with the trap located in the center of the tube and the food placed to one side of the trap. Trap Tube B is the transfer configuration with the trap located closer to one side of the tube and food placed in the same location within the trap that it appeared in the training tube. Whereas Trap Tube A required placing the stick in the side of the tube farthest from the reward to prevent the food from becoming trapped, Trap Tube B required changing this distance-based solution to one of inserting the stick into the side of the tube closest to the food. Reprinted from Limongelli L, Boysen ST, and Visalberghi E (1995) Comprehension of cause–effect relations in a tool-using task by chimpanzees (*Pan troglodytes*). *J. Comp. Psychol.* 109: 18–26, with permission from E. Visalberghi.

the food by pushing the food out of one end of the tube. On one side of the tube there is a hole that can trap the food if it is pushed across it. If the subject understands the nature of the trap, it should push the food out of the opposite end from the side with the trap.

In an initial study, three of four capuchins failed to learn to push the food out of the side of the tube away from the trap (see **Figure 17**), and even the successful subject only learned after about 60 trials.

Further tests revealed, however, that the successful subject did not understand how the action of the stick affected the displacement of the reward. Rather, it appeared to solve the task using a simple distance-based associative rule of placing the stick into the side of the tube farthest from the reward. A new trap tube was constructed with the trap placed closer to one end of the tube (**Figure 18(b)**). To prevent food from falling into the trap in Trap Tube B, the subject had to insert the stick into the side of the tube closest to the food rather than the side of the trap furthest from the food as was the correct solution for Trap Tube A. The successful subject, however, continued to insert the stick into the side furthest from the reward in Trap Tube B, hence causing the reward to fall into the trap. This clearly indicates that the successful monkey did not understand the relationship between the trap and the direction the food had to be moved to be successfully retrieved.

Five chimpanzees were also tested on the trap tube problem, and like the capuchins, only some of the chimpanzees learned to solve the task successfully (Limongelli et al., 1995). Unlike the capuchins, however, the two chimps that learned to solve the task did not appear to be using a simple distance-based strategy. When presented with Trap Tube B (**Figure 18(b)**), the chimps that were successful with Tube A correctly inserted the stick into the side of the trap closest to the food, thereby allowing them to push the food out of the other end of the tube (**Figure 19**).

Although the interpretation of how the chimpanzees solved the trap tube problem has been challenged with scrutiny (Tomasello and Call, 1997; Povinelli, 2000), more recent demonstrations that avoid some of the methodological problems of the earlier studies tend to support the existence of some form of appreciation of the causal nature of the task, at least by small samples of apes (Mulcahy and Call, 2006).

1.10.5.2 Tool Use in Corvids

Despite the extensive research on primates engaged in the trap tube task, some of the strongest evidence that animals can represent the causal structure underlying the tools they use comes from rooks (*Corvus frugilegus*), a member of the Corvid family, which includes crows, ravens, and jays (**Figure 20**). Although rooks are not known to use tools habitually in the wild, they will readily do so in a laboratory

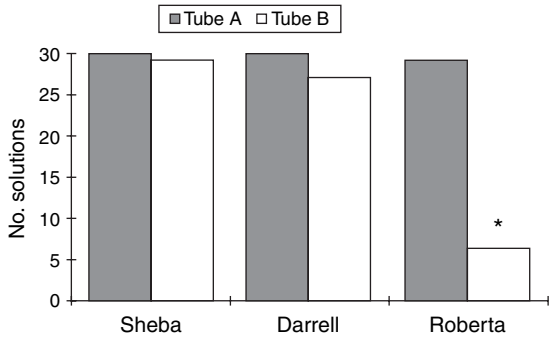

Figure 19 Performance of chimpanzees (Sheba and Darrell) and a capuchin monkey (Roberta) on Trap Tube B after having successfully learning to retrieve food from Trap Tube A. Both chimpanzees correctly inserted the stick into the side of the tube closest to the reward, allowing the successful retrieval of the food. The capuchin did not consistently insert the stick into the correct side of Tube B, and hence the food was trapped on most trials. Reprinted from Limongelli L, Boysen ST, and Visalberghi E (1995) Comprehension of cause–effect relations in a tool-using task by chimpanzees (*Pan troglodytes*). *J. Comp. Psychol.* 109: 18–26, with permission from E. Visalberghi.

setting. In a recent study rooks were presented with a modified trap-tube task (Seed et al., 2006).

Rooks were presented with Task A, shown in **Figure 21(a)**, whereas others were presented with Task B, shown in **Figure 21(b)**. Each task involved a tube with a small piece of food located in its center. A stick was already inserted into the tube at the start of the trial, and the food was enclosed by two plastic discs. Pushing the stick forward or pulling it backward would cause the food to move in the direction of the push or pull. A 'trap' was located below the floor of both sides of the tube. One of the traps was effective in that if the food was dragged across the top it would drop inside and become trapped – preventing the subject from retrieving the food. The other trap was ineffective and could not trap the food. For the tube in **Figure 21(a)**, the trap on the right side was functional and could trap the food, and the tube on the left was ineffective. Hence, to solve the tube-trap task shown in **Figure 21(a)**, the subject should move the food over the nonfunctional trap on the left, thereby allowing the food to be retrieved. (Note, the side of the functional trap was left–right counterbalanced across trials to prevent the subject from learning a simple side-bias to solve the task.) The tube shown in **Figure 21(b)** contained a similar functional trap to that shown in **Figure 21(a)**, but the nonfunctional trap was different. Rather than pulling the food entirely across the surface of the ineffective trap, the trap was completely open so that food would fall through and out of the tube, where the subject could retrieve it.

Seven out of eight rooks learned to solve the task they were given (**Figure 22**). Task B was learned more quickly than Task A. Furthermore, transfer was almost perfect to the other task (i.e., from A to B or from B to A). This excellent performance suggests that the rooks acquired a deeper causal understanding of the task. There is, however, a simpler alternative explanation for the superb transfer between tasks. Because both tubes have the same functional trap, it is possible that the birds had simply learned to avoid moving the food in the direction of the functional trap. To test this alternative hypothesis, the birds were presented with the trap tubes shown in **Figures 21(c)** and **21(d)**. These tubes lacked the functional trap present in both Tubes A and B, and both tubes contained the nonfunctional traps from Tubes A and B. One of the originally nonfunctional traps from the initial tasks was now made functional in the new tasks. For Tube C, the nonfunctional trap from Tube A was made functional by placing bungs at the ends of the tube. Thus, the food could only be retrieved by dragging it across the trap with the opening in the bottom. For Tube D, the nonfunctional trap from Tube B was made functional by lowering the entire tube onto the floor. Thus, food dragged across the trap from Tube B would trap the food inside, while dragging the food across the trap from Tube A would allow the bird to retrieve the food.

Figure 23 shows the performance on Tubes C and D. Only one bird (open squares) consistently performed well above chance on these tubes, suggesting that this bird had acquired a deep understanding of

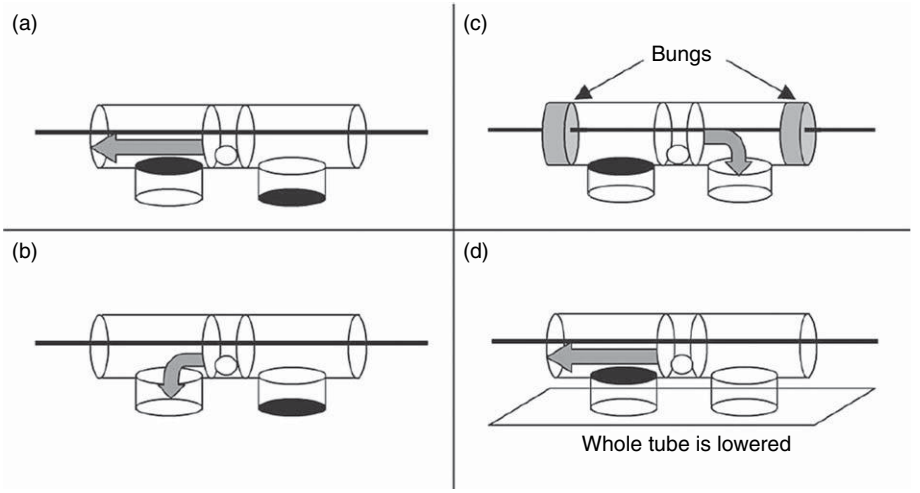

Figure 21 Trap tube problems used by Seed et al. (2006). See text. Reprinted from Seed AM, Tebbich S, Emery NJ, and Clayton NS (2006) Investigating physical cognition in rooks, *Corvus frugilegus*. *Curr. Biol.* 16: 697–701, with permission from Elsevier.

the causal structure of the trap tubes. None of the other birds were consistently above chance, and thus they likely had learned to solve Tubes A and B by avoiding the functional trap. Thus, although a majority of the birds appeared not to understand the causal properties of the tasks, one bird demonstrated knowledge of the causal properties of objects, such as that objects fall toward the earth when unsupported and that objects cannot move through physical barriers. The generalization of the knowledge about the properties of objects, and of the functional properties of the trap tube itself (i.e., how the food in the tube can be moved by moving the stick), allowed this bird to solve Tasks C and D.

The New Caledonian crow (*Corvus moneduloides*), another species of Corvid, has shown the ability to develop novel techniques to bend aluminum strips in order to use them as hook tools to retrieve food (**Figure 24**). The rapidity with which the crow achieved success not only shows that the behavior is goal directed but also conveys a deeper understanding of some of the properties of the tools and the materials and a representation of the kinds of solutions that are likely to work (Weir et al., 2002; Kenward et al., 2005). In fact, simple generalization of learned rules could not explain the excellent performance, because in most cases the solution required manipulating the tool in a way that was inconsistent or that conflicted with prior successful solutions. For example, one crow named Betty was able to correctly anticipate on four out of five trials whether bending or unbending pieces of novel materials was required to retrieve food (Weir and Kacelnik, 2007). Even this adept crow, however, often probed the recess containing the out-of-reach food with unmodified tools before modifying them or attempted to use the unmodified end of a modified tool. Though suggestive, the details of Betty's performance prevent us from determining whether she understood the physical causality underlying these tools.

1.10.5.3 Tool Use by Humankind

Although some animal species, in particular among the corvids and primates, have shown remarkable tool use abilities in the laboratory and the wild, these abilities pale in comparison to that shown by humankind. The earliest evidence for tool use among the hominids dates back by at least 2 million years, from which time modified stone tools consisting of struck flakes of volcanic rock have been found among the remains of our ancestor *Homo habilis* (**Figure 25**; Klein, 1989).

There is more extensive evidence of stone tool use by *Homo erectus* throughout Africa, Asia, and Europe dating from about 1.8 to 0.5 million years ago. By 40,000 years ago, when anatomically modern *Homo sapiens* – historically called Cro-Magnon but more appropriately referred to as *Homo sapiens sapiens* – first arrived at Europe, tool use had become quite sophisticated compared to earlier species of Homo. Furthermore, after 40,000 years ago, the evolution of tools and other technologies advanced at a very

rapid pace and showed major geographic diversification (Klein, 1989). Archeological sites throughout Europe show evidence of painting, engraving, sculpture, body ornamentation, and music. There is even indirect evidence for the weaving of wool into cloth, such as is used for clothing. Remains of dwellings, sculpture, and weapons are plentiful at many archeological sites, but perhaps Cro-Magnons are most famous for their cave paintings.

Humankind's extensive, habitual tool use, along with the evolution of language, contributes to our unique ability to adapt ourselves to life in almost every niche of the globe and to exploit a wide range of natural resources from engineered crops to nuclear energy and even allows for our occasional forays into space. This would not have been possible without our ability to represent the goals of our actions.

1.11 Categories and Concepts in Animals

O. F. Lazareva and E. A. Wasserman, University of Iowa, Iowa City, IA, USA

1.11.1 Introduction and Theoretical Distinctions

> Concepts . . . give our world stability. They capture the notion that many objects or events are alike in some important respects, and hence can be thought about and responded to in ways we have already mastered. Concepts also allow us to go beyond the information given. . . . In short, concepts are critical for perceiving, remembering, talking, and thinking about objects and events in the world. (Smith and Medin, 1981: p. 1)

The ability to categorize objects and events and to extend this categorization behavior to new instances is fundamental to many human activities. We sort the objects and events around us into categories, while still being able to recognize some or all of the individual members of each category. For example, we categorize a Ferrari, a Cadillac, and a Toyota as cars, even though they do not look identical, have different engines, and are manufactured in different countries. This ability is undoubtedly beneficial. When we encounter a new model of car, we immediately recognize it as a car and engage in appropriate behavior (e.g., driving).

We also construct higher-level categories – such as clothing, tools, or furniture – whose members are perceptually disparate, but functionally similar. A violin, a piano, a flute, and a cymbal may not look alike, but we nevertheless classify them as orchestral instruments because they play music. Furthermore, we create abstract concepts that go beyond any perceptual similarities or functional interconnections; such abstract concepts entail relations between or among objects. For example, in poker, a flush entails five cards from the same suit, regardless of the values of the cards. Our everyday life contains many examples of such abstract, relational concepts: Things can be faster or slower, larger or smaller, inside or outside, same or different.

The ability to form concepts is surely adaptive, because concepts allow us to respond appropriately to novel stimuli after having experience with only a few instances from a given category. The same ability should also be beneficial for animals. One can often

observe a red-tailed hawk attacking pigeons in downtown Iowa City; undoubtedly, those downtown pigeons should soon learn to flee when they spot members of this hawk species. But, there are other, albeit rarer, hawk species which prey on pigeons, such as Cooper's Hawk or the Northern Goshawk. Clearly, the ability to recognize these less frequent predators as a threat should be advantageous for the birds, just as is our ability to recognize a Toyota as a car is advantageous for us. Charles Darwin himself in *The Descent of Man* proposed that "the senses and intuitions, the various emotions and faculties, such as ... memory, attention, ... reason, etc., of which man boasts, may be found in an incipient, or even sometimes in a well-developed condition, in the lower animals" (Darwin, 1896, p. 126). In our chapter, we review empirical studies that strongly suggest that categories and concepts are not unique to the human brain (*See* Chapters 1.07, 1.08, 1.29). Before we begin, however, we attempt to define some relevant terms.

1.11.2 Operational Definitions of Category and Concept

Since C. Lloyd Morgan (1894/1977), comparative psychologists have struggled with the following question: Do animals exhibit conceptual behavior? As is often the case with controversial questions in animal cognition, providing an operational definition of the behavior in question is the first critical step.

Cognitive psychologists often define categorization as the process of grouping objects or events into categories and responding to these categories in a similar manner (e.g., Medin and Aguilar, 2001). Concepts, on the other hand, are thought to be the elements of knowledge that assist categorization (e.g., Smith and Medin, 1981; Hampton, 2001). Many authors suggest that the term 'category' should be used to refer to classes of items, whereas the term 'concept' should be used to refer to the mental representation of those classes (Laurence and Margolis, 1999). Still others propose that the term 'concept' should be used to refer to well-defined classes characterized by a set of necessary and sufficient features and the term 'category' should be reserved for ill-defined or fuzzy classes with gradual membership (Medin, 1998). In any case, concepts and categories are treated as entities: Things to be found either in the environment or in one's mind.

Keller and Schoenfeld (1950) were first to develop an operational definition of concepts that could be made suitable for animal research. These authors began by noting that "one does not *have* a concept, just as one does not *have* extinction – rather, one demonstrates conceptual behavior, by acting in a certain way" (Keller and Schoenfeld , 1950, p. 154). What behavior, then, do we call conceptual? Keller and Schoenfeld proposed that organisms exhibit conceptual behavior when they respond similarly to members of one class of stimuli and differently to members of other classes of stimuli: "Generalization *within* classes and discrimination *between* classes – this is the essence of concepts" (Keller and Schoenfeld, 1950: p. 155). In other words, when a child says 'doggie' if she sees any dog but not if she sees a cat, or when a pigeon pecks the screen if a human being is displayed but refrains from pecking otherwise, we could say that the child and the pigeon have behaved conceptually.

The Keller-Schoenfeld definition also suggests a useful distinction between categorization and discrimination: We speak of categorization when the organism discriminates among classes of multiple stimuli rather than among individual instances of each class. So, if an organism has been trained to make one response to a single photograph of a car and to make a second response to a single photograph of a chair, then we say that the organism discriminates the car from the chair. But, if an organism has been trained to make one response to multiple exemplars of cars and to make a second response to multiple exemplars of chairs, then we say that the organism categorizes the cars and chairs. In essence, categorization entails a subset of discrimination problems in which multiple stimuli are associated with a common response.

Suppose, however, that we trained an organism to associate ten photographs of cars with one response and to associate ten photographs of chairs with a second response. Is successful learning enough to claim that conceptual behavior has been exhibited? No. Because the organism might master this task by memorizing all 20 photographs, it is obvious that we need to expand our definition: Conceptual behavior ought to be transferable to novel instances from the familiar categories. Only if the organism can produce the correct response in the presence of novel cars and novel chairs should we speak of conceptual behavior.

Indeed, even this additional requirement may not be sufficient to define conceptual behavior. What if the novel cars and novel chairs were indistinguishable from

the familiar cars and the familiar chairs seen in training? Then, the organisms' performing the correct responses in the presence of the novel testing stimuli would be a trivial failure to discriminate. A revised Keller-Schoenfeld definition of conceptual behavior should now say that an organism exhibits conceptual behavior if it can learn to respond similarly to members of one class and to respond differently to members of another class, as well as to transfer these differential report responses to novel, discriminably different members of these classes (Wasserman et al., 1988).

1.11.2.1 Types of Concepts

Humans use concepts in an extremely broad and flexible manner, classifying objects and events because they look alike, because they perform the same function, or because they entail the same relationship. For example, people may classify an object as a Ferrari (subordinate level based on subgroups within basic-level categories), a car (basic level), or a vehicle (superordinate level based on aggregation of several basic-level categories). Consequently, many researchers place concepts into three broad types (e.g., Zentall et al., 2002). Perceptual concepts (e.g., German Shepard, tree, or airplane) entail categories based on physical similarities among their members; these concepts are reviewed in the sections titled 'Perceptual concepts as basic-level categories' and 'Perceptual concepts as subordinate-level categories.' In contrast, nonsimilarity-based concepts (e.g., tools or furniture) include perceptually diverse stimuli that are grouped on the basis of common function or association; these concepts are reviewed in the section titled 'Nonsimilarity-based concepts.' Finally, abstract concepts (e.g., above or different) are based on relations between or among stimuli instead of their physical properties; these concepts are reviewed in the section titled 'Abstract concepts.'

1.11.3 Perceptual Concepts as Basic-Level Categories

Perceptual concepts have often been studied in the context of human basic-level and subordinate-level categorizations. Categorization at the basic level is generally believed to be based on high perceptual similarity among members of the same category and low perceptual similarity among members of different categories (Rosch and Mervis, 1975). In contrast, categorization at the subordinate level distinguishes subgroups within basic-level categories. So, subordinate categorization entails high within- and between-category similarity, rendering this level of categorization less preferred by humans than the basic level (Rosch and Mervis, 1975; Rosch et al., 1976; but see Tanaka and Taylor, 1991).

In this section, we review studies exploring animals' sensitivity to basic-level categories based on perceptual similarity; categorization at the subordinate level is considered in the section titled 'Perceptual concepts as subordinate-level categories.'

1.11.3.1 History of Animal Categorization Research: Herrnstein's Studies

Studies of visual categorization in animals date back to the pioneering work of Herrnstein and Loveland (1964). Using the familiar go/no-go procedure, Herrnstein and Loveland reinforced pigeons for pecking at the response plate if the photograph projected on it contained a person, but they did not reinforce the pigeons' pecks otherwise. The researchers collected 1,200 color slides, some of which contained people and some of which did not. **Figure 1** shows examples of the photographic slides used in the study.

The photographs varied in coloration and lightning. Some of them contained a group of people, whereas others depicted a single person. The depicted person or people could be partially obscured by other objects, such as trees or window frames, or could appear off center and at a distance. Nevertheless, the pigeons learned the discrimination: That is, they predominantly pecked at the photographs containing people, in spite of the great variation in content of the photographs. Moreover, the pigeons successfully categorized previously unseen photographs, thereby demonstrating an important hallmark of conceptual behavior: transfer to new exemplars from the category.

In later experiments, Herrnstein and his colleagues demonstrated that pigeons could learn tree/nontree, fish/nonfish, and even water/nonwater categories, as well as transfer their discriminative performance to novel exemplars from each category (Herrnstein et al., 1976; Herrnstein and de Villiers, 1980). Although pigeons' long-term memory can retain over 800 associations between a specific picture and a correct response (Vaughan and Greene, 1984; Cook et al., 2005), successful transfer to novel

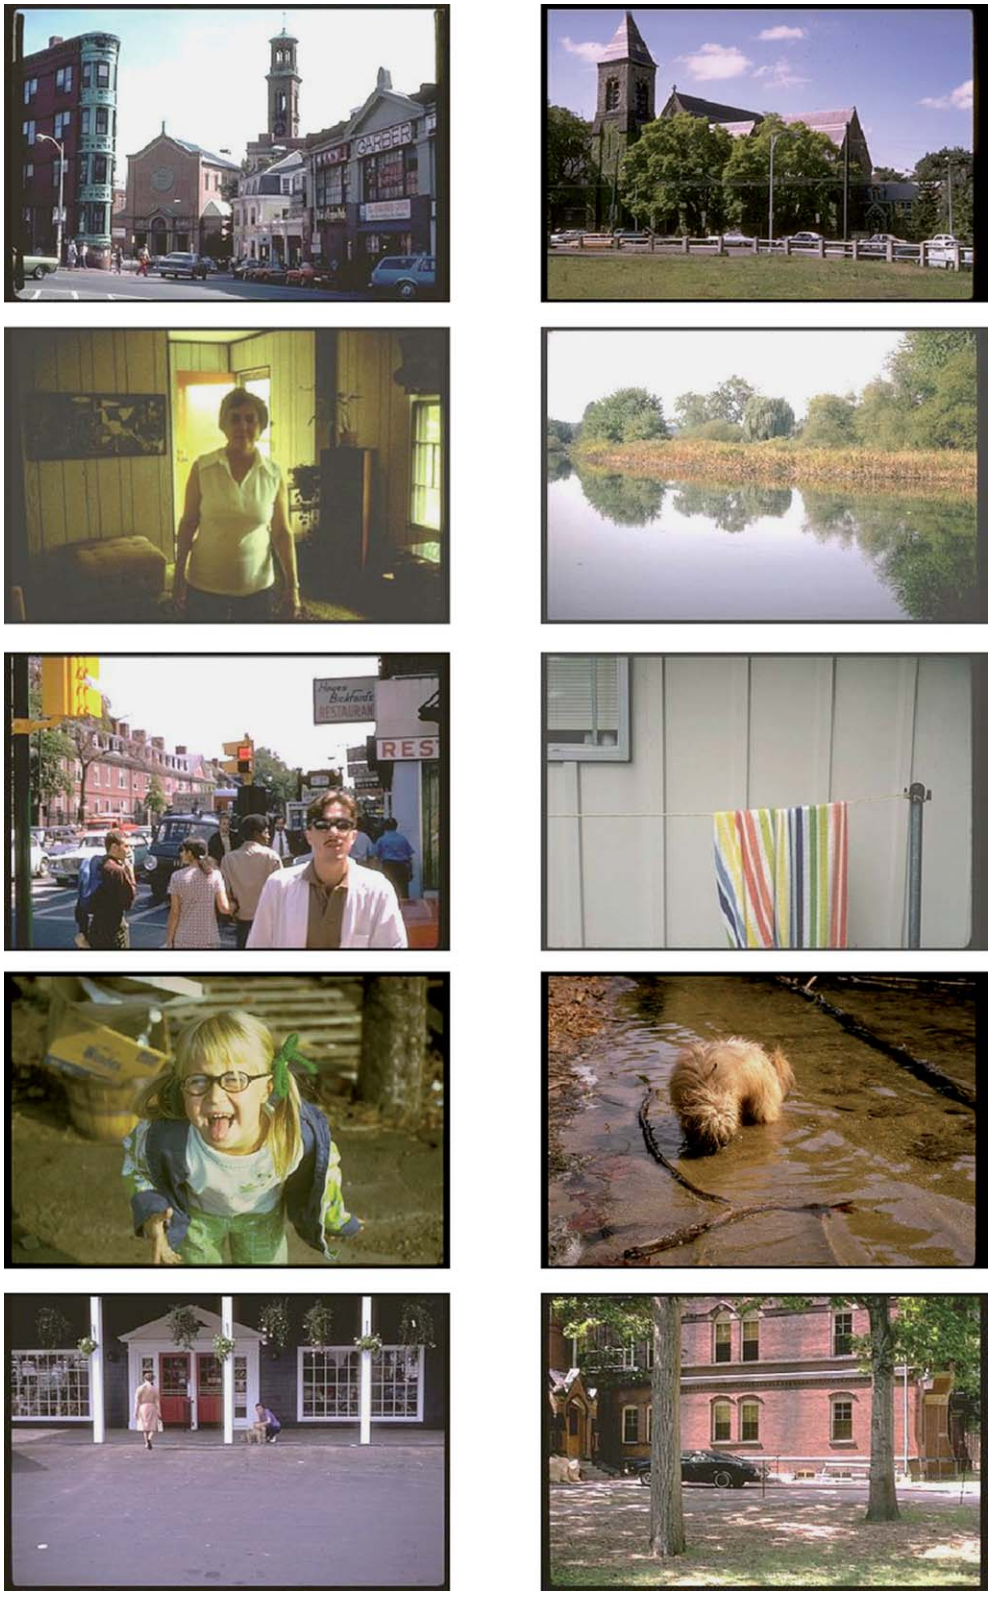

Figure 1 Representative stimuli from Herrnstein's early experiments on pigeon categorization. The left column depicts reinforced stimuli with people, and the right column depicts nonreinforced stimuli without people. Images courtesy of Will Vaughan.

members of the categories precludes simple memorization as an explanation for the pigeons' behavior.

Careful scrutiny of the slides on **Figure 1**, however, reveals a potential alternative explanation of the pigeons' performance. The backgrounds of the images in the person and nonperson categories were not matched; hence, if some features of the background (e.g., man-made objects) correlated with the presence of people, then those features might have come to control the pigeons' behavior, instead of the target object. In fact, later research has shown that, when presented with nonmatched photographs, pigeons might memorize category-relevant features, background features, or both (Greene, 1983), but when the photographs are matched, pigeons are more likely to learn category-relevant features (Edwards and Honig, 1987). Note that transfer to new exemplars can also be explained by background features being correlated with the presence or absence of the category member; such correlated features are likely to be present in the testing photographs, just as they were in the training photographs.

One could nevertheless argue that using background features together with (or instead of) the presence or absence of the target object does not mean that the pigeon cannot form the concepts of person or tree; rather, the concept formed by the pigeons may simply differ from that expected by the experimenter. Being nonverbal animals, pigeons have to discern the rules of the game from the stimulus material with which they are presented during the experiment: If the stimulus material permits an alternative strategy (e.g., trees are always located near shrubs), then the pigeons might learn to attend to such 'incorrect' cues.

Would we then conclude that pigeons' performance in these experiments fits the definition of conceptual behavior that we developed earlier? Yes. A more important and challenging question is: What features of the stimuli actually control the pigeons' behavior? The very strength of Herrnstein's approach, the use of highly varied, rich, and lifelike photographs, makes it problematic for researchers to answer this question. As we see in the next section, later studies have struggled with this problem with varying degrees of success.

1.11.3.2 Further Research on Basic-Level Categorization

Much of research that followed Herrnstein's pioneering studies continued to use the go/no-go procedure, in which one class of pictures is associated with some schedule of positive reinforcement and another class is associated with experimental extinction. Additionally, these studies generally used a single category (e.g., person) together with its complementary category (e.g., nonperson); we term this design mutually exclusive categorization. Most human language categories, however, are not of the presence/absence sort; instead, people partition the world around them into multiple clusters, such as cars, chairs, rocks, and flowers. Indeed, some authors have suggested that, although many animals can learn dichotomous presence/absence classifications, "only primates may sort the world, i.e. divide it into its indeterminately many classes" (Premack, 1976, p. 215). Although the go/no-go design can be used to study such noncomplementary categories as cats versus dogs (e.g., Ghosh et al., 2004; see also Roberts and Mazmanian, 1988), this categorization is still restricted to only two categories.

Another experimental design involves the multiple-alternative forced-choice procedure (**Figure 2**), which provides an effective means of studying categorization among multiple noncomplementary categories, such as cars, chairs, people, flowers, or cats. Using this multiple categorization scheme, pigeons have been found to be able to learn at least four noncomplementary categories of stimuli by pecking at four distinctively different choice keys and to transfer their discriminative responses to novel exemplars from those categories (Bhatt et al., 1988; Lazareva et al., 2004). Moreover, ongoing research in our laboratory suggests that pigeons' categorization is not limited to only four classes of stimuli: The birds can learn to discriminate 16 noncomplementary categories, such as ducks, bottles, trees, hats, and so on.

More than four decades of research on basic-level categorization in animals have made it clear that many animals, including primates and pigeons, can discriminate a great number of categories, including non-complementary categories (**Table 1**). Although some early reports suggested that pigeons may be unable to categorize human-made stimuli, such as cars or bottles (Herrnstein, 1985), later research has not supported this claim: Several studies have since found that pigeons can easily discriminate cars and chairs from flowers and people (Bhatt et al., 1988; Lazareva et al., 2004), and even Picasso's paintings from Monet's (Watanabe et al., 1995; Watanabe, 2001). Still, pinpointing the stimulus properties used for categorization has been elusive.

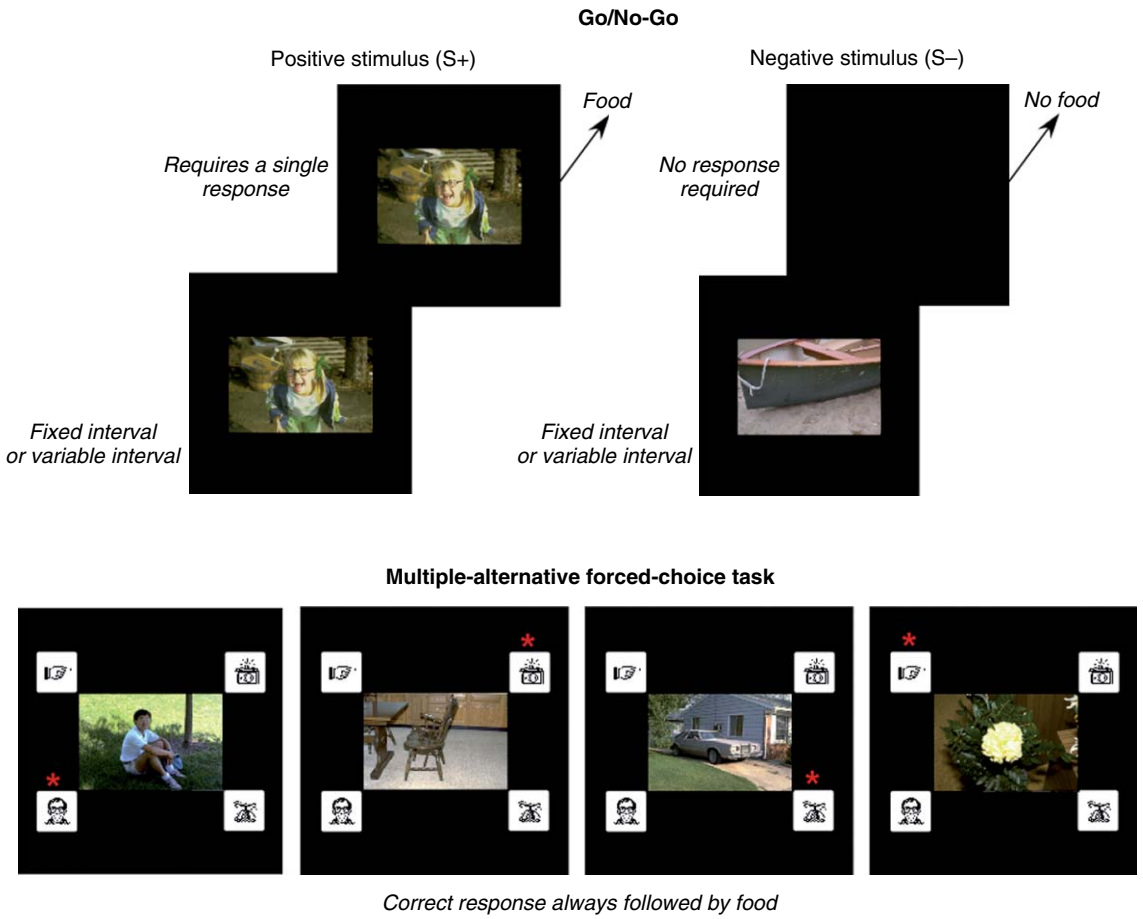

Figure 2 Comparison of go/no-go and multiple-alternative forced-choice procedures. The go/no-go procedure associates one class of stimuli (positive stimuli, or S + s) with reinforcement and the other class of stimuli (negative stimuli, or S − s) with experimental extinction. With a few exceptions, this procedure has been used with mutually exclusive categories, such as *tree/no-tree*. The multiple-alternative forced-choice procedure requires a subject to select one of the choice responses associated with a given class of stimuli (the red asterisks indicate the correct choices). This procedure has been used to study noncomplementary categories, such as people, flowers, cars, and chairs.

Humans	Pigeons, capuchin monkeys, rhesus monkeys, gorilla, baboons, chimpanzee	Fujita and Matsuzawa, 1986; Schrier and Brady, 1987; Bhatt et al., 1988; D'Amato and Van Sant, 1988; Wasserman et al., 1988; Astley and Wasserman, 1992; Watanabe, 2000; Aust and Huber, 2001, 2002; Vonk and McDonald, 2002; Aust and Huber, 2003; Lazareva et al., 2004; Matsukawa et al., 2004; Lazareva et al., 2006; Martin-Malivel et al., 2006

Studies attempting to disclose the stimulus properties controlling discriminative behavior in categorization tasks have generally used two different approaches. The first group of studies have used a *post hoc* analysis of already collected data concerning the presence or absence of some feature(s) on the target object (Schrier and Brady, 1987; D'Amato and Van Sant, 1988; Roberts and Mazmanian, 1988; Vonk and McDonald, 2004). For example, Schrier and Brady (1987) trained rhesus monkeys to discriminate photographs that contained people from photographs that did not. The photographs were rated from good (where people comprised at least 50% of the scene) to intermediate (25%–50%) to poor (less than 25%); monkeys' discrimination accuracy proved to be positively correlated with these ratings. However, other researchers using this method have often experienced difficulties in finding significant or meaningful correlations between the stimulus properties and the subjects' discriminative behavior (e.g., Roberts and Mazmanian, 1988; Vonk and McDonald, 2004).

The second and more successful group of studies has used different modifications of the training images or novel testing images varying along specific dimensions to discern the features controlling subjects' behavior (Herrnstein and Loveland, 1964; Schrier and Brady, 1987; Wasserman et al., 1988; Cook et al., 1990; Vogels, 1999; Watanabe, 2000, 2001; Aust and Huber, 2002; 2003; Ghosh et al., 2004; Lazareva et al., 2006). In a representative study, Aust and Huber (2002) trained pigeons to discriminate photographs based on the presence or absence of a person. **Figure 3** depicts some of

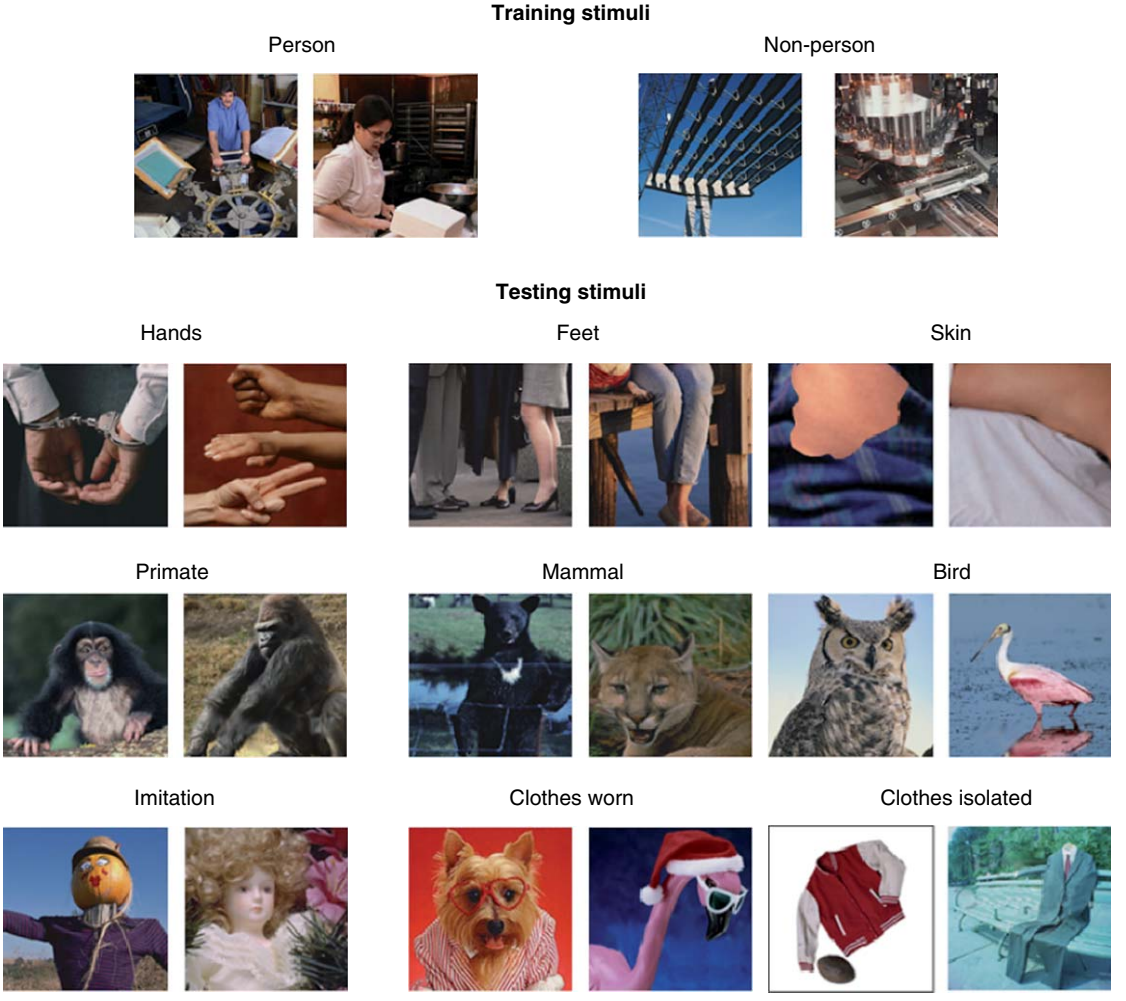

Figure 3 Examples of images used for training the *person/no-person* discrimination and for subsequent testing of features controlling pigeons' performance. Modified from Aust U and Huber L (2002) Target-defining features in a ''people-present/people-absent'' discrimination task by pigeons. *Anim. Learn. Behav.* 30: 165–176.

the images used in this study. As in earlier reports, pigeons successfully learned this discrimination. To find out which visual features controlled the pigeons' behavior, the birds were later presented with several sets of novel, nonreinforced probe stimuli that depicted some parts of the human body (hands, head, legs, and trunk) or patches of human skin of various sizes and shapes. The pigeons responded to images containing hands as if they were members of the person category, whereas images containing feet or skin patches generated the nonperson response. Aust and Huber (2002) also found that, as the similarity of the testing stimuli to the target category 'person' increased, the pigeons were more likely to classify the testing stimuli as members of the person category. Thus, artifacts imitating people (e.g., dolls or scarecrows) were more likely to produce the person response than were primates, mammals, or birds. Similarly, photographs of animals wearing clothes were more likely to be classified as members of the person category than either clothes in isolation or animals without clothes. Overall, these results suggest that pigeons' classification behavior was based on category-relevant features that were combined in an additive fashion: Exemplars with more category-relevant features were more likely to be classified as members of the person category than were exemplars with few such features.

Although some studies have been successful in identifying specific features controlling animal behavior in categorization experiments, many attempts have raised more questions than answers. For example, in our own recent study (Lazareva et al., 2006), we trained pigeons to discriminate cars, chairs, flowers, and people using a four-alternative forced-choice task. We then explored whether the pigeons' categorization behavior depended on the overall shape of the object or on its local details by using two stimulus manipulations: blurring and scrambling (**Figure 4**). Blurring

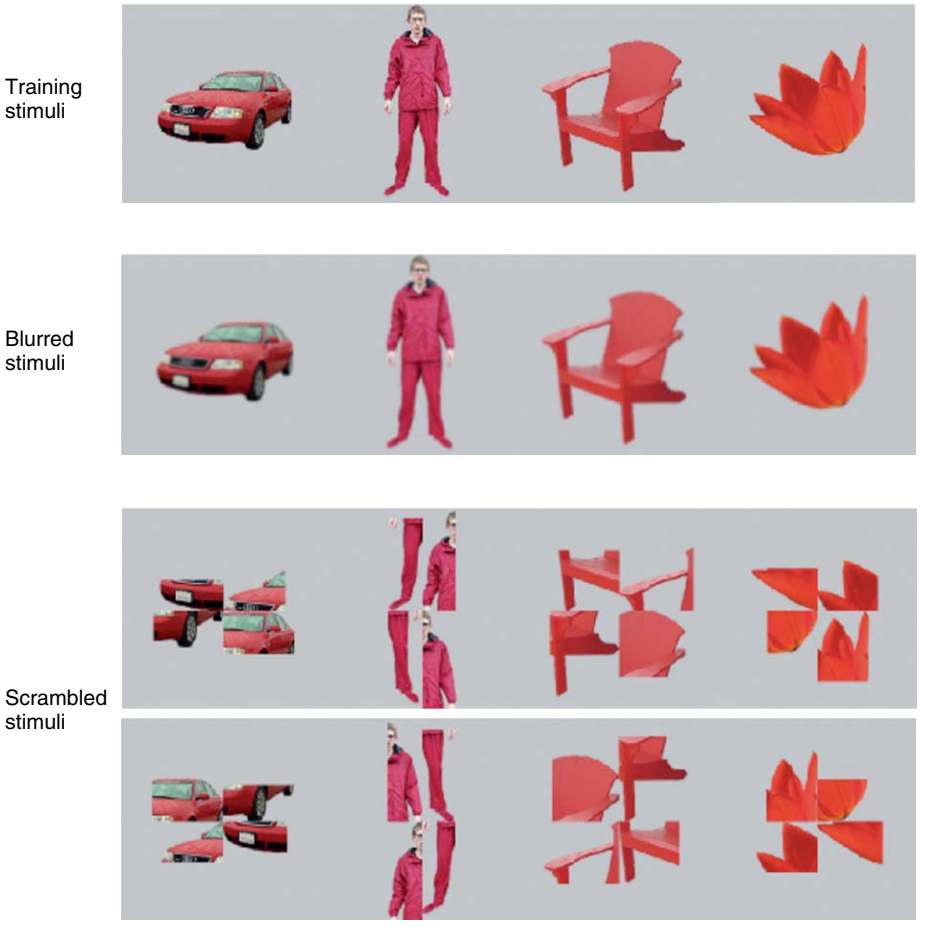

Figure 4 Examples of blurred and scrambled testing stimuli, together with the training stimuli from which they were derived. From Lazareva OF, Freiburger KL, and Wasserman EA (2006) Effects of stimulus manipulations on visual categorization in pigeons. *Behav. Process.* 72: 224–233.

distorts the fine details of the image while leaving the overall shape of the target object relatively intact, whereas four-part sectioning and scrambling leaves most of the fine details of the image unmodified but distorts the overall shape of the target object. Surprisingly, these two manipulations had decidedly different effects depending on the category of the target stimulus: Blurring impaired the discrimination of cars (and, to some extent, chairs), but it had no effect on the discrimination of flowers and people, whereas scrambling impaired the discrimination of flowers and people, but it had no effect on the discrimination of cars and chairs. These results suggest that the birds may have discriminated photographs of cars and, perhaps, chairs by using some local feature(s) and relied on the overall shape of the object when discriminating photographs of flowers and people.

But, what does it mean to say that cars and chairs were discriminated by pigeons' using some local feature? Just what might this local feature be? Similarly, what does it mean to say that pigeons relied on the overall shape of the object when discriminating flowers and people? In order to pinpoint these controlling features more precisely, additional tests, analogous to those used by Aust and Huber (Aust and Huber, 2002) are necessary. Given the large number of potential local and global features that can work alone or in combination with each other, conducting such tests for four categories would be impractical. This limitation of complex naturalistic stimuli has prompted researchers to use simpler stimuli that permit more precise analysis and manipulation to study stimulus control in categorization (see the section titled 'Artificial polymorphous categories as models of basic-level categories').

As well, innovative experimental procedures now allow researchers to efficiently isolate features of complex visual stimuli that control subjects' behavior. Martin-Malivel et al. (2006) have recently applied the reverse correlation method to disclose features controlling the categorization of human and baboon faces by humans and baboons. These researchers first trained participants to discriminate human and baboon faces at high levels of accuracy. Next, the training stimuli were warped so that the overall shape of all images was identical, a procedure that permitted the construction of a human–baboon morph. Finally, random visual noise was superimposed on the warped and morphed images to create the testing images (see top panel of **Figure 5**). The trials of interest were the morphed human–baboon images with superimposed random noise that could render the image more similar to the human face or more similar to the baboon face. The patterns of noise were then correlated with the subject's responses on a trial-by-trial basis, allowing the researchers to determine the areas of the image that were critical for categorization (see Mangini and Biederman, 2004, for procedural details).

This analysis revealed intriguing differences in the visual information utilized by people and baboons. Baboons' discrimination performance was controlled by the contrast between the eyes and the surrounding region: Lighter eye areas prompted human responses, whereas darker eye areas prompted baboon responses. People's discrimination performance, on the other hand, was controlled by this contrast information as well as by a number of other facial features, such as nose, mouth, and facial contour.

In another study deploying a different innovative technique (Gibson et al., 2005), some pigeons were trained to discriminate whether the depicted face was a man's or a woman's, whereas other pigeons were trained to discriminate whether the face had a happy or a neutral expression (see bottom panel of **Figure 5**). After pigeons' performance reached high levels of accuracy, the training stimuli were covered by a gray mask containing several openings or bubbles. The bubbles were presented at random locations on the screen, and their position determined trial difficulty. For example, the specific configuration of the mask on a 20-bubble face (**Figure 5**, bottom panel) makes it easy to determine gender, but not emotion. Thus, by correlating the locations of the bubbles with a subject's categorization responses, we can again determine the features that support reliable discrimination behavior (see Gosselin and Schyns, 2001, 2005, for details). Here, both pigeons and people were found to utilize similar pictorial information. When discriminating happy from neutral faces, both pigeons and people relied heavily on the bottom part of the face including the mouth. When discriminating male from female faces, both pigeons and people relied on regions near the eyes and the chin.

Clearly, both reverse correlation and bubbles procedures have great potential for elucidating the perceptual bases of categorization in animals (see Gosselin and Schyns, 2002, and Gosselin and Schyns, 2004, for a comparison of the techniques). Note especially that the conventional methods of modifying or deleting parts of the images to divulge which features might control performance requires some notion as to the identity of those features. In contrast, neither reverse correlation nor bubbles make such assumptions; instead, these techniques sample all of the information that is available in the images. We expect

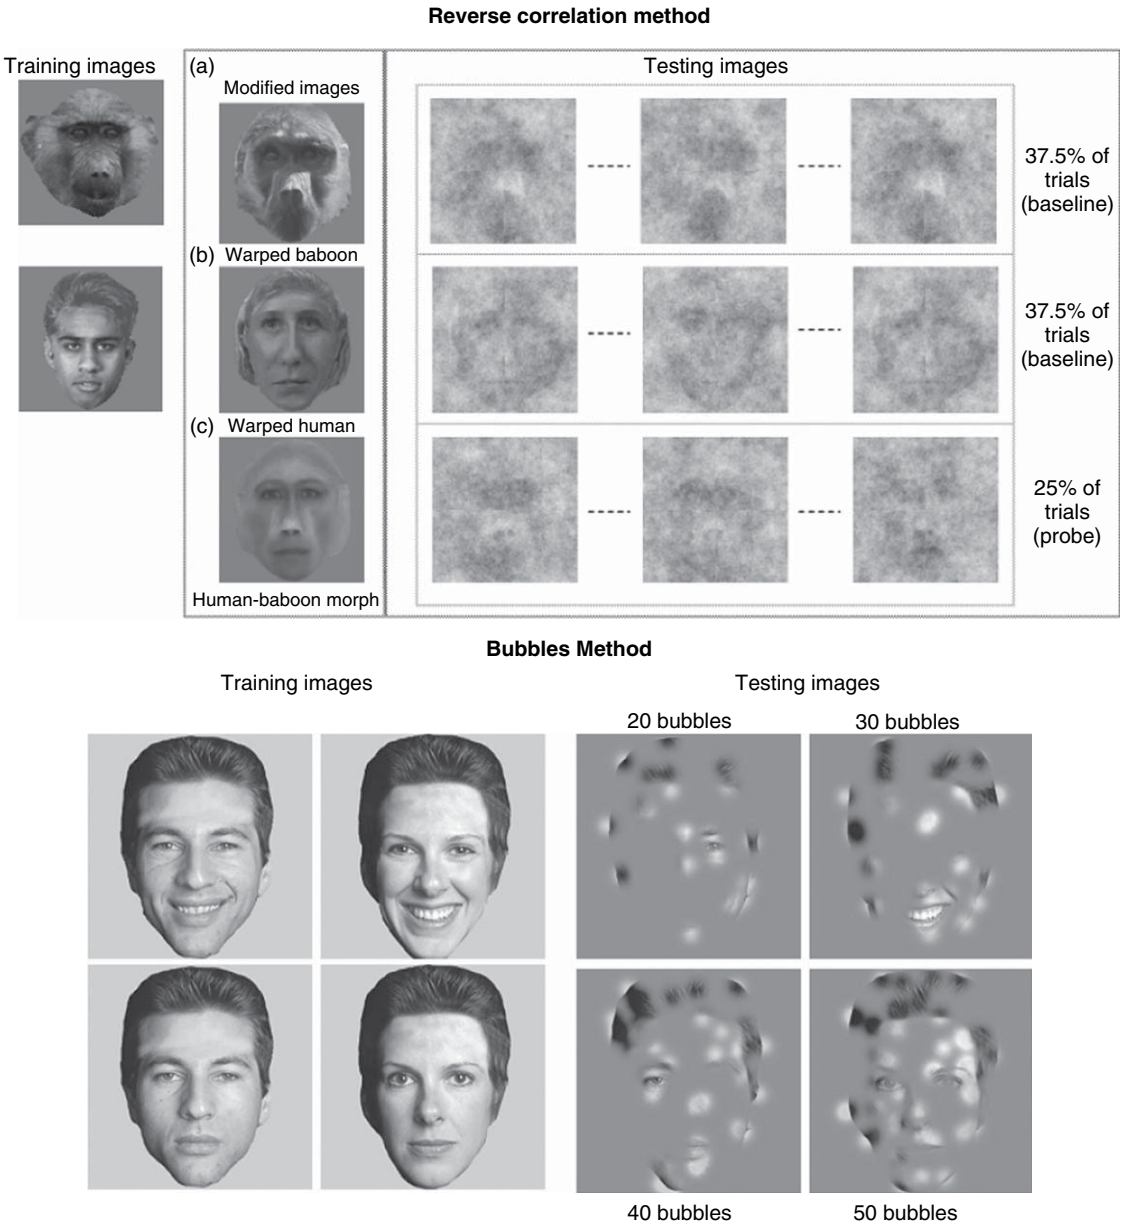

Figure 5 Illustration of training and testing stimuli for the reverse correlation method (top) and for the Bubbles method (bottom). Top: After subjects learned to discriminate human faces from baboon faces (training images), the training images were warped (modified images) or superimposed with random visual noise to obtain the testing images. Note that the human–baboon morph stimulus superimposed with random noise can look more similar to the human face on some trials and more similar to the baboon face on other trials. Modified from Martin-Malivel J, Mangini MC, Fagot J, and Biederman I (2006) Do humans and baboons use the same information when categorizing human and baboon faces? *Psychol. Sci.* 17: 599–607. Bottom: After training to report whether a face is happy or neutral or whether it belongs to a male or a female, the training stimuli were covered with a mask revealing only a portion of the stimuli through the openings or 'bubbles.' Note that the position of the bubbles randomly varied across trials so that different areas of the faces could be revealed on different trials. Modified from Gibson BM, Wasserman EA, Gosselin F, and Schyns PG (2005) Applying Bubbles to localize features that control pigeons' visual discrimination behavior. *J. Exp. Psychol. Anim. Behav. Process.* 31: 376–382.

that deploying these and other new methods will greatly advance our understanding of how animals categorize complex visual stimuli.

1.11.3.3 Do Animals Perceive the Cohesiveness of Basic-Level Categories?

Extensive experimental evidence suggests that animals can be assiduously trained to sort stimuli into different basic-level categories, including noncomplementary categories (cf. **Table 2**). But, do animals view the members of these categories as being perceptually coherent before such categorization training, as do people? In other words, do animals directly perceive the members of a basic-level category to be more similar to one another than to the members of other categories?

Several studies suggest that primates may indeed perceive basic-level categories to be perceptually cohesive clusters of stimuli. Fujita and Matsuzawa (1986) used a sensory reinforcement procedure to find out whether a chimpanzee can form the category 'person' without explicit reinforcement. The chimpanzee was shown a picture on a screen and was required to touch a response key repeatedly to keep viewing the same picture. If the response key was not touched within 10 s, a new picture was presented. Analysis of the intervals between responses and the duration of responses revealed that the chimpanzee preferred to view photographs containing people; it rarely pressed the key to repeat photographs that did not contain people. This nonpreferred, no-person category also included some ambiguous photographs in which the target object was very small as well as entirely white or entirely black photographs.

Table 2 Animal studies of artificial polymorphous categories

Species	*Technique*	*Reference*
Pigeons	Go/no-go	Lea and Harrison, 1978; von Fersen and Lea, 1990; Huber and Lenz, 1993; Jitsumori, 1993; Huber and Lenz, 1996; Jitsumori, 1996
	Two-alternative forced-choice	Lea et al., 1993
Rhesus monkeys	Go/no-go	Jitsumori, 1994
Baboons	Two-alternative forced-choice	Depy et al., 1997

In another experiment (Sands et al., 1982), rhesus monkeys were trained to move a lever in one direction if two successively shown pictures were identical and to move the lever in a different direction if the pictures were nonidentical. The set of pictures included six different exemplars of human faces, monkey faces, trees, flowers, and fruits. If the monkeys perceived members of the same category (e.g., fruit) to be more similar to each other, then they should have been more likely to erroneously respond same when a picture of an apple was followed by a picture of an orange than when it was followed by a picture from another category (e.g., an oak). Analysis of confusion errors found this to be the case: All pictures of fruit fell into the same region of multidimensional space. Interestingly, pictures of monkey faces and human faces were clustered together, as were pictures of trees and flowers, suggesting that rhesus monkeys viewed monkey faces as being similar to human faces and that they viewed trees as being similar to flowers.

What about pigeons? Several reports suggest that pigeons too perceive similarity among the members of basic-level categories (Wasserman et al., 1988; Astley and Wasserman, 1992). For example, Astley and Wasserman (1992) evaluated the perceptual coherence of basic-level categories using a go/no-go method. For some pigeons, 12 photographs of cars could serve as positive discriminative stimuli: The birds were reinforced for pecking these stimuli when they were shown. For other pigeons, 12 photographs of chairs, flowers, or people could serve as the positive discriminative stimuli. The set of negative discriminative stimuli was common to all of the pigeons and consisted of 12 photographs each of cars, chairs, flowers, and people that were different from the 12 photographs that were used as the positive discriminative stimuli. As pigeons learn this discrimination, their rate of responding to all of the negative discriminative stimuli is expected to fall. However, if pigeons see categories as collections of perceptually similar items, then the rate of responding to the negative stimuli from the same category as the positive discriminative stimuli should have fallen more slowly than to the stimuli from the other categories. Astley and Wasserman (1992) again found that the data supported such perceptual coherence: Pigeons committed most errors to the negative discriminative stimuli from the same category as the positive discriminative stimuli.

In sum, most researchers have found that, just like people, animals perceive basic-level categories to be perceptually cohesive clusters of stimuli (but see Sutton and Roberts, 2002). Recent research in our

own laboratory has also begun to explore similarities across different basic-level categories, specifically natural categories, like 'flower' or 'person,' and artificial or human-made categories, like 'chair' or 'car'. Studies of certain cerebral pathologies in humans have found an intriguing dissociation between impaired recognition and the naming of living objects and nonliving objects, suggesting that these types of categories could be represented in a qualitatively different manner (see Farah, 1999, and Martin and Caramazza, 2003, for a review). Some researchers have proposed that the categorization of artificial objects is based on their functional specifications or on the kinesthetic representation of the movements performed in using them, whereas the categorization of natural objects is based solely on their perceptual properties (Warrington and McCarthy, 1987; Damasio, 1990). Other researchers have suggested that the difference is one of degree and not of kind: The members of natural categories may be more similar to each other than are the members of artificial categories (Humphreys et al., 1988; Gaffan and Heywood, 1993; Lamberts and Shapiro, 2002; McRae and Cree, 2002).

Of course, when nonverbal animals are trained to sort photographs of cars, chairs, flowers, and people, this categorization ought to be based only on perceptual similarity. Thus, finding a natural–artificial dissociation in pigeons' categorization behavior suggests that people's categorization behavior may also be based on the perceptual coherence of the given categories. So far, our data suggest that pigeons perceive two natural categories, flowers and people, to be more similar to each other than to either cars or chairs, but they perceive cars and chairs as being just as similar to one another as they are to either flowers or people (Lazareva et al., 2004). Similarly, rhesus monkeys appear to perceive living objects as more similar to each other than to nonliving objects (Gaffan and Heywood, 1993). Although more research is needed, current data point to many potential similarities in how animals and humans perceive similarities within and between basic-level categories. The neural mechanisms of such classification behavior may be especially informed by comparative studies of the sort reviewed here.

1.11.3.4 Artificial Polymorphous Categories as Models of Basic-Level Categories

Although considerable research has demonstrated that animals can classify pictures of objects such as trees or cars, the stimulus features controlling such discriminative behavior have been much more difficult to determine (see the section titled 'Further research on basic-level categorization'). Consequently, some researchers have adopted a different approach: Instead of trying to deal with already-existing categories, they have constructed *m*-out-of-*n* artificial polymorphous categories, where a specific instance is a member of a category if it contains *m* out of *n* relevant features. Natural basic-level categories are often believed to be polymorphous; that is, there is no single feature that is necessary or sufficient for category membership. Thus, artificial polymorphous categories constructed in a similar manner might to be an effective way to model basic-level categories.

Figure 6 depicts one example of such an artificial polymorphous category studied by Jitsumori (1993). The relevant dimensions are the shape of the elements (circles or triangles), the color of the elements (white or black), and the color of the background (red or green). Here, as well as in many other similar studies, the dimensions are selected to be orthogonal, so that the contribution of each feature can be independently

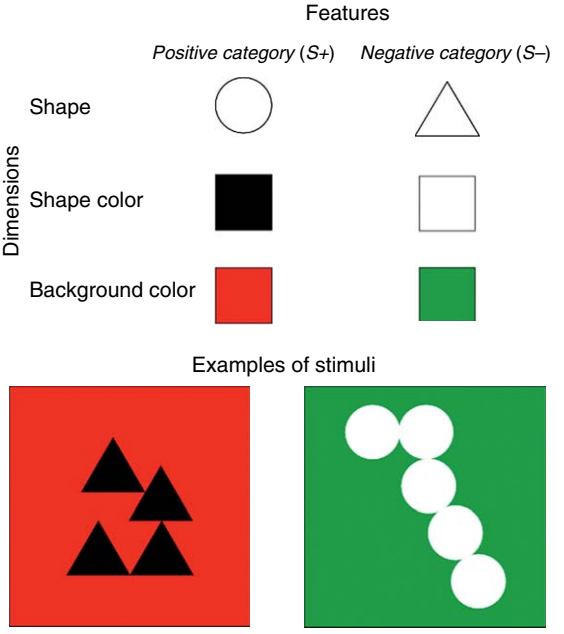

Figure 6 Construction of a two-out-of-three polymorphous category (Jitsumori, 1993). The stimuli were created by changing features from three dimensions: shape (circle or triangle), shape color (black or white), and background color (red or green). The features were randomly assigned to represent the positive and negative categories. The top panel depicts one such assignment. Stimuli with two positive and one negative feature belonged to the positive category, whereas stimuli with two negative and one positive feature belonged to the negative category.

assessed. The features are then randomly assigned to represent either a positive or a negative category. In Jitsumori's study, a stimulus with two positive and one negative features was assigned to the positive category, whereas a stimulus with two negative and one positive features was assigned to the negative category. Pigeons were then trained to respond when a member of the positive category was shown and to refrain from responding when a member of the negative category was shown, a standard go/no-go procedure. This experiment, and others listed in **Table 2**, has found that animals can learn such artificial polymorphous categories.

Despite such successful learning, other experimental data cast doubt on the similarity of artificial polymorphous categories to natural basic-level categories. Lea et al. (2006) observed that, although the discrimination of basic-level categories is easily learned, artificial polymorphous categories are often difficult to master for both animals and people. For example, pigeons took an average of 5400 trials to master the two categories depicted in **Figure 6** (Jitsumori, 1993). For comparison, pigeons trained to discriminate cars, chairs, flowers, and people in a four-alternative forced-choice task required fewer than 1000 trials to master all four categories (Bhatt et al., 1988; Wasserman et al., 1988).

Lea et al. (2006) proposed several factors that may affect the rate of learning artificial polymorphous categories. For example, in artificial polymorphous categories, each feature is equally valid: So, in the task presented in **Figure 6**, the color of the shape is as good a predictor of a category membership as is the shape itself. In contrast, the predictive value of different features identifying members of natural categories can vary. Therefore, if a subject is trained to discriminate cars from chairs, then the presence of tires on car images or the presence of thin elongated parts, such as chair legs, on chair images may be sufficient features for discrimination. Further research is needed to elucidate to what extent research on artificial polymorphous categories can be used as an effective model of basic-level categorization.

1.11.4 Perceptual Concepts as Subordinate-Level Categories

Subordinate categories are nested within basic-level categories. For example, the category monkey includes Japanese monkeys, rhesus monkeys, and capuchin monkeys. Subordinate categories have high within-category similarity, but unlike basic-level categories, they also have high between-category similarity; after all, most monkey species look quite similar to each other. Consequently, categorization at the basic level is preferred to categorization at the subordinate level (Rosch and Mervis, 1975). Nevertheless, the less-privileged status of subordinate categories can be moderated by expertise: Dog experts and bird experts identified objects at the subordinate level just as fast as at the basic level within their domain of expertise (Tanaka and Taylor, 1991; Johnson and Mervis, 1997).

Can animals learn to categorize at the subordinate level? Although categorization at the subordinate level has received far less attention than categorization at the basic or superordinate levels, several species have been successfully trained to categorize at the subordinate level (**Table 3**). Curiously, several animal studies suggest that some subordinate levels, namely, the level of species, may be a preferred level of categorization. For example, pigeons and rhesus monkeys readily learned and transferred the subordinate-level kingfisher/nonkingfisher discrimination, but they were unable to master the basic-level bird/nonbird discrimination (Roberts and Mazmanian, 1988). In another experiment (Yoshikubo, 1985), rhesus monkeys were trained to respond to photographs containing rhesus monkeys and to refrain from responding to photographs that did not contain rhesus monkeys or any other animals. In later testing, photos of Japanese monkeys were shown as probe trials. If, during initial training, rhesus monkeys formed the basic-level category 'monkey', then they should have responded to these photographs. However, they refrained from responding, suggesting that the subordinate category 'rhesus monkey' had instead been acquired. Similar data were obtained for other monkey species (Fujita, 1987).

Of course, rhesus monkeys, as well as other monkey species, have extensive experience recognizing and categorizing members of their own species. It can, thus, be argued that the shift in preferred level of categorization may be the result of high proficiency, just as in humans (Tanaka and Taylor, 1991; Johnson and Mervis, 1997). The Roberts and Mazmanian (1988) data seem to argue against this hypothesis, because both pigeons and monkeys preferred the subordinate-level category kingfisher; presumably, rhesus monkeys do not have extensive expertise with different bird species. However, other reports suggest that pigeons can, in fact, successfully master the bird/mammal discrimination (Cook et al., 1990), casting doubt on their failure to master the

bird/nonbird discrimination reported by Roberts and Mazmanian (1988). Future research systematically examining the preferred level of categorization across different species is needed to disclose potential differences and similarities in subordinate-level categorization in animals and humans.

1.11.5 Nonsimilarity-Based Concepts

Nonsimilarity-based concepts have often been studied in the context of human-language superordinate categories, constructed from several basic-level categories. For example, the category animal may include birds, frogs, and fish (e.g., Wasserman et al., 1992); this approach is reviewed in the section titled 'Nonsimilarity-based concepts as superordinate-level categories'. Another approach to nonsimilarity-based concepts involving equivalence class formation is reviewed in the section titled 'Nonsimilarity-based concepts as equivalence classes.'

1.11.5.1 Nonsimilarity-Based Concepts as Superordinate-Level Categories

Can animals learn to respond differentially to superordinate human-language categories? Starting with Herrnstein's studies, many animals have been found to be able to sort objects into various superordinate categories, such as bodies of water, vehicles, or food (**Table 4**). In one instance, Roberts and Mazmanian (1988) used a go/no-go task to train pigeons and squirrel monkeys to discriminate color photographs at three different levels: kingfisher versus other birds, birds versus other animals, and animals versus various outdoor scenes containing trees, furniture, houses, and other inanimate objects.

Food	Mangabeys, gorilla, rhesus monkeys	Delorme et al., 2000; Deputte et al., 2001; Vonk and McDonald, 2002

Both pigeons and squirrel monkeys readily learned the kingfisher/nonkingfisher discrimination, and both species transferred their performance to novel exemplars. The animal/nonanimal discrimination required additional training, but it was eventually mastered. In contrast, neither monkeys nor pigeons could correctly classify novel pictures in the bird/nonbird discrimination. Similar results were obtained for a juvenile gorilla that learned the orangutan versus human, primate versus nonprimate, and animal versus food discriminations, but that animal only showed reliable transfer to novel exemplars for the orangutan versus human and the animal versus food discriminations (Vonk and McDonald, 2002). In a replication of this study, Vonk and McDonald (2004) found that, unlike the gorilla, adult orangutans readily learned all three discriminations, and they transferred their discriminative performance to novel exemplars from all three categories. It is not clear why some animals appear to have difficulty with some of the superordinate categories (e.g., birds/nonbirds) but not with others (e.g., animals/nonanimals).

Most published studies have explored animals' categorization at different levels in different experiments and usually with different visual stimuli. Yet, flexible classification of objects and events at different levels is thought to be one of the most important and perhaps the unique features of human categorization (Markman, 1989): Humans can refer to the same object as a Toyota, a car, or a vehicle, depending on context. Recently, work in our laboratory has explored whether pigeons can flexibly classify the same photographs at the basic level or at the superordinate level, depending on task demands (Lazareva et al., 2004).

As **Figure 7** illustrates, our experiment used four basic-level categories (cars, chairs, flowers, and humans) that were arranged into two superordinate-level categories (artificial: cars and chairs, natural: flowers and humans). During training, the same photograph randomly required basic-level discrimination if four choice keys were presented and superordinate-level discrimination if two different choice keys were presented. Our pigeons readily mastered both discriminations, attesting to their ability to flexibly categorize the photos; as well,

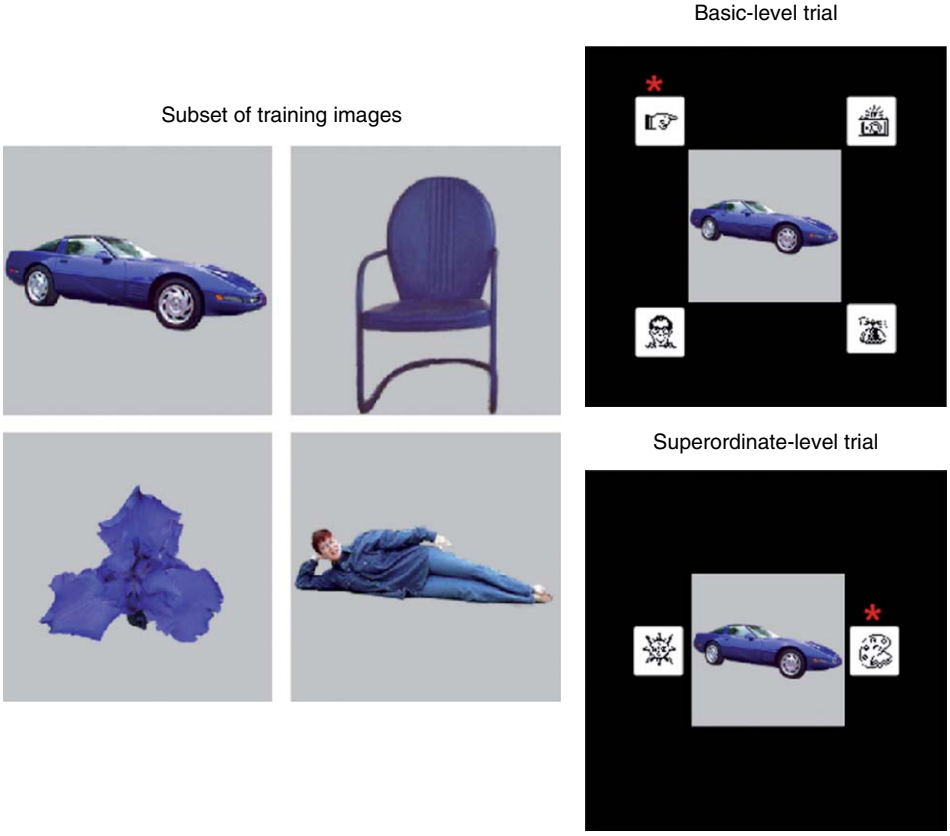

Figure 7 Examples of the photographic stimuli and the schematic layout of a basic-level trial and a superordinate-level trial used in Lazareva et al. (2004). The choice response assignments varied across birds.

our pigeons demonstrated reliable transfer to novel exemplars at both basic and superordinate levels. Flexible categorization therefore appears not to be a uniquely human ability.

1.11.5.2 Nonsimilarity-Based Concepts as Equivalence Classes

Instead of training animals to sort objects according to superordinate human-language categories, other experiments have studied how superordinate categories are created in the first place. If, by definition, superordinate categories are not based on perceptual similarity, then how and why are they formed?

One possibility (Astley et al., 2001) concerns learned or acquired equivalence: Perceptually distinct stimuli may be grouped together if all of them have been associated with the same outcome or with the same behavior. We know that the perceptually distinctive stimuli have formed a functional equivalence class if a change in response tendencies to some members of the class generalize spontaneously to other members of the class, when members of the class become interchangeable, or both (Schusterman et al., 2000; Sidman, 2000; Zentall, 2000).

Some theorists believe that functional equivalence classes need to be distinguished from stimulus equivalence classes, which represent a higher level of complexity and are empirically documented by reflexivity, symmetry, and transitivity (Hayes et al., 2001). Others argue that functional equivalence classes do not differ from stimulus equivalence classes (Sidman, 2000). Regardless of how this debate is resolved, functional equivalence classes appear to be quite close to superordinate human-language categories.

For example, we use both cars and motorcycles to travel; as cars and motorcycles each produce a common outcome (moving us from one place to another), we combine these two classes of objects into a single superordinate category, vehicle. Likewise, we call any organism that preys on other organisms (i.e., exhibits a common behavior) a predator, grouping together such diverse organisms as flatworms, ant lions, and killer whales. Is this aggregative ability uniquely human? Can animals also construct categories based on their functional, rather than perceptual, properties?

In the representative experiment depicted in **Figure 8** (Wasserman et al., 1992), pigeons were trained to peck one button when photographs of two basic-level categories (e.g., flowers and chairs) were presented and to peck a second button when photographs of other two basic-level categories (e.g., cars and people) were presented. Then, with the first two buttons unavailable, the pigeons were trained to peck a third button to photographs of flowers and to peck a fourth button to photographs of people, a procedure called reassignment training (Lea, 1984). No photographs of cars or chairs were shown during reassignment training. Finally, the researchers showed the pigeons photographs of cars and chairs with only the third and fourth buttons available. If, during original training, the pigeons grouped the two basic-level categories associated with a common response into a higher-order category, then they should have been able to select the response associated with the complementary basic-level category during reassignment training. In the testing phase, the pigeons did predominately peck the button that had been associated with the complementary basic-level category during reassignment training, thus documenting functional stimulus equivalence.

Later research in our laboratory has revealed that pigeons can form functional equivalence classes via associations with a common delay, a common probability, and a common quantity of reinforcement (Astley and Wasserman, 1999; Astley et al., 2001; see also Frank and Wasserman, 2005). For example, when cars and flowers were associated with a 15-s delay to reinforcement, or were reinforced on one out of ten trials, or were reinforced by five pellets, pigeons grouped these two basic-level categories together into a functional equivalence class.

Many other reports have documented the formation of functional equivalence classes via a many-to-one mapping procedure (e.g., Grant and Kelly, 2001; Neiman and Zentall, 2001; Urcuioli et al., 2006; see Zentall, 1998, for a review). In a typical many-to-one matching experiment, organisms are trained to make a common response after two or more entirely arbitrary stimuli. For example, pigeons could be presented with a red hue or a vertical line as an initial (or sample) stimulus; in this case, the choice of a vertical line (a comparison stimulus) is reinforced. Alternatively, a pigeon could be presented with a green hue or a horizontal line as a sample, and in this case the choice of a horizontal line is reinforced (Urcuioli et al., 1989). After that, one sample from each class is associated with a novel response: The red hue sample with the choice of a black circle and the green hue sample with the choice of a white circle. Finally, the second sample from each class, the vertical line and the horizontal line, was presented with the novel comparison stimuli, the black circle and the white circle. The pigeons selected the black circle when the vertical line was presented, and they selected the white circle when the horizontal

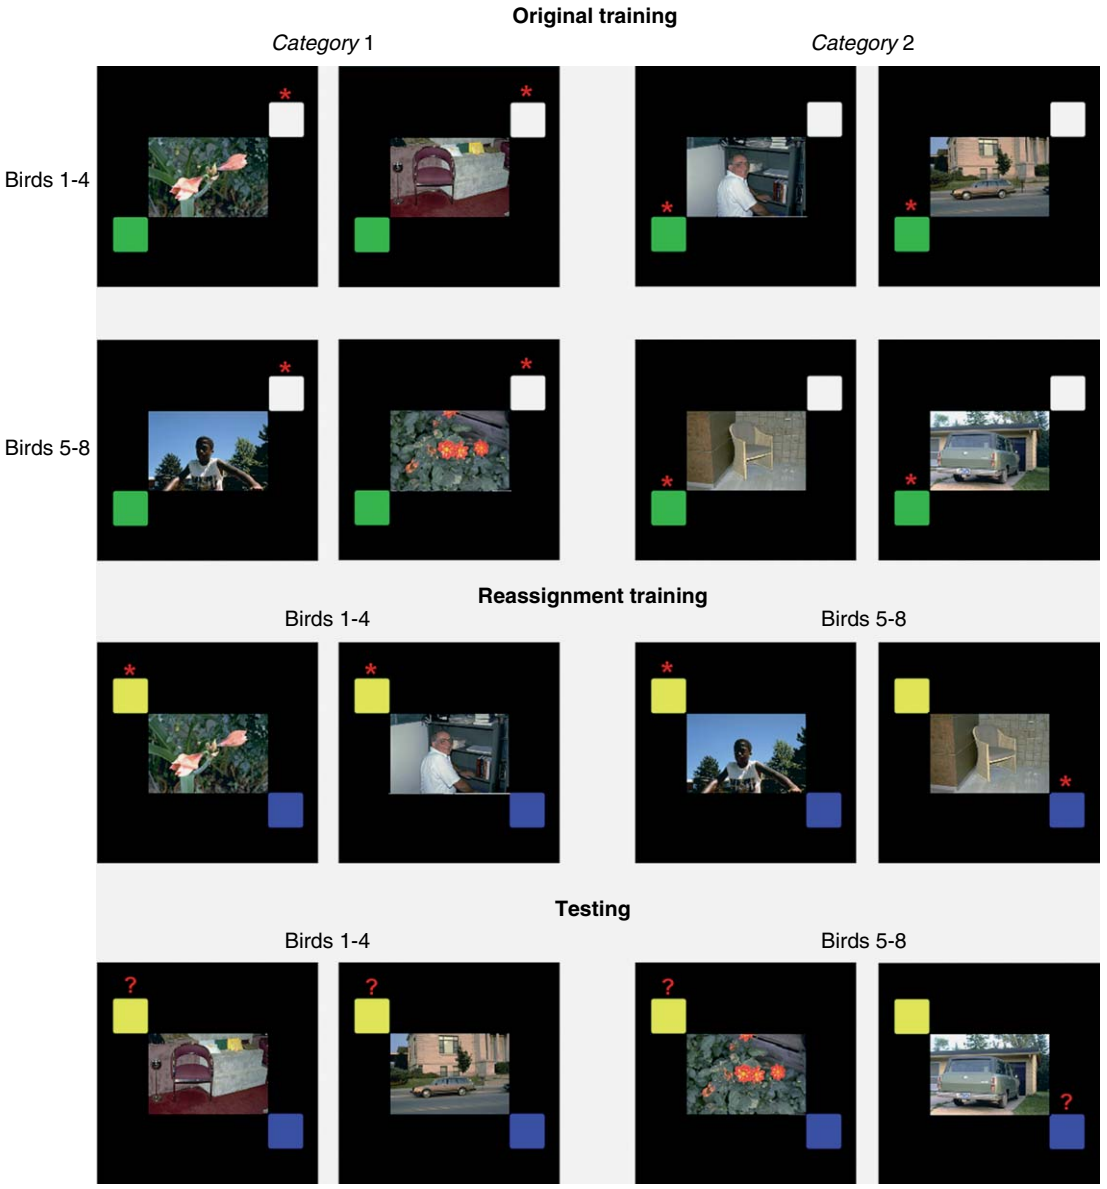

Figure 8 Schematic depiction of the training and testing procedures used in Wasserman et al. (1992). First, pigeons were trained to associate two basic-level categories with one response and two other basic-level categories with a different response (original training), creating two higher-level, superordinate categories. Later, one of the basic-level categories from each superordinate category was associated with a different response (reassignment training). Finally, the withheld basic-level categories were presented with the novel choice responses (testing). If the birds were forming superordinate-level categories during original training, then they should be able to select the correct response associated with the other class of stimuli during reassignment training. Different assignments were given to two subsets of birds in the experiment.

line was presented, divulging an emergent relation between the stimuli associated with the same event, quite similar to the experiments described earlier.

Note, however, that the functional equivalence classes in this design do not comprise several basic-level categories. Therefore, although research on many-to-one matching may have important implications for understanding superordinate categorization in animals, it does not entail many of the important features of superordinate categories, such as their hierarchical structure. To our knowledge, no research has explicitly explored to what extent superordinate-level categorization is comparable to many-to-one matching.

1.11.6 Abstract Concepts

Many theorists have drawn a distinction between natural concepts, such as tree or furniture, and abstract or relational concepts, such as above/below or same/different (Premack, 1983a; Lea, 1984; Herrnstein, 1990; Pearce, 1994; Thompson, 1995; Wasserman, 1995; Mackintosh, 2000; Wright et al., 2003; Cook and Wasserman, 2006). Members of natural concepts are grouped by perceptual, associative, or functional similarity, whereas abstract concepts are believed to go beyond the specific features of the stimuli. Instead, abstract concepts are based on relations between or among those stimuli. As C. Lloyd Morgan (1894/1977) stated in his *Introduction to Comparative Psychology*:

> Two particular objects, billiard balls for example, are perceived to be a span asunder. The balls are removed, and pieces of chalk being substituted they too are seen to be a span asunder. All sorts of small objects may be substituted for the chalk, and ... the space relationship remains unchanged. [...] We do not merely perceive those two billiard balls to be related in such a way, but we conceive the relationship in its abstract and general form. ... [T]his conception is not concrete, particular, and individual, but abstract, general, and of universal application. (Lloyd Morgan, 1894/1977, pp. 262–263)

Lloyd Morgan (1894/1977) considered whether animals can form such abstract concepts, but he later rejected this intriguing possibility, "in no dogmatic spirit, and not in support of any preconceived theory or opinion, but because the evidence now before us is not ... sufficient to justify the hypothesis" (Lloyd Morgan, 1894/1977, p. 377). Morgan's conservative assessment persists today (Premack, 1983a; Pearce, 1994; Mackintosh, 2000). Nevertheless, substantial experimental evidence now suggests that animals can, in fact, form concepts that transcend specific properties of the stimuli, such as symmetrical or same/different (see **Table 5** for more examples). We review the evidence relevant to the most extensively studied concepts in this section.

1.11.6.1 Concept of Number

Can animals count? One of the difficulties in answering this question lies in the enormous variety of behaviors that can be controlled by numerical attributes of stimuli. An organism may be trained to select the larger (or the smaller) of two arrays of items, with the experimenter controlling the nonnumerical attributes of the stimuli (e.g., area or density), so that only the number of items in the array can reliably predict reinforcement (e.g., Thompson and Chase, 1980; Zorina and Smirnova, 1996; Anderson et al., 2005). Is this evidence of counting? What about an experiment in which an organism is trained to select an array of three items, irrespective of the items' identity or configuration (e.g., Davis, 1984)? Do any of these studies represent clear evidence for the concept of number in animals?

According to Davis and Perusse (1988), who have proposed one of the most extensive theoretical analyses of numerical competence in animals, the concept of number is an abstract or modality-free numerical ability. As such, this ability ought to be revealed by means of transfer across different modalities (e.g., from visual to auditory) or across different procedures (e.g., from simultaneous to successive presentation). The concept of number is one of the attributes of true counting, "a formal enumerative process" that requires "the application of reliably ordered cardinal tags in one-to-one correspondence to the items in the array" (Davis and Perusse, 1988, p. 562). In other words, true counting requires the presence of cardinality, the one-to-one assignment of a numerical tag to an array, and the presence of ordinality, the ability to order these numerical tags. Finally, some authors have proposed transfer to new numbers as an indicator of the number concept. For example, a rat trained to press a lever two times after two light flashes and four times after four light flashes ought to be able to spontaneously press a lever three times after three light flashes with no additional training (Davis and Perusse, 1988; see also Boysen and Capaldi, 1993, and Brannon, 2005, for more recent discussion of numerical competence in animals).

To our knowledge, only one study has successfully obtained evidence for cross-modal transfer of a numerical discrimination. In this study (Church and Meck, 1984), rats were trained to press the right lever when two sounds were presented and to press the left lever when four sounds were presented. The nonnumerical features of the stimuli – such as the duration of each sound, the interval between sounds, and the total duration of the sound sequence – was controlled, so that a reliable discrimination could be based only on the number of the sounds in a sequence. After rats learned this discrimination, the sounds were replaced with light flashes; for half of the rats the response rule remained unchanged, whereas for the other half of the rats the response rule was reversed. As **Figure 9** illustrates, the rats in the nonreversal group continued to make the correct responses when sounds were

Identity: Same-different	Pigeons, African grey parrot, baboons, capuchin monkeys, rhesus monkeys	Pepperberg, 1987; Cook et al., 1995; Young et al., 1997; Wasserman et al., 2001; Young and Wasserman, 2001; Cook, 2002; Blaisdell and Cook, 2005; Gibson et al., 2006
Relation among relations	Pigeons, gorilla, orangutan, chimpanzees	Gillan et al., 1981; Premack, 1983b; Thompson et al., 1997; Fagot et al., 2001; Vonk, 2003; Cook and Wasserman, 2007

Because of the extremely large number of studies devoted to some of the concepts (e.g., the concept of number), only selected studies are listed.

replaced by flashes, although at a lower level of accuracy than in training. Moreover, the rats in the reversal group followed the previously learned rule: They continued to press the right lever in the presence of two light flashes and to press the left lever in the presence of four light flashes, even though the opposite response was now reinforced. Together, these results show that the rats' numerical discrimination was modality-free. More comparative research is needed to further explore this important competence.

Several studies provide evidence for cardinality: numerical tags that animals can use to identify arrays of items (see **Table 5**). For example, Boysen and Berntson (1989) trained the chimpanzee Sheba to select an Arabic numeral corresponding to the number of candies on a tray. Once Sheba mastered this task, she was presented with the Arabic numerals displayed on a computer monitor and was required to select the placard with the correct number of metal disks attached to it. After this training, Sheba could select the correct Arabic numeral for arrays consisting of novel, nonedible items, thereby demonstrating that she indeed learned the one-to-one correspondence between Arabic numerals and arrays of items. Similar evidence was obtained for other primates, for an African Gray parrot, and even for pigeons (see **Table 5**).

Evidence for ordinality – the ability to order numerical tags – was considerably more difficult to obtain. In order to conclude that animals are ordering numerical tags, one must eliminate the possibility that the ordering is based on other stimulus dimensions, such as density or surface area or the hedonic value of reinforcement. The latter possibility is particularly important because many studies have used

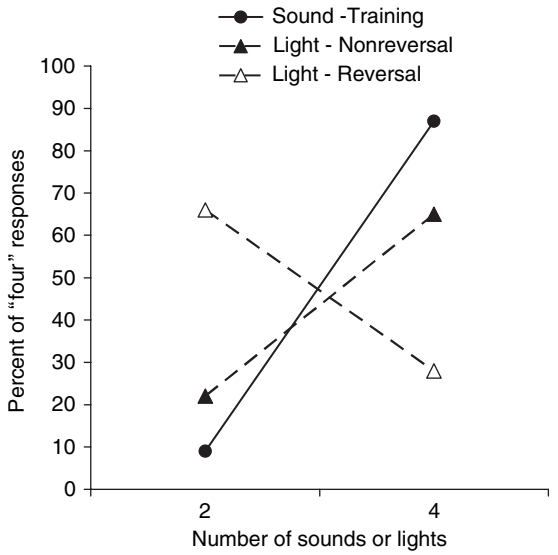

Figure 9 Transfer of the 'two' vs. 'four' discrimination from the number of sounds to the number of light flashes. For half of the rats, the response rule remained the same (Light – Nonreversal), whereas for the other half of the rats, the response rule was reversed (Light – Reversal). Data compiled from Church RM and Meck WH (1984) The numerical attribute of the stimuli. In: Roitblat HL, Bever TG, and Terrace HS (eds.) *Animal Cognition*, pp. 445–46. Hillsdale, NJ: Erlbaum.

the number of food items to establish a one-to-one correspondence between the number of items and the numerical tags (e.g., Washburn and Rumbaugh, 1991; Boyson et al., 1993; Olthof et al., 1997). In this case, the animals could have used the hedonic value of reinforcement to order the numerical tags instead of the number of items in the corresponding array.

Recently, Brannon, Terrace, and colleagues (Brannon and Terrace, 1998, 2000; Cantlon and Brannon, 2006) adopted a new approach for studying ordinality. Instead of training animals to use numerical tags, the researchers focused on the extent to which a nonverbal system for representing numbers in animals is similar to a nonverbal system for representing numbers in humans. When humans compare single-digit numbers or random-dot arrays, they exhibit a numerical distance effect (e.g., 1 vs. 7 is easier than 1 vs. 2) and a numerical magnitude effect (e.g., 1 vs. 2 is easier than 6 vs. 7), suggesting that number discriminability conforms to the Weber-Fechner Law (Dehaene et al., 1990). Does the discriminative behavior of rhesus monkeys exhibit the same regularities?

To find out, Brannon and Terrace (1998, 2000) trained monkeys to touch simultaneously presented arrays of one, two, three, and four items on a computer screen in ascending order to receive juice reinforcement. As **Figure 10** illustrates, the non-numerical attributes of the stimuli (e.g., area, density, or shape of the items) were carefully controlled, so that successful discrimination could be based only on the number of items in the array. Monkeys successfully learned the task and transferred their discriminative performance to novel arrays of five to nine items, providing strong evidence for ordinality. In a follow-up experiment, Cantlon and Brannon (2006) slightly modified the task, so that only two arrays were simultaneously presented; in addition, the number of items in the array varied from 1 to 30. The monkeys were still required to touch the arrays in ascending order. For comparison, human participants were trained to

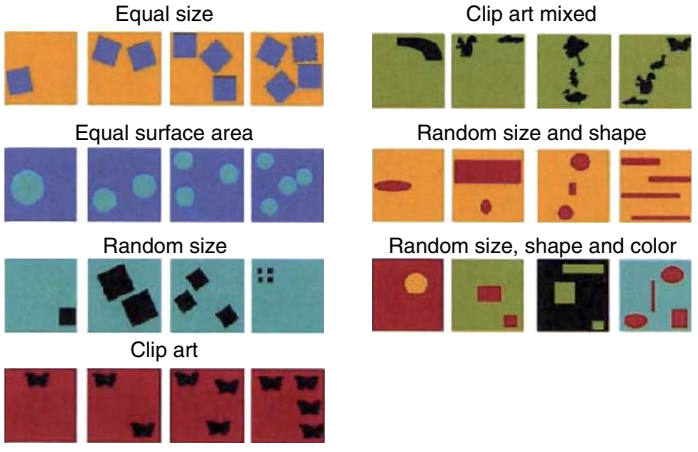

Figure 10 Examples of stimuli used during training in Bannon and Terrace (1998, 2000). Brannon EM and Terrace HS (2000) Representation of the numerosities 1–9 by rhesus macaques (*Macaca mulatta*). *J. Exp. Psychol. Anim. Behav. Process.* 26: 31–49.

perform a similar task. Cantlon and Brannon (2006) found that monkeys' performance exhibited both the numerical distance effect and the numerical magnitude effect. Moreover, monkeys' performance and humans' performance was similar not only qualitatively but also quantitatively, suggesting that monkeys and humans share the same nonverbal system for representing number. More comparative research is needed to establish whether this nonverbal system for number representation is shared by other animal species.

1.11.6.2 Relational Concepts in the Transposition Paradigm

Can animals respond to the relations between or among stimuli, rather than to the absolute properties of the stimuli? Perhaps the most famous attempt to experimentally examine this possibility comes from the case of transposition, first explored by Köhler (1918/1938). Suppose that an organism is given a simultaneous discrimination task in which the positive discriminative stimulus (S+) is a 2-cm-diameter circle and the negative discriminative stimulus (S–) is a 3-cm-diameter circle. When the organism masters the visual discrimination, just what has it learned? Has it learned that only the 2-cm circle signals food? Or has it learned the concept of smaller?

A possible answer to this question comes by considering how the organism ought to respond to new pairs of stimuli that are presented during a postdiscrimination test. If the former S+ is presented along with the even smaller 1-cm-diameter circle, then having learned to respond to the relation between the circles, the organism may actually choose the untrained stimulus over the former S+. In his pioneering studies, Köhler (1929, 1918/1938) found that chickens and chimpanzees did indeed respond in this relational manner, a result that led him to propose that stimuli are not judged in absolute terms but as relative to one another.

Does choice of the untrained stimulus over the former S+ necessarily indicate control by the relation between the stimuli rather than by specific features of these stimuli? Kenneth W. Spence (1937) famously demonstrated that relational responding in the transposition paradigm can be explained as the result of the interaction of learned tendencies to make responses to S+ and to withhold responses to S–.

If both training stimuli are located on the same dimension, then the algebraic summation of those learned tendencies leads to two peak shifts: The peak of maximal associative strength shifts away from the former S–, and the peak of minimal associative strength shifts away from the former S+. In other words, the organism may prefer the 1-cm circle because the associative strength of this stimulus is actually higher than associative strength of the formerly reinforced 2-cm circle. So, according to Spence's generalization theory, the preference for the novel stimulus over the former S+ found by Köhler was no more relational than was the tendency to approach S+ and the tendency to avoid S– after standard discrimination training. Spence's stimulus generalization theory yielded several important predictions that have been confirmed in different species, including humans, and in different experimental situations (e.g., Ehrenfreund, 1952; Honig, 1962; Cheng, 1999; Cheng and Spetch, 2002; reviewed by Reese, 1968; Riley, 1968; Purtle, 1973).

Several reports have provided data that have challenged generalization theory as the sole account of an organism's behavior in transposition tasks (**Table 5**). Consider the intermediate stimulus problem, in which an animal is presented with 1-cm, 2-cm, and 3-cm circles and is required to select the 2-cm circle to obtain reinforcement. In the test, the animal is presented with 2-cm, 3-cm, and 4-cm circles; if the animal had previously learned to respond according to the relation among the stimuli, then it ought to select the previously nonreinforced 3-cm circle. Generalization theory predicts that the animal ought to select the previously reinforced (2-cm circle) stimulus instead of the middle value. Nonetheless, chimpanzees have been found to transpose the solution of the intermediate-size problem (Gonzales et al., 1954).

Other studies have compared transposition after simultaneous and successive discrimination training. Unlike successive discrimination training, simultaneous discrimination training affords the subject the opportunity to compare the training stimuli at the same time; therefore, relational responding ought to be enhanced. Yet, stimulus generalization theory makes no distinction between simultaneous and successive modes of presentation. Several studies have indeed reported higher transposition after simultaneous training than after successive training (Riley et al., 1960; Marsh, 1967), suggesting that direct comparison does enhance relational learning (but see Hebert and Krantz, 1965; Wills and Mackintosh, 1999).

Finally, several reports, including our own, have found that presentation of multiple pairs of discriminative stimuli instead of a single pair enhances relational responding in pigeons, even when such responding is

contrary to the predictions of stimulus generalization theory (Marsh, 1967; Lazareva et al., 2005). It is well known that increasing the number of exemplars leads to better acquisition of a concept in many species of animals, including pigeons (Wright et al., 1988; Wright, 1997; Cook, 2002; Katz et al., 2002). Similarly, pigeons may need to encounter multiple instances of a rule in order to exhibit strong relational responding. Unfortunately, we do not yet know whether the same is true for other animal species. (*See* Chapter 1.29 for a corresponding experiment with honeybees).

1.11.6.3 Concept of Identity

The concept of identity, or sameness and difference, is perhaps the most extensively studied concept in animals. The most frequently used experimental procedures are matching-to-sample and same-different discrimination (**Figure 11**). In the standard matching-to-sample task, an animal first views a single stimulus, or sample, and performs several observing responses to it (e.g., touching or pecking the sample). After that, the animal is shown two comparison stimuli and is required to select the comparison that matches the sample (identity matching) or that does not match the sample (oddity matching). The simultaneous same-different discrimination task requires the choice of one response if the two presented stimuli are identical and a second response if the two stimuli are different.

Regardless of training procedure, evidence of successful transfer to novel stimuli is necessary to demonstrate the identity concept. The term full-concept learning is used when an animal discriminates the novel stimuli as accurately as the training stimuli, most strongly documenting the abstract nature of the acquired behavior. Partial concept learning refers to cases in which the novel stimuli are discriminated less accurately than the training stimuli, signifying the stimulus-dependent nature of the acquired behavior, even when discriminative performance is reliably above chance. Early research suggested that some species may only be capable of partial concept learning (e.g., Premack, 1983a). However, recent reports have shown that the number of stimuli used during training is an important parameter affecting identity concept learning, a sensible finding, as an increase in the number of training stimuli makes memorizing individual stimulus associations a more costly strategy. Different species, though, may require different numbers of training stimuli to achieve full identity concept learning, with as few as 16 stimuli for great apes and as many as 512 stimuli for pigeons (**Figure 12**; Wright et al., 2003).

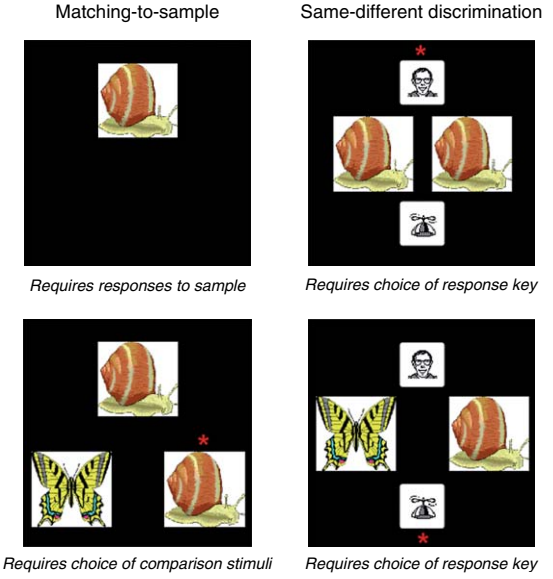

Figure 11 Comparison of matching-to-sample and same-different discrimination. In the (identity) matching-to-sample paradigm, the animal is required to select the correct (identical) comparison stimulus (the red asterisks indicate the correct choices). In the same-different discrimination, the animal is required to select one response key if the items are the same and the other response key of the items are different.

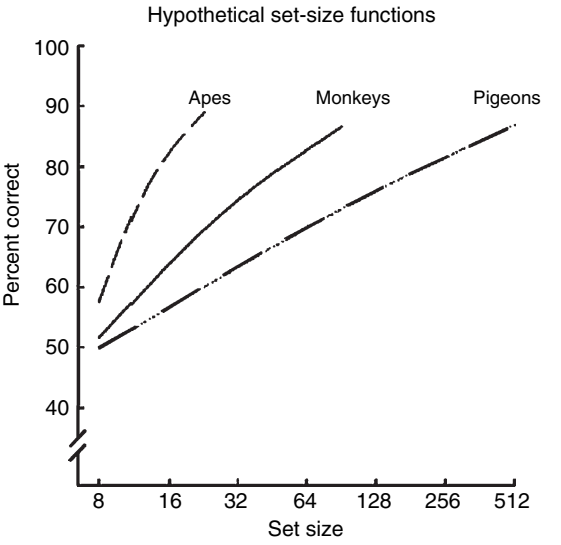

Figure 12 Hypothetical acquisition functions for apes, monkeys, and pigeons, showing low abstract-concept learning might vary as a function of training set size. From Wright AA, Rivera JU, Katz JS, and Bachevalier J (2003) Abstract-concept learning and list-memory processing by capuchin and rhesus monkeys. *J. Exp. Psychol. Anim. Behav. Process.* 29: 184–198.

Another important parameter affecting identity concept learning is the type of training procedure. Pigeons trained using simultaneous same-different discrimination or matching-to-sample procedures require hundreds of training stimuli to achieve full identity concept learning (Wright et al., 1988; Wright et al., 2003), but pigeons can also attain full identity concept learning when only two training stimuli are used (Cook et al., 2003).

What was the secret in successfully training pigeons with a small number of stimuli? In this experiment, pigeons were presented with stimuli that were alternated several times within a single trial, so that the birds had multiple opportunities to compare them. It is possible that these extended sequences were critical for the initial acquisition of the abstract concept, although the available experimental data are insufficient for substantiating this conclusion.

Interestingly, another experiment that used a similar procedure found only partial concept acquisition in pigeons (Young et al., 1997). In this experiment, pigeons were shown 16 computer icons, one at a time; either all 16 icons were nonidentical or all 16 icons were identical. Just as in the previous experiment, this procedure allowed for multiple opportunities to discern the relationship among the items. Nonetheless, pigeons' transfer to new icons, although well above chance, was below performance with the icons used in training. Clearly, additional research is needed to elucidate the factors affecting acquisition of the abstract same-different concept.

Another important consideration is the nature of the concept learned in different types of experimental procedures. Given the variety of stimuli and experimental approaches that have thus far been used, it is important to establish whether the same processes control animals' behavior in different tasks. In a representative study (Cook, 2002), pigeons were trained using a simultaneous same-different discrimination task with different types of stimuli (**Figure 13**). For some birds, all same displays and all different displays were associated with consistent report responses, regardless of the display type. For example, both different texture and different photo displays required the choice of the left key. This group was called the consistent group. In the inconsistent group, response assignment differed by display type; for example, all different texture displays required the choice of the left key, whereas all different photo displays required the choice of the right key. If pigeons learned a set of specific rules for each type of display, then they should have learned the inconsistent task just as easily as the consistent task. In fact, the consistent group learned the task faster and reached higher levels of accuracy by the end of the training than the inconsistent group. Moreover, only the consistent group demonstrated significant transfer to novel stimuli, indicative of concept formation. These results suggest that, despite dramatic perceptual differences among the types of displays, pigeons' discriminative performance was based on a single general rule that was abstract enough to be applicable to a wide variety of visual stimuli.

On the other hand, seemingly minor changes in experimental procedure may lead to dramatically different strategies employed for task solution as Gibson et al. (2006) demonstrated. In their study, pigeons were again trained to perform a simultaneous same-different discrimination. In the 16S versus 16D condition (**Figure 14**), the birds had to select one choice key if all 16 items in the display were the same and to select the other choice key if all 16 items in the display were different. In the 16S versus 15S:1D condition, different displays contained 15 identical items and 1 odd item, thus resembling previously described task (Cook, 2002; **Figure 14**). Although pigeons readily mastered the 16S versus 16D discrimination, they were unable to learn the 16S versus 15S:1D discrimination unless they were required to peck the odd item prior to making a choice response.

In a follow-up project, pigeons were trained to concurrently perform the already learned 16S versus 16D discrimination plus the newly introduced 16S versus 15S:1D discrimination. If the birds were using the same strategy in both tasks, then they should begin to make many more errors on same trials in the 16S versus 16D task, as the 16S displays are quite similar to the 15S:1D displays. On the contrary, the birds should make many fewer errors on different trials, as the 16D displays should appear even more different than the 16S display when the 15S:1D displays are introduced. Yet, none of these changes were observed. Acquisition of the 16S versus 15S:1D task did not come at the expense of 16S versus 16D task performance, suggesting that the pigeons may have used different strategies to solve these tasks. Other evidence also points to the conclusion that these two tasks are qualitatively different (reviewed by Cook and Wasserman, 2006).

1.11.6.4 Relations Among Relations

Can animals discriminate higher-order relations between multiple first-order relations? Suppose that an animal is shown a sample stimulus with two equal-size circles and comparison stimuli with two equal-size

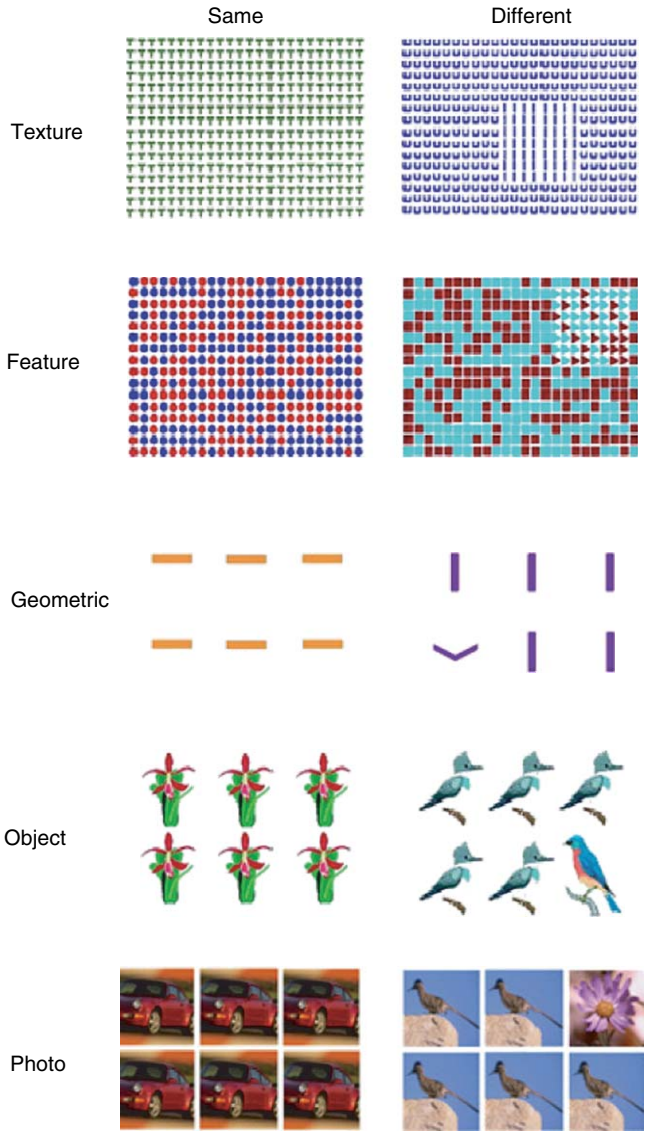

Figure 13 Examples of displays used by Cook (2002). The left column shows examples of same displays, and the right column shows examples of different displays for each display type. From Cook RG (2002) The structure of pigeon multiple-class same-different learning. *J. Exp. Anal. Behav.* 78: 345–364.

triangles and two unequal-size squares (**Figure 15**). Can the animal learn to select the comparison stimulus that entails the same relation (equal size), even though none of the shapes is identical? The ability to detect such higher-order relations is similar to human analogical reasoning, which is believed to be one of the central components of human cognition (Gentner et al., 2001).

Early research suggested that only language-trained chimpanzees can process second-order relations, whereas non-language-trained chimpanzees perform first-order same-different discriminations only on the basis of physical similarities (Premack, 1983b). Later research has found, however, that this conclusion was premature. Using a two-item display (**Figure 15**, left panel) task, several ape species have been found to respond in accord with second-order relations (Thompson et al., 1997; Vonk, 2003).

Two other studies have used a multiple-item display task (**Figure 15**, right panel) in which a sample contains an array of 16 items that are either identical or nonidentical. The comparison stimuli also contain arrays of 16 identical or nonidentical items; however, none of the items used for the sample display are

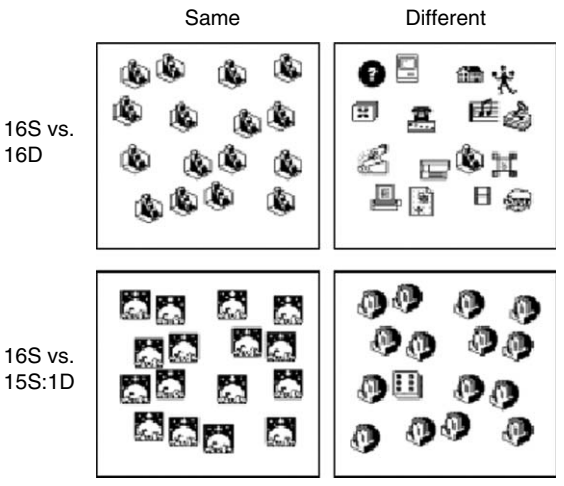

Figure 14 Examples of displays used in the 16S vs. 16D task and in the 16S vs. 15S:1D task. Modified from Gibson BM, Wasserman EA, and Cook RG (2006) Not all same-different discriminations are created equal: Evidence contrary to a unidimensional account of same-different learning. *Learn. Motiv.* 37: 189–208.

repeated in the comparison displays. Therefore, the correct response is only possible if the animal is able to detect the higher-order relations between the sample and comparison arrays. Both baboons (Fagot et al., 2001) and pigeons (Cook and Wasserman, 2006) have successfully learned this task and transferred their discriminations to arrays of novel items. It remains to be seen whether the mastery of two-item display tasks and multiple-item display tasks is based on the same cognitive mechanisms. In any case, these data suggest that the perceptual and cognitive foundations for analogical reasoning may exist not only in the mammalian brain but also in the avian brain.

1.11.7 Conclusion: What Does It All Mean?

Early in this chapter, we offered a definition of conceptual behavior that involves two key components: (1) the ability to respond similarly to members of one class of stimuli and to respond differently to members of other classes of stimuli and (2) the ability to transfer these differential responses to novel, discriminably different members of these classes of stimuli. The extensive evidence that we have reviewed here strongly supports the conclusion that concepts are not unique to human beings. Animals too form concepts based on perceptual similarity among their members, classifying objects into basic-level categories and subordinate-level categories. Moreover, animals appear to sense the perceptual structure of their environment, viewing members of basic-level categories (such as humans or trees) as being more similar to one another than to members of other categories. Animals can sort objects into non-similarity-based, superordinate categories, flexibly switching from basic-level categorization to superordinate-level categorization. Even the ability to form abstract concepts based on the relation between or among stimuli is not exclusively human; animals can respond to first-order and even to second-order relations between or among stimuli.

What does it mean to say that we share cognitive abilities with many animal species, from honeybees to chimpanzees? We are still far from answering that question. Most of the research until now has focused on whether a particular species is able to form a specific concept. Although such studies are an important first step in our understanding of categorization and conceptualization in animals, they do not tell us

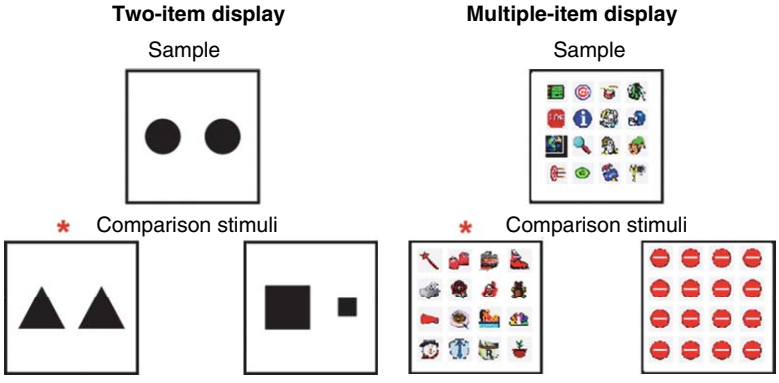

Figure 15 Examples of displays used for testing relational matching. For both types of displays, the correct choice is the comparison stimulus that involves the same relation as the sample stimulus (the red asterisks indicate the correct choices).

how the species attains concept mastery. With a few possible exceptions (e.g., Cantlon and Brannon, 2006), the mechanisms of concept formation in humans and animals remain mysterious.

Why do we need to understand the mechanisms of concept formation in animals? At least two reasons, one theoretical and one applied, can be suggested. The theoretical rationale centers on the relationship between the human mind and the minds of other animals. One exciting possibility is that the cognitive abilities of humans and animals have a common origin; that is, they may be based on some primitive trait shared by many species. For example, it is possible that conceptualization is based at least in part on fundamental laws of associative learning (Wasserman, 1995; Wasserman and Miller, 1997; Mackintosh, 2000), laws that apply to many species which are widely separated in evolutionary history. On the over hand, we may be witnessing another spectacular example of convergent evolution, similar to the bird's wing, the bat's wing, and the insect's wing. Although an adaptation for a similar function, flight, induced similar overall structures of those wings, there are enough differences in details (e.g., the absence of fused fingers in the bat's wings) that help us recognize it as an analogy (a gross similarity caused by similarity in function) rather than a homology (a detailed similarity in organization caused by common origin).

Perhaps conceptualization in humans and animals is similar only at the gross level but is dramatically different in details. Indeed, there may be dramatic differences between different animal species: Maybe the acquisition of the concept of sameness in honeybees with their compound eyes has nothing in common with the acquisition of the concept of sameness in pigeons with their lens eyes. Until we learn much more about the mechanisms of cognition in different species, we will not be able to answer this intriguing question.

From the applied perspective, sound knowledge of the mechanisms of cognition in different species may provide fresh insights for applied researchers. Indeed, research with animals may be of particular interest to applied mental health researchers, because that work usually explores the conditions under which concept formation is or is not likely to occur. For example, learning that the simultaneous presentation of stimuli and multiple instantiations of the relationship among stimuli each strengthen relational responding in pigeons may help applied mental health workers develop better techniques for teaching relational learning in humans, especially individuals who are otherwise inclined to respond to the absolute properties of stimuli instead of the relations between or among them (Carlin et al., 2003; Happe and Frith, 2006).

Fortunately, the focus of recent research has begun to shift to the mechanisms underlying the conceptual abilities of different species (Wasserman et al., 2004). Some remarkable similarities, as well as some remarkable differences, have already been revealed (e.g., Cook and Wasserman, 2006; Wright et al., 2003), and undoubtedly more await discovery. Such future research should provide essential information for elucidating the evolutionary origins of cognition. Together with Stewart Hulse (2006), we hope for "less and less research on existence proof, that is, whether or not a given species has the same cognitive capacity as we, or some other species, do" (Hulse, 2006, p. 674) and for more and more research on how these cognitive capacities operate.

1.12 Learning and Representation

C. R. Gallistel, Rutgers University, Piscataway, NJ, USA

In a representational theory of learning, the brain computes a representation of the experienced world, and behavior is informed by that representation. By contrast, in associative theories of learning, which dominate neurobiological thinking, experience causes a plastic brain to rewire itself to make behavior better adapted to the experienced world, without the brain's computing a representation of that world (Pavlov, 1928; Hull, 1952; Hawkins and Kandel, 1984; Rumelhart and McClelland, 1986; Smolensky, 1986). The computation of a representation seems to require a functional architecture that is not transparently consistent with our current understanding of neurobiological mechanisms (Gallistel, 2006), which is why representational theories of learning have not found favor among neurobiologists. Associative theories, in contrast, have been strongly influenced by neurobiological considerations for more than a century. For them, consistency with the current understanding of neurobiology is a major consideration (e.g., Gluck et al., 2005), which is why they predominate in neurobiological thinking about learning.

The results of behavioral experiments on nonhuman animals have increasingly implied that much learned behavior is informed by enduring temporal and spatial representations (e.g., Menzel et al., 2005), as even some prominent advocates of associative theories have recently acknowledged (Clayton et al., 2006a). Moreover, direct electrophysiological observation of neural activity has shown that the nervous system represents where the animal is and has been within the environment (O'Keefe and Nadel, 1978; Muller, 1996; Lee et al., 2004; Hafting et al., 2005; Foster and Wilson, 2006; *See* Chapter 1.21), how it is oriented (Ranck, 1984; Golob et al., 2001; Sargolini et al., 2006; Yoganarasimha et al., 2006), where objects are in relation to it (Muller et al., 2005; Campos et al., 2006; Goossens and Van Opstal, 2006), and the timing of repetitive or predictable events (Schultz and Dickinson, 2000; Leon and Shadlen, 2003; Meck, 2003; Ivry and Spencer, 2004; Penney, 2004; *See* Chapter 1.19). Thus, there is a conceptual tension between the behavioral and electrophysiological findings that seem to imply a computational–representational architecture, on the one hand, and on the other hand, current conceptions of neural structure and mechanism, in which seemingly essential elements of the requisite functional architecture appear to be absent.

The extent to which one believes that consistency with currently understood neurobiological mechanisms should be a constraint on models of learning depends on whether one believes that those mechanisms provide, or could provide, satisfactory accounts of the behaviorally well-documented phenomena that are the focus of this chapter – dead reckoning in insect navigation, the capacity of insects to record landmark 'snapshots,' and the capacity of food-caching jays to remember and make versatile use of a large number of episode-specific facts about each cache. They also depend on whether one believes that computation in the brain must be consistent with the principles that computer scientists believe constrain physically realizable computations. Perhaps, as many neuroscientists believe, the brain escapes the limitations and requirements that computer scientists believe are imposed by mathematics, logic, and physics.

Instructive instances can be found in the history of science where findings and analyses at a higher level

of inquiry seemed to require mechanisms at a more basic level for which there was then no explanation. Throughout the latter part of the nineteenth century, the eminent physicists William Thompson (Lord Kelvin) and P. G. Tait argued that Darwin and the geologists must be grossly in error in their estimates of the age of the earth, because no heat-generation process known to physics was consistent with a solar age of more than 100 million years. (Tait thought the upper limit imposed by physical considerations was 10 million years – see Lindley (2004) for an account.) Thompson (1862) wrote, for example, "It is impossible that hypotheses assuming an equibility of sun and storms for 1,000,000 years can be wholly true." Importantly, Kelvin did not have a satisfactory theory of where the sun's heat came from – he worked on the problem off and on throughout his career – but he was confident that a satisfactory explanation could be based on physical principles and phenomena that were then understood. Radioactivity was not discovered until 1896, and it was only in 1903 that the Curies showed that it was accompanied by the liberation of heat. The following contemporary quote gives an idea of just how revolutionary this discovery was:

> [this phenomenon] can barely be distinguished from the discovery of perpetual motion, which it is an axiom of science to call impossible, [and] has left every chemist and physicist in a state of bewilderment. (Lindley, 2004: 302)

This discovery of something that Kelvin and Tait literally could not imagine bore tellingly on their argument with Darwin and the geologists.

Whether we are in such a situation now remains, of course, to be seen. However, I argue in this chapter that the behavioral evidence for representation and computation, together with basic insights in computer science about the centrality of a read-write memory mechanism in physically realized computation, implies the existence of a neurobiological read-write memory mechanism. Given the centrality of such a mechanism to computation, as computer scientists understand it, the discovery of such a mechanism may someday have an impact on neuroscience comparable to the impact of the discovery of radioactivity on physics.

1.12.1 Representations: Definition and Explication

From the perspective of cognitive science, the brain is an organ of computation (Newell and Simon, 1975; Marr, 1982). What it computes are representations of selected aspects of the world and the animal's relations to it (the distal stimuli). It computes these representations from the signals engendered in sensory organs by the stimuli that impinge on them (the proximal stimuli) and from signals generated by the motor system, which carry information about how the animal is moving (efference copy signals; Holst and Mittelstaedt, 1950).

A representation consists of signals, symbols, and the operations on them (see **Figure 1**). The signals and symbols carry information about properties of the experienced world. The operations on those signals and symbols enable the brain to compute explicit

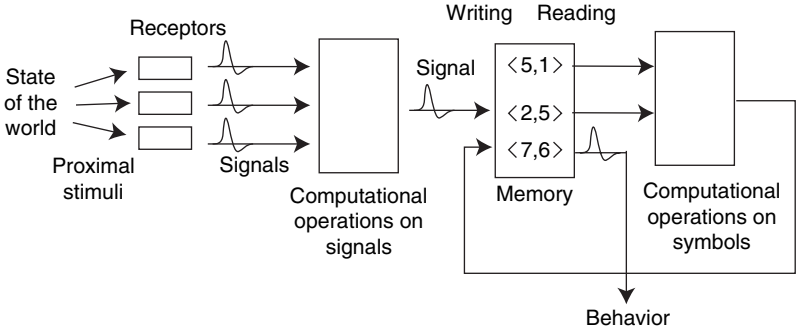

Figure 1 Schematic representation of the flow of information in a neurobiologically realized representational system. Proximal stimuli deriving from a state of the world (distal stimulus) act on sensory receptors to generate sensory signals, from which a perceptual signal specifying that state of the world is computed. The perceptual signal conveys the information to memory, where it is written into a symbol, which carries the information forward in time. Computational operations combine that symbol with other symbols to create further symbols and symbol strings in memory. The information contained in a symbol is read from memory and converted to signals in the motor system that give form to behavior.

representations from implicit ones and to anticipate behaviorally relevant states of the world.

Information is an abstract quantity carried by any signal or symbol that can reduce the brain's uncertainty about the present state of some aspect of the world (Shannon, 1948; Rieke et al., 1997). Information cannot be communicated to a device that has no representation of the world because the measure of the amount of information communicated is the reduction in the receiver's uncertainty about the state of the world. A receiver that has no representation of states of the world cannot have uncertainty about those states; more technically, it cannot have a probability distribution defined on those states. Thus, a receiver incapable of representing at least some states of the world is not something to which information can be communicated; it cannot extract from information-bearing signals the information that they carry.

Signals carry information from one place to another (from one spatial location to another). In a computer, the signals are current pulses. In the nervous system, they are action potentials, synaptic transmitters, and hormones. Symbols carry information forward in time (from one temporal location to a later one). In a computer, the symbols are bit patterns in a memory register. We do not know the physical realization of symbols in the nervous system. One school of thought doubts that they exist (Rumelhart and McClelland, 1986; Wallace and Fountain, 2003; Hay and Baayen, 2005).

The essential features of a physically realized symbol are that it encodes information about something else (to which it refers) and that it enters into symbol processing operations appropriate to the information that it encodes. Base-pair sequences in DNA are biological examples of physically realized symbols. The sequence of exon codons (base-pair triplets) between a start codon and a stop codon encodes the sequence of amino acids that compose a protein. These codon sequences carry forward in time evolutionarily accumulated information about functional amino acid sequences. They enter into combinatorial operations that recreate the sequences they encode. Base-pair sequences also encode promoters. The binding and unbinding of translation factors (themselves usually proteins) to one another and to promoters control the timing and amounts of protein synthesis. The base-pair sequences in promoters carry forward in time evolutionarily accumulated information about functional patterns of protein synthesis (when and where it is functional to synthesize which proteins). The two kinds of information carried by base-pair sequences in DNA – exon information and promoter information – are roughly analogous to the two kinds of information carried in computer memory – data and program information.

In order to refer, the signals and symbols in a representational system must be causally connected to the things or states of the world to which they refer. In a process-control computer, the causal connection is effected by means of the transducers that generate signals proportional to critical variables, such as temperature, torque, concentration, velocity, and force. Often these signals are analog signals (voltages), but these are usually converted almost immediately to symbols (bit patterns stored in memory buffers) by analog-to-digital converters. The bit patterns are then converted to digital signals (current pulses) that are transmitted over signal lines to the input registers (memory buffers) of the computer, where they write the bit patterns into memory registers. This chain of causes and effects causally connects the bit pattern in a memory register that represents the current temperature to the temperature to which it refers. The function of the memory register is to carry that bit pattern (hence, the information about temperature that it encodes) forward indefinitely in time for use in later computations. When it is to be used in a computation, the pattern is read from the register. In short, a symbolic memory register is written to by impinging information-conveying signals and read from by computational processes.

In the nervous system, inputs acting on, for example, the retina of the eye or the basilar membrane of the ear are converted first into analog signals (receptor potentials) and then into digital action potentials, which carry the information into the central nervous system. The behavioral evidence implies that the nervous system possesses a read-write memory mechanism that performs the same essential function performed by the memory registers in a computer, but we do not yet know what that mechanism is.

Because a symbolic memory mechanism has not so far been identified, it is often assumed not to exist. It is assumed that "memory [elements in the brain take the] form of modifiable interconnections within the computational substrate" so that "no separate 'fetch' [read] and 'store' [write] cycles are necessary" (Koch and Hepp, 2006). These modifiable interconnections (synaptic conductances) are thought to be the physical realization of the associations in

associative learning theory (Fanselow, 1993; *See* Chapters 1.33, 1.34, 1.35). There are, however, no proposals about how either associations in the abstract or experientially modified synaptic conductances (physically realized associations) can encode acquired information in a computationally accessible form. There are, for example, no proposals about how associations could specify the coordinates of a remembered location. Generally speaking, for associative theories of learning, this is not a problem. Because they are nonrepresentational theories, they do not require a symbolic memory mechanism.

For representational theories of learning, however, the absence of a symbolic memory mechanism is a problem, because a mechanism functionally equivalent to the tape in Turing's abstract conception of a general purpose computing machine (Turing, 1936, 1950) is essential to computation and representation (Gallistel, 2006). Representations are computed by combining information that arrives in dribs and drabs spread out in time, as is illustrated shortly with the example of the dead reckoning process. For new information to be combined with old information, a mechanism must carry the old information forward in time in a computationally accessible form.

Symbols and the processes that operate on them create functioning homomorphisms between the symbol system and the aspects of the world to which the symbols refer (Gallistel, 1990). A homomorphism between two systems is a (partial) sameness in their abstract, mathematical form. Symbolic processes and relations in the representing system formally parallel nonsymbolic processes and relations in the represented system. A functioning homomorphism is one in which the representing system exploits this parallelism to inform its interactions with the represented system.

1.12.2 Behavioral Evidence for Representations in Learning

1.12.2.1 Dead Reckoning

The position of an animal in its environment, as a function of time, is the integral of its velocity with respect to time. This is a mathematical fact about the relation between these vector variables (velocity and position). In mobile animals, a representation of their position relative to places of behavioral importance (nest or resting area, food sources, hiding places, landmarks with reference to which these other places can be located, and so on) informs their behavior in many fundamental ways. The animal brain computes a representation of the animal's position by integrating with respect to time signals that convey information about its velocity. This symbolic integration process is called path integration in mathematical work and dead reckoning in traditional texts on marine navigation. It is a foundation of animal navigation (Mittelstaedt and Mittelstaedt, 1973; Wehner and Srinivasan, 1981; Gallistel, 1990; Wehner and Srinivasan, 2003; Collett and Graham, 2004; Etienne and Jeffery, 2004; Kimchi et al., 2004; Grah et al., 2005; *See* Chapter 1.20).

Dead reckoning is a particularly simple example of representational learning – if by 'learning' we understand the process of acquiring knowledge from experience. The animal acquires knowledge of its current position (and of past positions of behavioral interest) by means of a neurobiological process that integrates experienced velocity, as conveyed by signals from sensory and motor mechanisms sensitive to correlates of velocity. The process of neurobiological integration in the brain, which is the representing system, parallels the physical integration of velocity that occurs as the animal moves within its environment. The animal's location in its environment is the represented system. In technical jargon, the symbolic processes in the brain are homomorphic to the displacement process in the system that the brain is representing, because there is a partial correspondence in the abstract (mathematical) form of the processes going on in the two systems. The resulting symbolic specification of position enables the brain to, for example, set the animal on the course for home. Insofar as the courses the brain sets actually bring the animal to its home, the symbolic representation of position informs functional behavior. This makes the neurobiological integration of velocity signals to obtain position symbols an example of a functioning homorphism, that is, a representation.

Dead reckoning provides a particularly clear and simple example of the need for a symbolic memory in computation. The essence of dead reckoning is the adding of the current displacement to the sum of the previous displacements. For this to be possible, there must be a mechanism that carries the sum of the previous displacements forward in time in a form that makes it possible to add to it. The mechanism that carries the sum forward in time must not leak; the sum must not get smaller simply from the passage of time. It must not get smaller because it is the physical realization of the symbol that specifies the

subject's displacement from the origin of the reference frame, typically the nest. If the sum gets smaller simply with the passage of time, then the brain represents the animal as getting closer to home just by sitting still.

1.12.2.2 Learning the Solar Ephemeris

The integration of the velocity vector in dead reckoning is meaningless unless the velocity vector is represented in a stable geocentric coordinate framework. The velocity vector specifies the subject's rate of displacement in two orthogonal directions (for example, latitudinal displacement and longitudinal displacement or radial displacement and tangential displacement – see Gallistel, 1990, Chapter 4, for a detailed explication of path integration computations in different coordinate frameworks). Thus, a consistent directional reference must be maintained. In navigational jargon, this is called carrying the parallel, because lines of direction at different locations (e.g., lines running north–south) are parallel. The line from the observer to any nearby landmark changes its direction as the observer moves. This is called parallax. The farther away the landmark is, the less the parallax, and hence the better it functions as a directional referent. Extraterrestrial landmarks like the sun and the stars are, for practical purposes, infinitely far away, so they have negligible parallax. These extraterrestrial landmarks are strongly preferred as directional referents by animals of many different species (Gallistel, 1990). However, they have one drawback: Because of the earth's rotation about its own axis, their terrestrial direction changes continuously.

The solar ephemeris is the direction of the sun in a terrestrial frame of reference as a function of the time of day (that is, as a function of the angular position of the earth in its daily rotational cycle; *See* Chapter 1.25). To use the sun as a directional referent in dead reckoning, the brain must learn the azimuthal component of the solar ephemeris (Schmidt-Koenig, 1960). This function (solar compass direction versus time of day, see **Figure 2**) varies greatly, depending on which hemisphere the observer is in (northern or southern), its latitude (angular distance from the equator), and the season of the year. Thus, it is a highly contingent fact about the animal's environment, the sort of thing that must be learned from experience.

There is an experimental literature on the learning of the solar ephemeris by homing pigeons and

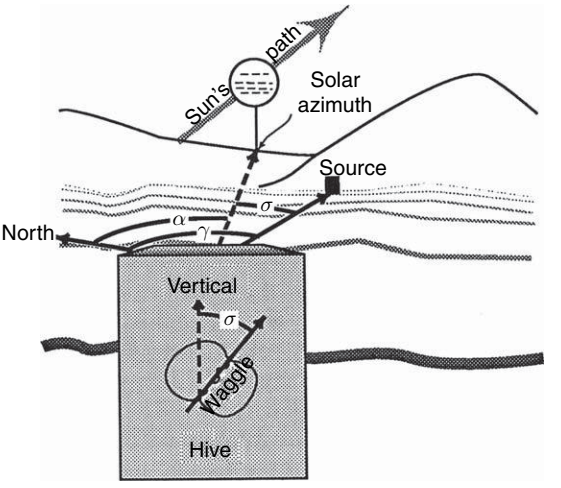

Figure 2 In the waggle dance, the returned forager circles in alternate directions from one waggle run to the next, forming a figure 8. The angle of the repeated waggle runs, relative to vertical, indicates the solar bearing of the source from which the forager has returned. The number of waggles indicates its distance. $\alpha =$ the solar azimuth, its compass direction; $\sigma =$ the solar bearing of the source, its direction relative to the direction of the sun; $\gamma =$ the compass direction of the source. Note that the compass direction of the source is the sum of the solar azimuth and the solar bearing: $\gamma = \alpha + \sigma$. (Reproduced by permission of the author and publisher from Gallistel CR (1998) Symbolic processes in the brain: The case of insect navigation. In: Scarborough D and Sternberg S (eds.) *An Invitation to Cognitive Science,* vol. 4, pp. 1–51. Cambridge, MA: MIT Press.)

foraging bees (e.g., Budzynski et al., 2000; Dyer, 2002; Towne et al., 2005). To learn the solar ephemeris is to learn, for some point of view (e.g., the hive entrance or the nest), what parts of the local horizon profile the sun is over as a function of the time of day (see **Figure 2**). To learn that, the brain must represent the horizon profile, the position of the sun relative to this horizon profile, and the time of day. The time-of-day signal is provided by the animal's circadian clock (Mouritsen and Frost, 2002; Giunchi et al., 2003; Homberg, 2004; Stalleicken et al., 2005). The universally valid parameter of the circadian clock, its period, is genetically specified. The clock parameter that must be adjusted based on local experience is the phase. The entrainment mechanism adjusts the phase of the clock in response to the rapid changes in photon flux that occur at dawn and dusk (Takahashi et al., 1984; Foster et al., 2003; Bertolucci and Foa, 2004; Foster and Bellingham, 2004).

The learning of the relation between the time-of-day signal provided by the circadian clock and the

position of the sun relative to the horizon profile at the chosen point of view appears to be a curve-fitting process (Dyer and Dickinson, 1994, 1996; Dickinson and Dyer, 1996). Built into the learning mechanism is a parameterized dynamic process – the physical realization of an equation (function) specifying the relation between two circular variables: time of day and position on the horizon. This built-in equation specifies what is universally true about the solar ephemeris, namely, that the sun is somewhere to the east all morning and somewhere to the west all afternoon. Incubator-raised bees that have seen the sun only in the late afternoon when it is declining in the west nonetheless represent it as being due east all morning long, stepping abruptly to due west around noon (Dyer and Dickinson, 1994). This default form for the ephemeris function is in fact valid only near the equator.

Notice that the information about where the sun is in the morning cannot have come from these incubator-raised bees' experience, because they never saw it in the morning. It is carried forward in time from the remote evolutionary past by the genes that code for the built-in dynamic process relating the horizon position cycle to the circadian clock's cycle, just as the information specifying the period of the circadian clock is carried forward in time by the genes that specify its molecular structure. In experienced bees, which have observed the sun at the hive at several different times of day, the parameters of the built-in function are adjusted so that the function specifies locally appropriate horizon positions for the sun throughout the day. In the summer at midlatitudes in the northern hemisphere, where the Dyer and Dickinson (1994) experiments were conducted, the sun rises north of east, moves continuously along the horizon in the clockwise direction to reach due south at noon and then on through west to north of west in the late afternoon. (By contrast, in winter at midsouthern latitudes, it rises north of east and moves continuously counterclockwise along the horizon to due north at noon and then on to north of west in the late afternoon.)

What bees learn from their experience of the sun's position over the horizon at different times of day is the locally appropriate values for the parameters of their built-in solar ephemeris function. These parameter settings are not explicitly specified by the bees' experiences of the sun's position above the horizon profile. There is no first-order sensory signal generated by any aspect of the bees' experiences that directly specifies appropriate parameter values in the way in which, for example, the signal from a photoreceptor explicitly specifies the number of photons captured by that receptor. Even the positional data – where the sun is over the profile – are only implicitly present in the spatiotemporal distribution of action potentials from the retina. The sun's profile-position coordinate must be computed from this pattern. And even then, the appropriate values for the parameters of the ephemeris equation are only implicit in data specifying several different profile positions at several different times of day. Thus, the explicit parameter values, the actual settings of the parameters, must be computed from these positional data. Moreover, the positional data are not given all at once. Experience provides different data points at different times of day. When it has extracted from the incoming retinal signals an explicit representation of the sun's profile position, the brain requires a symbolic memory to carry that information forward in time, so that it may be computationally combined with the positional data obtained later in the day to determine the appropriate values of the ephemeris parameters.

The symbolic information provided by the learned ephemeris informs not only the dead reckoning process but other behaviors as well. When a foraging bee returns from a rich source, it does a waggle dance on the vertical surface of the hive, which symbolically specifies the direction and distance of the source (**Figure 2**). The direction is specified by the angle of the waggle run relative to vertical in the solar bearing of the source, the angle at which an outbound forager must hold the sun to fly toward the source. The solar bearing communicated by the dance is not the bearing that the returning forager has just flown; rather, it is the inverse of that bearing. If the returning forager flew with the sun at its back to reach the hive, then its dance tells the other bees to fly toward the sun. This information about the relation between the direction of the source from the hive and the direction of the sun from the hive was acquired many minutes earlier. A symbolic memory is required to carry this direction vector forward in time until it is used to inform the waggle dance (cf. Menzel et al., 2006; *See* Chapter 1.25).

The information communicated by the dance is carried forward in the nervous systems of both the dancer and the observers of the dance in a computationally accessible form. If the hive is closed for several hours and then opened, outward-bound foragers do not fly the solar bearing indicated by the dance they witnessed hours earlier; rather, they fly a

time-compensated solar bearing, a bearing that takes into account the intervening change in the sun's compass direction (Frisch, 1967). This implies that either (1) a recruited bee remembers the danced solar bearing and uses its solar ephemeris to compute the expected change in solar bearing over the interval since the dance, or (2) the remembered solar ephemeris was used at the time of the dance to compute a compass bearing or the indicated location on the cognitive map (map coordinates). The remembered compass bearing (or remembered map coordinates) must then be combined with the solar ephemeris function at the time of the outward-bound flight to compute an appropriate solar bearing (how to fly relative to the sun to fly a remembered direction relative to the earth).

The learning and use of the solar ephemeris illustrates the manner in which different bits of information, gathered from experience at widely different times in the past, are computationally combined to obtain the explicit information (the current solar bearing of the food source) that informs current behavior.

1.12.2.3 The Cognitive Map

A map is a record of two or more locations in a common coordinate framework. It gives access to other (nonpositional) information about those locations (for example, information that enables the navigator to recognize surrounding landmarks and information about the food to be found there or the dangers to be wary of). A cognitive map is a map of experienced terrain computed by a brain and recorded in its (presumed) symbolic memory. Dead reckoning and the construction and use of a cognitive map are intimately interrelated (Gallistel, 1990, 1998; Collett et al., 1999; McNaughton et al., 2006; *See* Chapter 1.25).

The information that dead reckoning provides about the animal's current position becomes more valuable as the number of locations on the cognitive map increases. It also becomes more valuable as the brain records more information that will enable it to recognize those places on subsequent occasions (for example, 'snapshots' of surrounding landmarks, together with their direction and distance from the point of interest; Cartwright and Collett, 1979, 1983, 1987; Collett et al., 1986). The information about current position becomes more valuable as the map becomes richer in information, because a major function of the cognitive map is to enable the brain to compute the range (distance from the animal) and bearing (direction from the animal) of points of behavioral importance like food and the nest (Collett et al., 1999). The directional information extracted by this vector computation is critical to the setting of a course toward or away from those points. The distance information is critical to the making of decisions based on estimates of the time it will take to reach a point.

Often, dead reckoning itself provides the estimate of the animal's position on its map, but sometimes either natural circumstances (gusts of wind) or experimental intervention renders the dead reckoning position useless, in which cases the brain must rely on landmark recognition to reestablish its position on its cognitive map and compute the course back to home or to the destination it had before it was displaced (Fukushi and Wehner, 2004; Menzel et al., 2005, 2006).

Conversely, the better the positional information supplied by the dead reckoning process, the more accurate a cognitive map becomes and the easier it is to recognize relevant landmarks (Cartwright and Collett, 1979, 1983, 1987; Durier et al., 2003; Graham et al., 2004). The map becomes more accurate as dead reckoning improves because it is likely that dead reckoning is the principal determinant of the position vectors recorded on the map. When the animal finds a point of behavioral interest, such as a food source, the position vector that represents that location on the brain's cognitive map is the dead reckoning position vector (the symbol that specifies where it is in the frame of reference used for dead reckoning, for example, 50 m south and 22 m east of the nest) plus the egocentric position vector for the point of interest (the symbol that specifies the location in the egocentric frame of reference, for example, 30° left and 2 m away). Combining these two symbols is an exercise in coordinate transformation. The computation is spelled out in Gallistel (1990: 106ff; see also Gallistel, 1999). Thus, errors in the dead reckoning become errors in recorded locations. This is a major reason for the inaccuracies in early marine charts; in those charts, too, estimates of longitude were largely based on dead reckoning.

It becomes easier to recognize landmarks as dead reckoning becomes more accurate because estimates of one's location play a major role in the process. To recognize a landmark is to identify what is now perceived with something recorded on the chart. In both human and animal navigation, position confers identity (Gallistel, 1990: 140, 168ff). That is, for a

navigator to recognize a landmark, the navigator's estimate of its location must be within his uncertainty about where he is in relation to it on his cognitive map (Cartwright and Collett, 1983; Collett et al., 2002; Dale et al., 2005). A sailor on Long Island Sound seeing to her east something that looks exactly like Mount Vesuvius will not conclude that she is in Italy. She will ponder either why she never knew there was any part of Long Island that looked anything like Mount Vesuvius or, more likely, how remarkable it is that a cloud formation could look exactly like Mount Vesuvius. Thus, contrary to the common assumption, a major factor in the recognition of a landmark is that it be roughly where it is supposed to be. Being where it is supposed to be is an essential aspect of its identity. If it is not where it is supposed to be, it is not that landmark.

In short, dead reckoning provides major input to the computations that determine the recorded locations (position vectors) of points on the cognitive map. The recognition of landmarks along familiar routes (these are called waypoints in traditional navigation) is a substantial aid to dead reckoning (Kohler and Wehner, 2005). However, the animal's estimate of its position and orientation on the cognitive map is a major determinant of whether it looks for a given landmark and whether it accepts a possible landmark as the one it is looking for. Finding a looked-for landmark helps to correct error in the dead reckoning (Etienne et al., 2004) and get the animal back onto a familiar route (Kohler and Wehner, 2005).

All of this – all of our understanding of animal navigation – presupposes a symbolic memory, a memory capable of encoding information about the world and the animal's relation to it and carrying that information forward in time in a computationally accessible form. The physical realization of the geocentric position vector in the dead reckoning machinery must be such that it can be computationally combined with the physical realization of the egocentric position vector in the machinery that assigns egocentric positions to perceived landmarks (see Gallistel, 1999, for a review of the neurobiology of coordinate transformations). The resulting vector symbol (the physical realization of the geocentric coordinates of a perceived landmark) must preserve the information about the location of the landmark on the cognitive map. It must do so in a form that makes it possible to add and subtract that position vector from other position vectors, because that is what is required in computing the range and bearing of one location from another location (cf. Collett et al., 1999).

In order to recognize a landmark, the brain must previously have made a record of what that landmark looks like (a 'snapshot,' cf. Collett and Collett, 2002; Graham et al., 2004). The record must contain enough information to distinguish between that landmark and other landmarks the animal has encountered in that vicinity. The number of distinguishable snapshots that the brain of an ant or bee might make is for all practical purposes infinite – larger than the number of elementary particles in the universe. Thus, there cannot be for every possible snapshot a genetically specified neural circuit excited by that snapshot and only that snapshot. There cannot be a "gnostic neuron" (Konorski, 1967) for every possible visual scene the ant or bee may need to record. This is derisively known as the grandmother-neuron theory of perceptual encoding.

When applied to, for example, a digital camera, the grandmother-neuron theory is that the factory builds into each camera all possible pictures that might ever be taken. When you press the shutter release, the camera detects the correspondence between the image on the camera's retina and one of the images built into it at that factory, so the 'neuron' for that picture is activated. In this way, the camera (or the brain) 'recognizes' the picture that you are taking.

Clearly this will not do; the possible snapshots cannot be genetically specified and prewired into the nervous system of the ant or the bee. There must be some decompositional encoding scheme that permits finite representational resources to encode the finite number of actual snapshots taken in any one lifetime. No matter how enthusiastic a photographer you are, the pictures you actually take are a negligible fraction of all the possible pictures! A digital camera decomposes images into pixels. It uses symbolic memory to record the image values for each pixel. Thus, it encodes in memory only the pictures actually encountered, not all the pictures that might ever be encountered.

There are much more efficient encodings, as we learn when we compress image files. The use of basis functions, as in Fourier decomposition, is an example of a less obvious and potentially much more efficient encoding. Efficient encodings reduce complex inputs to vectors (in the loose sense of ordered strings of numbers) that specify parameter values for the functions that form a basis of the encoded space. Another

example of the use of finite resources to encode an infinite range of possibilities is the encoding of to-be-printed pages of drawings and text using Postscript. The number of distinguishable pages that may be printed is infinite. However, the file for any actual page is surprisingly short, which is a tribute to the efficiency of the encoding scheme.

This approach to understanding how the decidedly finite nervous system of an ant might preserve the information in a snapshot presupposes that there is a symbolic memory mechanism capable of preserving the decomposition of a snapshot (a visual scene) for later computational use. The decomposition made when the landmark was first encountered must be available when the animal encounters that landmark again, and it must be available in a form that allows it to be compared to the decomposition of the currently viewed landmark. The computational architecture should allow for the generation of a measure of similarity between the two encodings being compared (the encoding of the old image in memory and the encoding of the image now on the retina). Moreover, the making of a snapshot, as the term implies, cannot require repeated presentation of the image to be recorded; it must be a one-off process, like the process in a digital camera, which makes fundamental use of a symbolic memory mechanism (but *See* Chapter 1.33).

Recognition is, of course, what attractor networks do (*See* Chapters 1.33, 1.34, 1.35) and they do not have a symbolic memory. (The lack of a symbolic memory is what distinguishes a neural net from a conventional computing machine.) However, because it lacks a symbolic memory, a neural net cannot compute measures of similarity or relative probability. Thus, a neural net recognizer cannot provide information about two different possible matches at the same time. Activity in the net must migrate to one attractor state or another. The net cannot be in two different activity states at the same time. When it is not in one attractor state or another, its activity state does not specify anything about the input. Activity states intermediate between two attractor states do not specify, for example, the relative probabilities of two different possible matches (two different attractor states that the net might be in but is not).

The net's inability to specify a probability distribution over possible states of the world (possible matches between the current image and previous images) makes it difficult to combine the evidence from different computational procedures. For example, it makes it difficult to combine the evidence from image comparison (the probability distribution on the possible matching images, considering only the information in the images themselves) with the evidence from dead reckoning (the prior probability distribution over the possible matching images in memory, given the probability distribution on the animal's position and orientation on its cognitive map).

This last point is important because it relates to recent findings demonstrating that (1) the cognitive map gives access to other information about the world, and (2) even insects engage in what looks like Bayesian inference, combining probabilistic information acquired at different times from different sources. In these experiments (Gould and Gould, 1988; Tautz et al., 2004), foraging bees return from a food source on a rowboat in the middle of a pond or small lake. The returning foragers do the waggle dance, indicating the range and bearing of the food source, but the dance fails to recruit other foragers. This implies that (1) what the dance really communicates is not flying instructions (range and solar bearing) but rather map coordinates, and (2) the bees that observe the dance consult their cognitive maps before deciding whether to act on it (*See* Chapter 1.25). If their own past experience, as recorded on their map of where they have found food, indicates that no food is to be found anywhere near the location indicated by the dance, they decide not to go. Most interestingly, when the boat with the food source is moved close to an island, then the dance of the returning foragers does recruit new foragers. However, the recruits do not come to the boat but rather to the shore near the boat (Tautz et al., 2004). This implies that they have combined the probability distribution for the source location indicated by the dance (the approximate location of the source implied by the dance) with the prior probability distribution (based on their experience, as recorded on their map) to arrive at a posterior distribution, whose modal point is the nearby shore (the most probable location, all considered).

These findings suggest how grossly we may have underestimated the representational and computational capacities of even very small brains. Our gross underestimation of the representational capacity of brains as small as the head of a pin has allowed us to suppose that brains can get along without the symbolic memory mechanism that makes representation possible.

1.12.2.4 The Representation of Past Episodes

Our memory for episodes is another example of one-off memory for specific occurrences, where the number of possible episodes is infinite. Episodes by definition happen only once. We often recall them, however, long after they were encoded and committed to memory (albeit not as accurately as we like to think). More importantly, we combine the information from one episode with the information from another to draw conclusions not justified by any single episode: The fourth time you see a man dining with an attractive woman not his wife, you begin to think he might be a philanderer. When this conclusion becomes a fixed belief, it is an example of a declarative memory ("The man's a philanderer") inferred from a sequence of episodic memories. This does not, of course, imply that the episodic memories are forgotten. Indeed, we may call on them to justify our inference to others. Recent ingeniously constructed experiments with food-caching jays show that we are not alone in our ability to remember episodes, nor to draw behaviorally informing inferences and declarative memories from them.

In times of plenty, many birds gather food and store it in caches (*See* Chapters 1.22, 1.23). Western scrub-jays are particularly remarkable cachers. They make more than 30 000 different caches spread over square miles of the landscape (Vander Wall, 1990). Weeks and months later, during the winter when food is scarce, they retrieve food from these caches, one by one. This is another illustration of the vast demands on memory made by a cognitive map. It also emphasizes the critical importance of a computational architecture that can effect the same computation (vector subtraction) on many different symbol combinations (pairs of vectors) without having a different neural circuit for each possible symbol combination. If we suppose that the jay can set a course toward the remembered location of any one cache while at the location of any other, then, given 30 000 locations, there are on the order of 10^{10} possible course computations (vector subtractions with distinct pairs of vectors formed from the 30 000 vectors in memory). Whatever the computational architecture of the nervous system, it cannot be such as to require 10^{10} different genetically specified neural circuits to effect these 10^{10} different computations.

A long series of ingenious experiments by Clayton and Dickinson and their collaborators have shown that jays remember much more than simply the locations of their caches (Clayton and Dickinson, 1998, 1999; Emery and Clayton, 2001; Clayton et al., 2003a,b; Emery et al., 2004; Dally et al., 2005a,b; de Kort et al., 2005; Clayton et al., 2006b). They remember what kind of prey they hid in each cache, when they made each cache, which other jay, if any, was watching when they made that cache, and whether they have subsequently emptied that cache. They also remember whether they themselves have pilfered the caches of another bird. They remember the intervals that have elapsed in the past between the hiding and retrieval of a given kind of food and whether the food, when retrieved, had or had not rotted. All of this remembered information combines to determine the order in which they will visit caches they have made. The information drawn from memory that is combined to inform current behavior comes from a mixture of episodic memories ("Three days ago, I hid meal worms there, there and there, and 5 days ago, I hid peanuts there, there and there") and declarative memories ("Meal worms rot in 2 days; peanuts don't rot").

These experiments demonstrate a rich representation of the jay's past experience and the ability to compute with the symbols that carry the information gained from that experience forward in time. For example, the birds compute from the current date-time and the remembered date-time at which they made a particular cache the time elapsed since they made that cache. They compare the time elapsed since that cache was made with the remembered time that it takes the contents of that cache to rot. If the computed time elapsed is greater than the remembered rotting time, they visit first the caches where they put the peanuts, even though they prefer (unrotted) meal worms to peanuts, and even though they made the meal worm caches more recently.

When their caching is observed by another jay, they combine the memory of which particular jay it was with a memory of their own much earlier thieving (from which they appear to infer the existence of evil) and their memory for the social status of that jay. If it was a dominant jay and if their experience of their own behavior (their own pilfering) has made them believe in the evil nature of jays, then they are likely to return to the cache when no one is looking, retrieve the food, and hide it elsewhere.

The rich representation of past episodes implied by these results again implies a decompositional scheme of some kind, because the number of possible caching episodes is infinite. Indeed, it suggests the

kind of representation of our experience that appears in our linguistic descriptions of episodes (agents, actions, objects of actions, locations, markers of temporal position relative to the present and to other events, and so on). Perhaps we should not be surprised to find evidence for such representations in nonverbal animals. Our ability to use language to communicate to others the information we have extracted from our own experience of the world is itself astonishing. It would be far more astonishing if we assumed that our nonverbal ancestors had no high-level decompositional representation of the world prior to the emergence of language.

1.12.3 Implications for Neurobiology

As mentioned at the outset, the hypothesis that learning depends on the brain's computing representations of selected aspects of the experienced world is controversial because we do not know what the neurobiological realization of key components of the requisite machinery is. Indeed, we do not even have a clear notion of what this realization might be, let alone persuasive evidence that a hypothesized realization is in fact the realization. The keystone in any symbolic computation is a symbolic read-write memory mechanism. That is a mechanism to which information conveyed in signals can be written and that will carry this information forward into the more or less indefinite future, until such time as it is needed in further computation. From a neurobiological perspective (that is, from a material reduction perspective), symbols are the enduring physical changes in the nervous system that carry the information forward in time.

The behavioral evidence implies that a vast amount of acquired information is carried forward by this mechanism, even in the brains of birds and insects. This constrains physically plausible mechanisms (Gallistel, 2002). Whatever the mechanism is, it must realize a very high density of information storage; it must pack gigabytes into cubic microns. It must be thermodynamically stable, so that the preservation of the information has little or no metabolic cost. One cannot pack a great deal of information into a very small volume using a mechanism that depends on the expenditure of metabolic energy to preserve the information, because (1) there is no way to supply the requisite amount of energy within the small volume, and (2) if there were, there would be no way to dissipate the heat generated.

In short, we must remember that the laws of thermodynamics apply to whatever symbolic memory mechanism we may imagine. These thermodynamic considerations make reverberating circuits an implausible physical realization of a mechanism whose essential function is to store large amounts of information for long periods of time. This is important because reverberating activity is the mechanism for storing previously computed information in recurrent neural net models, for example, in moving-activity-bump models for dead reckoning (Samsonovich and McNaughton, 1997; Stringer et al., 2002; Conklin and Eliasmith, 2005; Song and Wang, 2005).

Another constraint on the physical realization of the symbolic memory is that it must both be capable of encoding information and be in a readable form. That is, it must be possible to envision how the enduring physical change hypothesized to be the physical realization of a symbol could in principle specify a fact about the world and how that fact could be recovered (read) from it. It is this consideration that makes Hebbian synapses implausible as the physical realization of symbolic memory. Hebbian synapses are synapses that enduringly change their conductance as the result of the pairing of pre- and postsynaptic activity. The conductance of a synapse is the amplitude and duration of the transient change in the postsynaptic membrane potential when a spike arrives at the presynaptic terminal.

The first thing to be noted in this connection is that there are few if any published suggestions that it is the synaptic conductances themselves that encode information about the world (as opposed to the gnostic neurons that are connected through those conductances). As already noted, changes in synaptic conductances are the hypothesized physical realization of changes in the strengths of associative bonds. Associative theories of learning have traditionally not been representational theories, for the simple reason that it is hard to make a symbol out of an association.

Traditionally, associative strengths have been assumed to change slowly and in a manner dependent on many different aspects of a repeated experience: how close two stimuli are in time, how strong each of them is, how often they have occurred in close temporal conjunction, and so on. Thus, the strength of an association, that is, the conductance of a modifiable synapse, is the product of many different aspects of experience. This means that it cannot encode any one of those aspects. Mathematically speaking, the mapping from experience to an

associative strength is a many-one function, and many-one functions are not invertible; you cannot recover the many from the one.

Even if the process of modifying a synaptic conductance were somehow constrained in such a manner that the conductance of a memory synapse could be made, for example, proportional to a to-be-remembered distance, the architecture of the nervous system, as currently understood, would not permit the conductance of that synapse to be read. The postsynaptic signal is a product (or joint function) of the presynaptic signal and the synaptic conductance The synaptic conductance is usually called the synaptic weight, because it is a multiplicative constant that weights or scales the presynaptic signal to determine what is seen by the postsynaptic integration process. Unless the postsynaptic mechanism has independent access to the presynaptic signal (unless it has information about that signal by a pathway other than the presynaptic pathway), it cannot estimate from the postsynaptic signal what the conductance of the synapse is. Thus, even if experience had made the strength of a synaptic conductance proportional to the distance to the food, it is hard to see how that information could be recovered by the postsynaptic integration process.

The mathematical impossibility of recovering the conductance of a synapse from the postsynaptic effect of an unknown presynaptic signal does not go away when one considers instead the problem of recovering the synaptic conductances (weights) in a neural network from the activity in its output neurons. If the postsynaptic effects are linear in the presynaptic signal strengths, then the activities of the output neurons may be regarded as the known values in a linear algebra problem, in which the input signal strengths and the intervening synaptic conductances are the unknown values. Unless there are as many knowns (output signals) as there are unknowns (input signals and synaptic conductances), it is a basic algebraic truth that the values of the unknowns cannot be recovered.

If the network is a richly connected one, with more synapses than inputs and outputs combined, then the conductances of the synapses cannot be recovered, even when both the output and the input signals are known. If postsynaptic effects are nonlinear in the inputs, the problem is still worse, because there is loss of information in nonlinear operations. Intuitively, this is because when there are thresholds, one cannot estimate from the signal on the other side of the threshold what is going on below the threshold. Thus, recognizing that the synapses whose alteration is supposed to carry information forward in time are embedded in complex networks does not on the face of it make the problem of readability less of a problem; it makes it more of a problem.

This is not to say that some particular network architecture may not solve the problem. A particular architecture dictated by the logic of the problem is just what we see in the read-write memory of a computer. One might imagine, for example, that modifiable synapses only had two states, conducting and nonconducting, and that information about facts like distance and direction was encoded in banks of such synapses, using the same binary code by which distance and direction information is encoded in the memory registers of conventional computers. However, this, too, would require revising our conception of the functional architecture of the nervous system to enable write and read operations. As indicated by the quotation from Koch (Koch and Hepp, 2006), the current understanding of the nervous system has led to the conclusion that this is precisely what its architecture does not support. Moreover, as the Koch quotation indicates, this is taken to be an advantage of the architecture, not a deficiency. Thus, within our current understanding of the functional architecture of the nervous system, there does not appear to be a way to make modifiable synaptic conductances be the mechanism of symbolic memory. This accounts in some measure for the strong strain of antirepresentational theorizing in neurobiologically inspired models of learning.

The presence of a read-write memory mechanism has far-reaching architectural implications. There is no point in writing information to memory if you cannot find it later. Thus, the existence of a read-write mechanism implies or presupposes that the architecture of the system supports memory addressing. It makes no functional sense to have a read-write memory in a machine whose architecture does not support memory addressing.

It is memory addressing that makes possible (1) the distinction between a variable and the value of that variable, (2) the ability to bind a value to a variable, and therefore, (3) the creation of symbolic structures (data structures). Memory addressing makes all this possible because the address in memory at which a given piece of information (a symbol) is to be found is itself information that may be written to memory at another address. This leads to indirect addressing in which the value to be operated on is specified not by its address but, rather, by the address where its address is stored. The bit pattern specifying

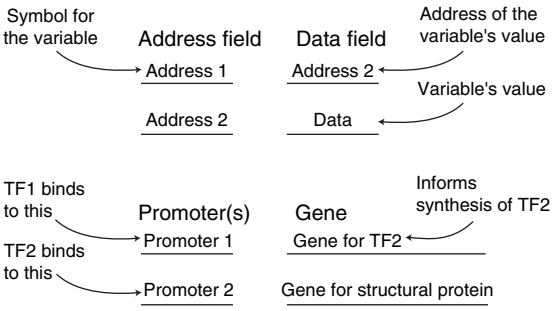

Figure 3 Indirect addressing in computers and the genome. TF = transcription factor. In both examples, the entry in the bottom right field ('Data' or 'Gene for structural protein') may be yet another address (another gene for a TF). This recursive addressing logic makes possible hierarchical data structures with a (potentially) unlimited number of levels.

the first address (Address 1 in **Figure 3**) is the symbol for the variable itself (e.g., the distance to the food source), not for the value that the variable happens to have at any one time (e.g., 10 m). The symbol for the variable gives access to the value of the variable by means of the bit pattern stored in the data field at the address specified by the symbol for the variable. The datum stored in that field is the address of the value (Address 2 in **Figure 3**). The bit pattern (symbol) that specifies the value is in the data field at the second address. To change the value of the variable, the computer changes the bit pattern stored at the second address, not the bit pattern for the first address (the symbol for the variable) nor the bit pattern stored at the first address (the address of the variable's value).

This sounds far removed from biological reality, but, as shown in **Figure 3**, the information stored in DNA is retrieved by the same functional architecture, implemented now at the molecular level, which is to say more compactly than in current computer memory. The address at which a datum (the codon sequence specifying a protein) is stored is the promoter for that gene. Transcription factors initiate the reading of that information (transcription) by binding to the promoter. When a transcription factor binds to the promoter for a gene, the amino acid sequence coded for by that gene is used by the molecular machinery that synthesizes proteins to control the synthesis of the protein defined by that sequence. The protein thereby synthesized may be either a structural protein (a building block of cellular structure, analogous to the actual value of variable) or a transcription factor (an address). Addressing the promoter of a transcription factor (synthesizing a protein that binds to its address) gives access to the addresses (promoters) of the genes to which that transcription factor binds. As that transcription factor is synthesized, it binds to those promoters, leading to the synthesis of the proteins coded by their genes, many of which proteins may themselves be yet further transcription factors. This indirect addressing makes possible the hierarchical structure of the genome. It makes it possible to have an 'eye' gene that, when activated (addressed by the transcription factor for its promoter), leads to the development of an entire eye (Halder et al., 1995). The eye gene codes only for one protein, but that protein does not itself appear anywhere in the structure of the eye. It is a transcription factor. It gives access to the addresses of other transcription factors and, eventually, through them, to the addresses of the proteins from which the special tissues of the eye are built and to the transcription factors whose concentration gradients govern how those tissues are arranged to make an organ.

What is needed for a brain to have learned representations is a similar architecture for accessing the information acquired from experience, an architecture in which it is possible to write information into biochemically realized symbols as well as read it from them.

The other critical components of a machine capable of representation that is missing from our current conception of the nervous system are the machines that operate on symbols. Needed are mechanisms that perform unary operations, such as negation, and binary operations, such as the arithmetic operations, string-building operations (e.g., concatenation), and logical operations (e.g., AND and OR). The existence of mechanisms operating on symbols would be implied by the existence of a symbolic memory mechanism, because it does not make functional sense to have a read-write memory if there are no mechanisms for operating on the symbols in it. (It's like having chromosomes without ribosomes, which are the machines that put the amino acids together to form a protein.) What makes a representation are the symbols, together with the operations on them. The operations enable the extraction of explicit representations from information that is only implicitly present in the symbols already computed. A representation, that is, a functioning homomorphism, exists only when a machine can operate on its symbols to construct new symbols, symbol strings, and data structures.

A constraint on the mechanisms that operate on symbols is that there not be as many different

mechanisms as there are distinct variables. As noted earlier in connection with the 30 000 cache locations that a jay can remember, it is not plausible to imagine an architecture in which there is a separate neural circuit dedicated *a priori* to each different vector subtraction that might ever have to be performed. The reason is once again the infinitude of the possible; there are too many possibilities.

This last constraint may seem almost too obvious to mention. However, in many neural net models of even simple computations, such as those involved in dead reckoning, the combinatorial operations are implemented by a table-look-up architecture (e.g., Samsonovich and McNaughton, 1997). There is a separate look-up table for each instance of a given kind of operation – a different table for each different case in which two variables must be added. A given table can effect the multiplication of all possible values of two variables, but it can operate only on those two variables. Moreover, each such table is composed of tens of thousands of neurons because each different combination of values for the two variables is effected by the neurons that compose the corresponding cell in the table. In short, there are as many different look-up tables as there are pairs of variables whose values may have to be combined, and within each such table, there are as many different neural subcircuits as there are pairs of values for the two variables. Such an architecture is prodigally wasteful of material resources. It is nakedly exposed to combinatorial explosions that lurk behind every tree in the computational forest. That appears to be the price that must be paid for doing without a symbolic memory.

These considerations suggest that the nervous system may in fact contain a yet-to-be discovered read-write memory mechanism. They suggest, moreover, that the mechanism is likely to be found at the level of molecular structure, rather than at the level of cellular structure. Finally, they suggest that the discovery of such a mechanism and the functional architecture that is required to make it effective would change our conception of how the brain works in fundamental ways.

1.13 Attention and Memory in Mammals and Primates

P. Dalton, Royal Holloway University of London, Egham, Surrey, UK

C. Spence, University of Oxford, Oxford, UK

1.13.1 Introduction

Our brains continuously receive huge amounts of sensory information concerning the busy and complicated world in which we live. In fact, Koch and Tsuchiya (2007) recently estimated that primates receive on the order of 1 megabyte of raw information per second through their eyes alone. In order to make sense of all of this sensory input, and to act upon it appropriately, it is essential that we are able to focus our attention selectively on certain stimuli at the expense of others (*See also* Chapters 1.07, 1.08). For example, as you read this sentence, you will probably be ignoring the feeling of the clothes on your body (see Graziano et al., 2002) and any number of background sounds from the world outside. In this chapter, we consider the extent to which our brains can achieve such selectivity of information processing in the visual, auditory, and tactile modalities and the means by which they might do so.

Empirical evidence from many different experimental methodologies now supports the claim that unattended sensory information is processed less thoroughly by the brain than is attended information. The results of many behavioral studies have demonstrated that unattended sensory information is perceived and/or remembered less successfully than attended information. From a neurophysiological viewpoint, attentional modulation of neural activity has now been observed both in humans and in other animals. Here, we review the evidence from both of these lines of research, integrating the findings that have emerged from studies examining the cognitive constraints on information processing in audition, vision, and touch – the sensory modalities where attention has, to date, been most widely studied. We also draw out a number of the parallels in the mechanisms of selective attention as they affect the processing of information in the different senses.

Our focus for this chapter relates to what has perhaps been one of the most enduring questions in the study of selective attention, namely, the stage of processing at which unattended information is excluded. It is generally agreed that all information must be processed to some level, so that it can, at the very least, be designated as being either potentially relevant or irrelevant. However, estimates of the extent to which unattended information is processed in the brain have varied widely. The lively debate over this issue has continued apace for more than 50 years and is still a topic of interest for many attention researchers today. Below, we describe the origins of the debate and highlight some of the most important experimental evidence that has emerged over the years from studies of this issue in audition, vision, and touch.

1.13.2 Behavioral Evidence for Early Selection

Many of the earliest studies of attention focused on the selection taking place within the auditory modality. This research began in the early 1950s with the

development of the dichotic listening paradigm (Cherry, 1953, 1954). The participants in these early studies were typically presented with two different auditory messages, one to either ear. They had to repeat out loud (i.e., 'shadow') the message presented to a specified ear while trying to ignore the message presented simultaneously to the other (unattended) ear. The typical finding reported in many different studies was that following the shadowing task, participants were unable to remember anything of the unattended message apart from its most basic physical characteristics. For example, participants failed to notice (or at least to recall) changes to the language being spoken but were often able to recall changes in the pitch of the speaker's voice (e.g., Cherry, 1953). Indeed, Moray (1959) reported that participants often failed to recognize words that had been repeated as many as 35 times in the unattended channel. In the light of such evidence, researchers argued that attentional selection must occur at a relatively early stage of information processing, such that unattended stimuli were rejected as soon as their simple physical characteristics (such as their location, frequency, etc.) had been determined, and were not subject to any significant further processing (Broadbent, 1958). We note, however, that the definition of a "simple, physical characteristic" may not be as straightforward as it might at first seem (Allport, 1992). For example, properties that are coded early in processing in one sensory modality (such as location in vision) may only be derived much later in other sensory modalities (e.g., location is derived comparatively late in auditory processing; see Spence and Driver, 1994).

It is important to emphasize that these demonstrations of early selection assessed the extent of processing of the unattended information in terms of participants' subsequent memory for the content of the unattended stream. This approach was soon criticized on the grounds that, by the time the participants were asked about the contents of the unattended stream, they may simply have forgotten the information, rather than never having perceived it in the first place (see Wolfe, 1999, for a discussion of this critical distinction between inattentional amnesia and genuine inattentional blindness).

Nevertheless, the proposal that unattended stimuli were ruled out at a relatively early stage of information processing was also supported by subsequent studies examining the effectiveness of selective attention within the visual modality. At first, these visual studies drew inspiration from the auditory studies described above and were therefore typically designed to create a more or less direct visual analogue of the dichotic listening task. For example, in one of the earliest studies of visual selective attention, reported by Neisser and Becklen (1975), participants were presented with two superimposed video streams, one showing two people playing a hand-slapping game and the other showing three people passing a basketball between one another. The participants in this study had to attend to one of the two video streams in order to carry out a task on this attended information (such as counting the number of ball passes or hand slaps) while ignoring the other stream (in which unexpected events, such as the appearance of a new person carrying an umbrella, occasionally occurred). Just as had been found in previous auditory studies, the participants in Neisser and Becklen's study were unable to recall any of the unusual events in the unattended visual stream, despite the fact that this stream had been presented from the same location as the attended stream.

However, one might argue that the failure to remember the unattended information in Neisser and Becklen's (1975) seminal study could reflect the fact that participants would have been focusing their overt attention on the attended stream and hence may have been making eye movements to keep track of the action occurring in that stream. Any such eye movements may simply have reduced the visibility of the unattended stream (due to retinal smearing). Note that this criticism also applies to a number of the more recent demonstrations of inattentional blindness, in which participants have typically been asked to carry out a task based on the events contained within a single video (in contrast to earlier studies involving superimposed videos). The striking finding to have emerged from this type of research is that participants can remain seemingly unaware of apparently salient visual events (e.g., the appearance of a person in a gorilla outfit) occurring in the same video as the visual task (e.g., counting the number of ball passes occurring in a basketball game) (Simons and Chabris, 1999). However, because the unexpected visual event never completely coincides spatially with the attended events, these findings are also open to alternative explanations in terms of participants' eye movements.

We note that early studies of selective attention may have used auditory stimuli (at least in part) in an attempt to rule out potential alternative explanations of any attentional effects obtained in terms of overt

orienting involving eye movements. However, subsequent research has now demonstrated that eye movements can in fact influence auditory attentional allocation during dichotic listening tasks (Gopher, 1973; Hynd et al., 1986), so this assumption may not, after all, have been valid.

Nevertheless, results in favor of early selection have also been found in studies that have controlled for the potential influence of eye movements. For example, Rock and Gutman (1981) presented the participants in their study with pairs of superimposed outline drawings (either familiar or nonsense shapes) in different colors. The participants had to focus their attention on the line drawings that were presented in a particular color (with the dummy task of rating each drawing's pleasantness) while attempting to ignore the drawings presented in the other color. In a subsequent surprise memory test, the participants were often unable to recognize any of the unattended shapes, even if the test occurred no more than a second after the presentation of the shape in question (see Rock and Gutman's Experiment 4). By contrast, participants' performance on a similar memory test for the attended shapes was fairly good. The use of static presentation in this experimental design helped to reduce the likelihood that eye movements played any role in determining the pattern of results obtained (an assertion that was confirmed by the monitoring of the eye position of a subset of the participants in Rock and Gutman's Experiment 1).

However, all of the above findings of early visual selection (along with any research that attempted to assess the processing of unattended information in terms of the participants' memories for that information) are open to the criticism, already mentioned in relation to the research on auditory selective attention, that the unattended information may have been perceived but then rapidly forgotten, rather than not having been perceived at all (Wolfe, 1999). Nevertheless, the recent development of brain imaging techniques has allowed researchers to assess the neural processing of unattended information more directly, thereby removing the need to rely on participants' memory for the information. The neuroimaging approach has also provided evidence in favor of early selection. For example, Rees et al. (1999) presented the participants in their study with a series of pictures, each one superimposed with a string of letters (which formed a familiar word on certain trials but consisted of a meaningless string of letters on others). Note that the use of superimposed visual stimuli in this experimental design is similar to that of Rock and Gutman (1981) described earlier. The participants in Rees et al.'s study had to detect immediate stimulus repetitions, either in the picture stream or in the letter stream. When the participants attended to the stream of letter stimuli, the neural activity elicited by the words differed from that elicited by the nonwords (i.e., the random letter strings). However, when the participants were attending to the pictures, the neural activity elicited by the words and nonwords did not differ significantly. This result suggests that the unattended words were not even being processed to the level at which they would have been differentiated from nonwords, despite the fact that the participants were looking directly at them (because they were presented at fixation). Thus it seems that unattended visual stimuli can be eliminated from processing at a relatively early stage, at least under the particular experimental conditions used by Rees et al.

It should, however, be noted that a more recent event-related potential (ERP) study by Ruz et al. (2005), based closely on the experimental design reported by Rees et al. (1999) in their functional magnetic resonance imaging (fMRI) study, found a somewhat different pattern of results. Specifically, they observed that the patterns of ERP components elicited by words and nonwords differed significantly, even when the letter stimuli were not attended. This result would appear to suggest that unattended stimuli can be processed to a semantic (and therefore relatively 'late') level after all. Given that the experimental designs used in the two studies were so similar, this difference in the pattern of results seems likely to be due to the differences in the relative sensitivity of fMRI and ERP techniques. Note, however, that Ruz et al. found that the nature of the word processing (as indicated by the differences in patterns of ERP components elicited by words and by nonwords) was different in the unattended and attended conditions. Thus, even though Ruz et al.'s results suggest that semantic processing of unattended stimuli can occur to some extent, they nevertheless suggest that unattended stimuli are processed differently (and presumably less thoroughly) than attended stimuli. The suggestion that unattended stimuli might in fact be processed to a semantic level of information processing is supported by a large amount of behavioral evidence, as described in the following section.

1.13.3 Behavioral Evidence for Late Selection

Despite the above evidence in favor of early selection, behavioral research has also provided much evidence to suggest that supposedly 'unattended' stimuli can in fact be processed to a degree beyond that of the simple registration of their physical characteristics. As with the evidence for early selection, these observations began with research on the dichotic listening paradigm. For example, Moray (1959) reported that many of the participants in his now classic study remembered hearing their own name when it was presented unexpectedly in the unattended channel (along with some instructions that followed the name in that channel). By contrast, the participants could not remember those same unattended instructions if they were not preceded by the participant's name (indeed, Moray demonstrated that participants could not even remember words that had actually been presented 35 times in the unattended stream).

In addition, other researchers found that participants could often be influenced implicitly by the information being presented in the unattended stream, even if they could not later recall it explicitly. For example, Mackay (1973) presented ambiguous sentences to the participant's attended ear (e.g., "they threw stones toward the bank yesterday"), along with disambiguating information to the unattended ear (e.g., 'river' or 'money'). A subsequent memory test (based this time on recognition of the attended information) suggested that the participants had resolved the meaning of the ambiguous sentences in line with the information presented to the unattended ear, despite being unable to recall the content of this stream explicitly.

Corteen and Dunn (1974; see also Corteen and Wood, 1972) also reported an elegant study in which they showed that people could process unattended stimuli to the level at which semantic information became available, without any explicit awareness of having done so. In particular, they conditioned their participants to expect a small electric shock upon hearing a city name. Then, during dichotic listening, they presented city names to the participant's unattended ear, with the additional instruction that participants should press a button every time they heard a city name. Less than 1% of the city names were explicitly detected by the participants. However more than 30% of the city names elicited a galvanic skin response (GSR), consistent with the sound of the city name triggering a small psychophysiological fear response, presumably linked with the expectation of the electric shock. This finding suggests that the information in the unattended ear had been processed to a semantic level. Importantly, GSRs were even found for city names that had not been presented during the training phase of the experiment, thus demonstrating that the unattended names had been processed to a level at which semantic generalization had become possible. Based on findings such as these, late selection theorists (e.g., Deutsch and Deutsch, 1963) proposed that information was processed to a semantic level before being filtered out of the processing stream.

This proposal soon received support from studies of visual selective attention, as significant behavioral evidence emerged to suggest that, in many cases, unattended visual stimuli could be processed to a deeper level than had at first been thought. For example, many studies have now shown that participants' responses can be primed by the semantic content of apparently ignored visual stimuli. For instance, Tipper (1985) presented participants with superimposed line drawings and asked them to attend to the drawing in one color and to ignore the drawing presented in the other color. The participants had to try and name the object represented by each of the attended pictures. Tipper reported that participants' responses to a particular attended stimulus were affected by the identity of the stimulus presented on the immediately preceding trial, whether or not that previous stimulus had been attended. For example, the participants were able to name a picture of a dog more rapidly if they had named a dog (or a semantically related item, such as a cat) on the preceding trial than if they had previously named a neutral stimulus (such as a chair). This effect is often referred to as positive priming. In contrast, if participants had previously ignored a picture of a dog (or a semantically related item), they were found to be slower to name the picture of the dog on a subsequent trial (as compared with having previously ignored a neutral stimulus) – a result that is now commonly referred to as negative priming. Thus, even though participants were unable to recall the unattended stimuli explicitly (as shown on occasional catch trials in which they were asked to report the unattended stimulus but frequently failed to do so), their performance was nevertheless influenced by these stimuli at a semantic level. This result suggests that unattended visual stimuli can often be processed to a

relatively advanced stage. In fact, Tipper (1985) suggested that the relatively poor subsequent recall of the unattended items in his study reflected the fact that the representation of these stimuli had been inhibited, following the relatively extensive processing necessary for producing priming effects (see also Tipper and Cranton, 1985; Tipper and Driver, 1988). Tipper went on to suggest that this inhibitory process might have been responsible for people's failures to remember the unattended information when subsequently tested (e.g., as found in the early dichotic listening studies). This view would appear to support an account of the early selection findings in terms of inattentional amnesia (aided by the inhibition of the representation of unattended stimuli), rather than inattentional blindness.

Another very popular task developed by cognitive psychologists in the attempt to determine the extent to which irrelevant distractors are processed has become known as the flanker task (Eriksen and Eriksen, 1974). Participants in a typical study are asked to respond to a central target letter, which is flanked by one or more distractor letters (which participants have to try and ignore). The distractor letters can be associated with responses that are congruent, incongruent, or neutral with respect to the target response. If the unattended distractors received no processing whatsoever, one would expect there to be no difference in target responses (in terms of participants' speeded response latencies or accuracy) as a function of the type of distractor that has been presented. If, however, the distractors are processed to some extent, then target performance would be expected to be better on congruent trials and worse on incongruent trials, as compared with performance on neutral trials. Thus, cognitive psychologists can infer the extent to which distractor stimuli are processed from the magnitude of any congruency effects observed in the target discrimination task (where congruency effects are usually calculated in terms of the impairment of performance seen on incongruent trials relative to that seen on the neutral or congruent trials). Eriksen and Eriksen's original study (along with many subsequent studies) demonstrated significant congruency effects due to the visual distractors, implying that, at least under certain conditions, the distractors could be processed to the level at which responses are programmed despite being irrelevant to the task.

The flanker paradigm has recently been extended to the auditory modality. Chan et al. (2005) presented participants with three simultaneous voices, each saying a different word from a different spatial location. On each trial, the participants had to make a speeded discrimination response regarding the identity of the word spoken by the central speaker, while trying to ignore the distracting words being spoken by the speakers situated to either side of the central speaker (at spatial separations varying between 30 and 90 degrees). Just as shown previously in the visual modality, the participants responded significantly more slowly (and less accurately) on the incongruent trials than on the congruent distractor trials, thus showing interference by task-irrelevant distractors in the auditory modality.

Generally speaking, there has been much less research on selective attention within the tactile modality than there has been in either vision or audition. However, this area of research has begun to grow over the last few years and is now attracting considerable empirical interest (see Johansen-Berg and Lloyd, 2000; Spence, 2002; Gallace and Spence, 2007) related, at least in part, to the very real practical implications that are now emerging in the area of tactile interface design (see Gallace et al., in press, for a recent review). For example, laboratory-based research has established tactile analogues of the Eriksen flanker paradigm already described. In one such study, Evans and Craig (1992) asked their participants to discriminate the direction of a moving tactile stimulus on one finger while ignoring a moving distractor presented to another finger. The participants responded more rapidly and more accurately when the direction of the distractor stimulus was congruent (vs. incongruent) with that of the target stimulus, suggesting that the tactile distractor was processed to a level at which it was able to influence responses, despite being clearly irrelevant to the task.

More recently, Soto-Faraco et al. (2004) developed a tactile response competition paradigm using static (rather than moving) tactile stimuli. The participants in their study had to discriminate the elevation of a series of continuous target vibrations (presented to either the top or bottom of a foam cube held in one hand) whilst trying to ignore pulsed distractor vibrations (presented to the other hand at an elevation that was either congruent or incongruent with that of the target stimulus). In line with the results of Evans and Craig's (1992) earlier study, Soto-Faraco et al. observed significantly better performance when the elevation of the vibrotactile distractor was congruent (vs. incongruent) with that of the tactile target, suggesting that the distractors

were processed despite being entirely irrelevant to the participants' task (see also Driver and Grossenbacher, 1996). Note that, although these distractor congruency effects were most pronounced when the target hand was unpredictable, the same pattern of results (although somewhat reduced in magnitude) was also found when the target hand was made predictable throughout a block of trials. Thus tactile distractors can interfere with the processing of tactile targets, even when targets and distractors are made clearly distinguishable from one another spatially (thus allowing for the focusing of a participant's selective attention on the target hand). This might be taken as preliminary evidence that attentional selection within the tactile modality occurs relatively late in information processing. Indeed, subsequent research by Soto-Faraco et al. found that the magnitude of the tactile interference effect was modulated both by actual changes in the separation between the participant's hands (implying a role for proprioception in guiding selection) and by illusory changes in hand separation, induced by a mirror illusion (implying a role for visual information prior to tactile selection). This suggests that tactile selective attention was operating upon a representation of the tactile stimuli that was derived subsequent to the multisensory integration of tactile, proprioceptive, and visual information. This finding supports the idea that tactile selection occurs relatively late in information processing. However, it should be noted that little of the research on tactile selective attention has been designed specifically to address questions of early versus late selection. More research on this question might therefore be useful in the future.

Taken together, there is now a considerable body of evidence from research in audition, vision, and touch to suggest that supposedly unattended information can in fact be processed beyond the level of the simple registration of its physical features. However, as was the case with the research taken to support early selection, these findings have been subject to several alternative interpretations. For example, one particularly important criticism relating to all of the experiments that have provided evidence in favor of late selection is that although participants are asked to ignore the irrelevant information (and presumably attempt to do as they have been instructed), they may nevertheless fail to ignore this information completely, despite their best intentions. Any observations of semantic processing of the unattended information could therefore reflect failures in attentional focus, rather than necessarily indicating extensive processing of truly unattended material (e.g., Holender, 1986).

Indeed, there is some evidence to suggest that, under certain conditions, the apparent processing of unattended information can be prevented when controls are taken to ensure that the unattended information remains genuinely unattended. For example, Lachter et al. (2004) asked the participants in their study to decide on each trial whether a target stimulus constituted a word or a nonword (this is often referred to as a lexical decision task). Each target was preceded by a prime word, which was presented very briefly and then 'masked' (i.e., replaced by other visual stimuli to ensure that no trace of the original visual stimulus remained). The prime word was either identical to the target word or unrelated to it. Participants in this type of experiment are typically faster and more accurate on the lexical decision task when the target and prime are identical, as compared with when they are unrelated (an effect known as repetition priming). However, Lachter et al. (2004) demonstrated that this effect could be eliminated if the participants were prevented from paying any attention to the prime stimuli (e.g., by presenting the primes at an unattended location and for a duration that was too short to allow a shift of attention to that location). This suggests, in line with earlier results (e.g., Rees et al., 1999), that genuinely unattended words can be eliminated from information processing at a reasonably early stage. Indeed, Lachter et al. put forward a robust defense of Broadbent's (1958) original model of early selection based on their data and on the argument (mentioned above) that all evidence in favor of late selection can actually be explained in terms of a process they term slippage, in which attention is inadvertently paid to task-irrelevant items (see also Wood and Cowan (1995a,b) for evidence to suggest that hearing one's own name in the unattended stream during dichotic listening might reflect the consequences of a temporary failure of selective attention, rather than the semantic processing of unattended information). It should be noted that to date, the findings to support Lachter et al.'s claims relate only to very specific experimental paradigms and conditions. It will be interesting to see whether the finding that late selection results can be eliminated by preventing slips of attention can be generalized more widely.

1.13.4 Neural Mechanisms of Selective Attention

The behavioral evidence outlined in the previous two sections suggests that, under some circumstances, unattended information can be eliminated from information processing at a very early stage (see also Driver, 2001, for a review). This idea has been supported by neuroscientific findings suggesting that spatial attention can modulate even the very early stages of neural information processing in the auditory, visual, and tactile modalities.

One important advantage of the neuroscientific approach (as compared to the cognitive psychological approach described earlier) is that it has allowed researchers to examine whether the activation of specific brain areas at identifiable points in particular hierarchies of information processing can be modulated by attention. This approach might therefore appear to be able to provide more concrete definitions of early and late selection effects than those provided by the cognitive approach (see Allport (1992) for a discussion of some of the problems faced by cognitive researchers in this regard). However, it is important to emphasize that the notion that information passes sequentially through strict neural processing hierarchies has little support these days. For example, it is now generally agreed that visual information processing involves feedback (or 'recurrent') processing, in which later areas feed information back to earlier areas (Lamme et al., 1998). Indeed, some researchers have argued that such recurrent processing is essential for visual awareness (Lamme, 2003). In addition, there is reliable evidence to suggest that different aspects of incoming information can be processed in parallel by the brain, as demonstrated in vision (e.g., see Goodale and Milner (1992) for a review of evidence to support the existence of two parallel processing streams – known as the 'ventral' and 'dorsal' streams – in the neural processing of visual information), in hearing (see Rauschecker and Tian (2000) and Alain et al. (2001) for suggestions that a similar distinction may also apply to the processing of auditory stimuli), and in touch (see Pons et al. (1992) for early work on the possible parallel processing of different aspects of tactile information).

Nevertheless, the mounting evidence that even primary sensory areas (through which it is agreed that all incoming information from that particular sensory modality must pass) can be subject to attentional modulation is often taken to support an early selection view. In addition, researchers have sought to demonstrate that attentional modulations can occur soon after stimulus onset, providing a definition of early selection in terms of processing time rather than brain region. Below we discuss the evidence for attentional modulations of visual, auditory, and tactile information processing at stages that are defined as early either in terms of brain area or in terms of processing time, or both. We then examine the contribution that these findings have made to the question of the extent to which unattended information is processed. Note that our discussion here is focused on the neural mechanisms of spatially selective attention (rather than attention to other, nonspatial stimulus attributes) simply because this is the area in which the majority of the research has been carried out.

1.13.4.1 Audition

There is now considerable evidence to suggest that spatial attention can affect the early stages of auditory information processing (see Giard et al. (2000) for a review). One fruitful line of research has used ERP recording to assess neural processing of auditory information. In a typical design, participants are asked to attend to auditory stimuli presented at a particular location while attempting to ignore task-irrelevant stimuli at another spatial location. ERPs elicited by stimuli presented at the attended location are then compared with the ERPs elicited by the same stimuli when that location is unattended. Although there is no physical difference between the stimuli, they typically elicit different ERP patterns even at relatively short latencies after stimulus presentation, thus suggesting that auditory selective attention can have an important effect even on early perceptual processes. Specifically, the amplitudes of certain early, sensory-related ERP components elicited by attended stimuli have been shown to be greater than those elicited by unattended stimuli, with these differences starting as early as 60–80 ms after stimulus presentation (Hillyard et al., 1973; Näätänen et al., 1978; Hansen and Hillyard, 1983). There is now even some evidence to suggest that, under certain conditions, these differences can occur as early as 20–50 ms after stimulus presentation (Hoormann et al., 2000).

Neuroimaging studies of spatially selective auditory attention have also demonstrated that paying attention to the location of auditory stimuli

(as compared with ignoring those very same stimuli) can activate areas of primary auditory cortex as well as temporal lobe auditory association areas (O'Leary et al., 1997; Alho et al., 1999). In line with the ERP research described above, this research implies that selective attention can have effects on relatively early stages of auditory information processing.

This assertion is further strengthened by studies using single-cell recording techniques in nonhuman primates, in which researchers have been able to measure the responses of individual neurons while an animal performs a particular task. This type of research has also demonstrated an attentional modulation of neuronal responses in auditory cortex (Benson and Hienz, 1978). Thus, overall, the neuroscientific research appears to agree that attentional modulations can occur very soon after stimulus onset and in brain areas that are involved in the early processing of auditory information.

1.13.4.2 Vision

There is also a consensus in the neuroscience community that spatial attention can modulate the early stages of processing of visual information. For example, O'Connor et al. (2002) carried out an fMRI study in which the participants either had to attend to a checkerboard stimulus or else attend to the other side of the screen (while the checkerboard remained present but was relatively unattended). Activity levels in the visual cortex (pooled in this case across several early visual processing areas, including primary visual cortex) were found to be higher in the attended condition than in the unattended condition. This result has been replicated frequently throughout the literature (see Kastner (2004) for a review). However, O'Connor et al. extended previous findings by demonstrating that this attentional modulation effect could also be found in the lateral geniculate nucleus (LGN) of the thalamus – a brain area that is known to be involved in the very early processing of visual information.

The finding that spatial attention can modulate brain areas that are involved in the early processing of visual information has been accompanied by findings of attentional modulations of certain visual ERP components soon after stimulus onset (for reviews see Mangun, 1995; Hillyard et al., 1998). Several studies have also combined brain imaging with ERP recording in order to exploit the high temporal resolution of ERP techniques as well as the relatively high spatial resolution of PET or fMRI. For example, Heinze et al. (1994) used positron emission tomography (PET) and ERP recording to demonstrate an attentional modulation of responses in certain areas of visual cortex within 80–130 ms of stimulus onset.

Similar findings have also emerged from studies of attentional function at the neuronal level using single-cell recording techniques in nonhuman primates. In fact, there is now reliable evidence to suggest that spatial attention can modulate the responses of individual neurons throughout the macaque visual system (see Treue (2001) for a review). However, findings relating to the issue of whether or not neural responses in primary visual cortex (V1) are subject to attentional modulation have, until fairly recently, been rather mixed (see Posner and Gilbert (1999) for a review). For example, Moran and Desimone (1985) and Luck et al. (1997) both failed to find any attentional modulation of the activity of V1 neurons, despite finding clear evidence for attentional effects occurring in other early visual areas (e.g., in V2 and V4). Nevertheless, there is now an increasing body of evidence that V1 neurons can be subject to attentional modulation, at least under certain conditions (see Treue (2001) for a review). For example, Roelfsema et al. (1998) devised a task in which their monkeys had to fixate a dot, which was then joined to one of two curves, each leading to another dot. The monkey's task was to make an eye movement to the dot that was joined by the curve originating from the fixation dot. Using this task, a curve passing through a particular area of the visual field could either be made a target (by connecting it to the fixation dot) or a distractor (by not connecting it). Thus, the same cell's receptive field (RF) could fall on the target curve in one trial and on the distractor curve in another trial. Recordings were taken from 45 neurons in the primary visual cortex of two monkeys. Overall, firing rates were higher when the RF fell on a target curve than when it fell on a distractor curve, indicating that neuronal responses in primary visual cortex could be modulated by the attentional demands of the monkey's task.

Given the variability of the results concerning the attentional modulation of V1, it is perhaps not so surprising that studies looking at the possible attentional modulation of LGN neurons have also reported mixed results. Although there is some limited evidence to suggest that the activity of neurons within the LGN can be modulated by attention (Vanduffel et al., 2000), the few single-cell recording

studies in this area have usually failed to find attentional effects at this very early level of information processing (e.g., Mehta et al., 2000; Bender and Youakim, 2001). Nevertheless, taken together, the findings from visual neuroscience studies in humans and nonhuman primates appear to agree that the attentional modulation of neural processing can occur in brain areas involved in the early stages of visual information processing and within around 100 ms of stimulus onset.

1.13.4.3 Touch

Just as we have seen to be the case for both audition and vision, the neuroscientific evidence also suggests that attention can affect the early stages of the neural processing of tactile information (see Johansen-Berg and Lloyd (2000) for a review). For example, researchers have demonstrated attentional modulations of ERP components relating to tactile perception as early as 80 ms after the onset of a tactile stimulus (Eimer and Forster, 2003).

Similarly, attentional effects in primary somatosensory cortex (S1) have been demonstrated in humans using fMRI (Johansen-Berg et al., 2000) and PET (Meyer et al., 1991). Note, however, that these results might depend on the exact parameters of the experimental design used, as other studies have failed to demonstrate clear attentional effects on activity in S1 (Mima et al., 1998; Burton et al., 1999), although these studies have nevertheless often demonstrated attentional modulation of other (later) somatosensory areas (e.g., S2).

This overall pattern of results is supported by a small number of single-cell recording studies demonstrating a significant attentional modulation of neuronal responses in primary somatosensory cortex (Hyvarinen et al., 1980; Hsiao et al., 1993). Thus, although there has been less research performed on the neural mechanisms of tactile selective attention than there has been on the mechanisms of visual and auditory attention, the available research appears to agree that attention can modulate the early stages of tactile information processing.

1.13.4.4 Implications for the Early versus Late Debate

Overall, there is a significant body of evidence to suggest that attentional modulation of visual, auditory, and tactile information can occur in brain areas involved with early information processing and at times very soon after stimulus onset (see also Driver and Frackowiak (2001) for a review). However, the fact that the brain differentiates between attended and unattended inputs at an early stage of processing does not necessarily mean that unattended information is ruled out of processing altogether at that stage. Instead, these results simply demonstrate that attended and unattended stimuli are differentiated from this stage of processing onward. In fact, most of the studies described above demonstrated an attenuated response to unattended stimuli, rather than no response at all. Nevertheless, the research might suggest that unattended stimuli become less and less well represented as processing proceeds. For example, the extent to which attention can modulate neuronal activity has been seen to increase throughout the visual system, such that the attentional modulations of activity in V1 are typically smaller in magnitude than those elicited by the same experimental manipulation to activity in a higher visual area such as, for example, V4 (Kastner et al., 1998; Martinez et al., 1999; Mehta et al., 2000; O'Connor et al., 2002; Vibell et al., 2007). Recall that the research looking at possible attentional modulations of the neural processing of tactile information also found more reliable modulations in secondary somatosensory cortex than in primary somatosensory cortex (Mima et al., 1998). Such results might be taken to suggest that the neural representation of unattended stimuli is gradually reduced as processing progresses, rather than unattended stimuli necessarily being completely eliminated at one fixed point in information processing.

This suggestion would fit with the biased competition model of visual selective attention put forward by Desimone and Duncan (1995; reviewed in Duncan, 2006). According to this model, neuronal activity can be biased in favor of those neurons that respond to a particular attended stimulus. This initial prioritization of selected neurons gives them an advantage in their subsequent interactions with neurons that are not preferentially activated (because they do not respond to the attended stimulus). Thus, according to this model, unattended information would not be ruled out of processing at a particular point but would instead be subject to a continued bias against it throughout processing. This intermediate position is echoed in recent proposals for a resolution to the early versus late selection debate, as outlined here.

1.13.5 Possible Resolutions to the Debate

The studies reviewed so far all agree that, at some stage, attended information is processed with a higher priority than is unattended information. However, many of these studies differ in their estimates of the effects that this process of prioritization might have on the level to which the unattended information is processed. In contrast to the extreme positions espoused by the early selection theorists (e.g., Broadbent, 1958) and the late selection theorists (e.g., Deutsch and Deutsch, 1963), several researchers noted the variability of the findings and proposed compromise positions (see Shulman (1990) for a discussion of the dangers of failing to acknowledge the extent of the variability of the results in this research area). For example, Treisman (1960) proposed that unattended information was attenuated early in processing, rather than being filtered out completely. Her model accommodated the findings concerning the limited processing of unattended stimuli but also allowed for the possibility of further processing of this information if it were sufficiently salient (in which case, according to the model, it would be able to reach consciousness despite having been attenuated, because the thresholds for activating salient information were lower than for other information). This proposal of variable thresholds for triggering the processing of incoming information allowed for different participants to have different threshold levels for different types of information. Treisman's model was therefore capable of accounting for the observations of individual differences in the efficiency of selective attention, as described earlier (recall, for example, that Moray (1959) found that, although a subset of his participants noticed their own names when they were presented in the unattended ear, a significant number of participants did not). However, whereas these ideas relate mainly to the nature of the irrelevant information, subsequent research has indicated that the nature of the relevant information can also play a part in determining the amount of processing that unattended stimuli receive.

For example, Lavie (1995) reinvigorated the early/late selection debate by putting forward the suggestion that selection could occur either early or late in information processing, depending on the perceptual load of the relevant task (i.e., the demands placed on the perceptual system by that task; see Johnston and Heinz (1978) for an earlier hybrid model of selection). Lavie argued that the perceptual system has a limited capacity, but that all stimuli are automatically processed unless that capacity is exceeded. According to this view, selection can only occur at an early stage of information processing if the relevant task uses up all of the available processing capacity (i.e., under conditions of high perceptual load). If the perceptual load of the task is insufficient to exhaust the processing capacity, then distractors will be processed automatically, and selection will be seen to occur at a later stage of information processing.

In order to provide a direct test of this theory, Lavie (1995) assessed the performance of participants on a response competition task similar to that designed by Eriksen and Eriksen (1974; and described in the section titled 'Behavioral evidence for late selection'). Distractor interference was measured in terms of distractor congruency effects (in which responses are typically shown to be slower when distractors are associated with responses that are incongruent, vs. congruent, with the target response). Lavie also manipulated the demands of the target task, such that the perceptual load was either high (e.g., searching for an N among several other letters) or low (e.g., searching for an N among Os). Lavie reported that the participants were able to ignore the distractors more effectively (implying early selection) under conditions of high perceptual load than under conditions of low perceptual load (implying later selection in this case).

The idea that the stage of processing at which selection occurs can vary depending on the perceptual load of the relevant task has now been supported by a number of subsequent studies (Lavie, 2000; 2005). For example, Rees et al. (1997) carried out an fMRI study in which the participants viewed a peripheral display of moving dots that was irrelevant to a word-based task presented at fixation. Neural activity in motion areas MT/MST was reduced when the word-based task was highly demanding (i.e., identifying words containing two syllables) as compared to when it was less demanding (i.e., identifying words written in uppercase vs. in lowercase letters). This suggests, in line with perceptual load theory, that the neural processing of the irrelevant information was modulated by the perceptual demands of the relevant task. Similar effects have now been shown as early in visual processing as the LGN (O'Connor et al., 2002).

Given the wide range of experimental evidence now supporting perceptual load theory, it is often considered to have provided something of a resolution to the long-running early/late selection debate (although see Eltiti et al. (2005) for a possible alternative account of certain findings in terms of distractor salience). However, it is important to note that, as yet, no independent measure of perceptual load has been provided. Instead, researchers have had to rely on operational definitions, based on observations that a given manipulation of perceptual load worked in a given experimental setting. (Note that this raises particular problems when trying to interpret the results of studies where a manipulation of perceptual load is found to have no effect on distractor processing.)

Another possible limitation of the research in this area so far is that it has concentrated almost exclusively on perceptual load within the visual modality (although see Alain and Izenberg (2003) for evidence that ERP components elicited by deviant – yet task-irrelevant – auditory stimuli can be reduced under a high (vs. low) perceptual load in a relevant auditory task). Given that this line of investigation began with experiments looking at audition (with the dichotic listening paradigm) and has since expanded to look at attentional processes within the somatosensory modality, it would seem important to test the predictions of the perceptual load theory within those sensory modalities, as well as between combinations of different sensory modalities.

Despite a relative lack of unimodal studies of perceptual load effects in audition and touch, there have been a small number of recent studies that have investigated the possibility of crossmodal perceptual load effects. One possible advantage of this line of investigation is that it might provide a test of whether the limited perceptual capacity described within the perceptual load theory is modality specific (Wickens, 1984, 1992) or whether instead it consists of a common pool of processing resources that is shared between the different sensory modalities.

There is some variability in the results of the small amount of research published on this question so far, with some studies having failed to find reliable crossmodal effects of perceptual load (Rees et al., 2001; Tellinghuisen and Nowak, 2003), while others have found some suggestion of crossmodal effects (e.g., Otten et al., 2000). This variation in the results of the studies of crossmodal perceptual load might be related to the lack of an independent measure of the extent of the load imposed on the perceptual system by a particular task. It could, for example, be argued that any failures to demonstrate significant crossmodal perceptual load effects may have been due to the studies in question simply using too weak a manipulation of perceptual load. For example, the auditory discrimination of the number of syllables, used in a crossmodal study by Rees et al. (2001), is likely to have been much easier than the discrimination of the number of syllables in words presented visually, which was used in their successful intramodal study of perceptual load in vision (Rees et al., 1997). Given these limitations of the research to date, it would seem premature to draw firm conclusions at the present time, especially given the general variability in the literature on the question of whether or not attentional resources are shared between the different sensory modalities (e.g., see Treisman and Davies, 1973; Martin, 1980; Spence et al., 2001; Soto-Faraco et al., 2002; Arnell, 2006, for successful demonstrations of crossmodal competition for attention; but see Duncan et al., 1997; Soto-Faraco and Spence, 2002; and Alais et al, 2006, for a failure to find any such crossmodal competition under slightly different experimental conditions).

Earlier, we outlined how the neuroscientific evidence appears to support a compromise position, suggesting that unattended stimuli might be gradually filtered out throughout information processing, rather than being completely eliminated from processing at one fixed point in the system. This suggestion from neuroscience, along with the behavioral evidence that unattended information receives more or less processing depending on the specific perceptual demands of the attended task (e.g., Lavie, 1995), would appear to agree that there is no fixed point at which unattended information is excluded from processing, but rather that the prioritization of processing is flexible, depending on the salience of the stimuli involved, the particular demands of the task at hand, and the current goals of the observer.

1.13.6 Working Memory and the Locus of Selection

There is also evidence to suggest that the extent to which unattended information is processed can vary from participant to participant. Recall, for example, that only one in three of Moray's (1959) participants noticed their own names being presented in the unattended stream. There is now evidence to suggest

that this interparticipant variability might be related to individual differences in working memory capacity. For example, Conway et al. (2001) have shown that participants with lower working memory capacities, as assessed by their performance on the operation span task, in which participants are asked to remember short lists of words while carrying out mathematical operations (Turner and Engle, 1989), are more likely to notice their own name in the unattended stream in a dichotic listening experiment than participants with higher working memory capabilities. This finding suggests that working memory plays a key role in controlling attentional allocation, such that people with lower working memory capacities find it harder to control the deployment of their attentional resources. Note that such an interpretation might also imply, in line with the proposals of Holender (1986) and Lachter et al. (2004) mentioned earlier, that the semantic processing necessary to recognize one's own name in the unattended stream occurs as a result of the unintentional allocation of attention toward that stream (because if it simply reflected true semantic processing of all unattended information, there would have been no effect of individual working memory capacity on the likelihood of noticing the name). We note, however, that because Conway et al.'s study is correlational in nature, it cannot demonstrate a causal role for working memory in successful auditory selective attention (as it is also possible that participants' attentional abilities determined their performance on both tasks).

Nevertheless, further evidence has recently begun to emerge to support the suggestion of a causal role for working memory in control of selective attention, at least in the visual modality (De Fockert et al., 2001; Lavie et al., 2004). For example, Lavie et al. (2004) asked the participants in their study to respond to the identity of a target letter (X or Z) while ignoring a concurrently presented distractor letter, which could either be congruent with respect to the target letter (e.g., an X when the target was also an X) or incongruent (e.g., a Z when the target was an X). The participants carried out this task under conditions of either high working memory load (where they were asked to remember six randomly chosen digits) or low working memory load (where they only had to remember one digit). Incongruent distractors produced greater interference (by comparison with congruent distractors) under conditions of high working memory load than under low load conditions, suggesting that working memory availability is important for minimizing interference by irrelevant stimuli, presumably through the active maintenance of current stimulus-processing priorities (see Lavie, 2005).

The latest research to emerge from our laboratory has suggested that working memory availability might also be important for the successful control of tactile selective attention. Dalton et al. (2006) asked the participants in their study to carry out a tactile response competition task similar to that used by Soto-Faraco et al. (2004), described earlier, under conditions of either high working memory load (in which the participants were asked to remember six randomly chosen digits) or low working memory load (in which the memory set always consisted of the digits 1–6 presented in ascending numerical order). In line with the results of the visual studies carried out by Lavie et al. (2004), Dalton et al. found that distractor congruency effects within the tactile modality were significantly larger under high working memory load than under low load, suggesting that working memory is also important for the control of tactile selective attention. Similar results have also emerged from a very recent study of the role of working memory in auditory selective attention (Dalton, Santangelo, and Spence, in preparation).

1.13.7 Summary

We have considered visual, auditory, and tactile research that has addressed the question of the extent to which unattended information is processed. While certain studies reported that participants are able to recall very little about information they had ignored (e.g., Cherry, 1953; Rees et al., 1999), other studies found evidence suggesting that supposedly ignored information had in fact been processed to a relatively late stage, involving semantic processing and/or response selection (e.g., Corteen and Dunn, 1974; Ruz et al., 2005). The emergence of these conflicting findings has led to a long-lasting debate in the literature over the exact stage of processing at which unattended information is excluded.

Proponents of early selection (e.g., Broadbent, 1958; Lachter et al., 2004) have argued that unattended information is filtered out early on in information processing, on the basis of simple physical characteristics. By contrast, late selection theorists (e.g., Deutsch and Deutsch, 1963) proposed that information was processed to a much deeper level before being excluded from the processing stream.

More recently, many researchers have converged on a more flexible position, in which the locus of selection can vary according to the task demands (Lavie, 2005), the salience of the stimuli (Eltiti et al., 2004), and the individual characteristics of the participant (Conway et al., 2001). When deeper processing of unattended stimuli is observed, it seems likely that it results from some level of attentional allocation toward the unattended stimuli, either due to inadvertent slips of attentional focus (e.g., Holender, 1986; Lachter et al., 2004) or due to automatic processing of irrelevant information under conditions of low perceptual load (e.g., Lavie, 2005). Research in recent years has also identified a key role for working memory in the control of selective attention, such that selection is more effective when working memory resources are available for the attention task than when they are not (e.g., Lavie et al., 2004).

1.14 Amnesia: Point and Counterpoint

E. A. Kensinger, Boston College, Chestnut Hill, MA, USA

S. Corkin, Massachusetts Institute of Technology, Cambridge, MA, USA, and Massachusetts General Hospital, Boston, MA, USA

1.14.1 Introduction

In 1953, a man known by his initials, H.M., underwent an experimental brain operation to relieve his intractable epilepsy. This bilateral removal of medial temporal lobe (MTL) structures (see Corkin et al., 1997, for detailed report of his lesion location) was successful in lessening the frequency and severity of his epileptic seizures; however, it left him with a profound anterograde amnesia and an extensive retrograde amnesia extending to at least a decade before his surgery (Corkin, 1984; Scoville and Milner, 1957). Although H.M.'s intellectual abilities remained intact after the operation, and he was able to acquire new skills, he has not been able to consciously record any new experiences (see **Figure 1**; Corkin, 2002 for review).

H.M.'s pattern of spared and impaired abilities indicated not only that declarative (explicit, conscious) memory is dissociable from other forms of memory (e.g., implicit, unconscious) and from other perceptual and cognitive processes but also that the hippocampus and other MTL structures play a role in declarative, but not nondeclarative, memory formation (Scoville and Milner, 1957; Milner, 1962; Corkin, 1968, 1984, 2002). These realizations have spurred decades of research focusing on the role of MTL structures in learning and memory. Although initial studies focused primarily on the importance of the hippocampus in episodic memory, subsequent research has demonstrated that the surrounding cortical regions also are essential for normal declarative memory performance. Thus, patients with damage limited to the hippocampus tend not to show the magnitude of amnesia demonstrated in patients with more extensive MTL damage (e.g., Mishkin, 1978; Zola-Morgan and Squire, 1986; Meunier et al., 1993; Zola-Morgan et al., 1993; Barense et al., 2005). While these findings suggest that regions outside of the hippocampus proper contribute to declarative memory, the extent to which the different MTL structures make divergent contributions to learning and memory – and the nature of those regional specializations is hotly debated.

This chapter begins with a description of the anatomy of the MTL. We then discuss three ongoing debates concerning the role of different MTL

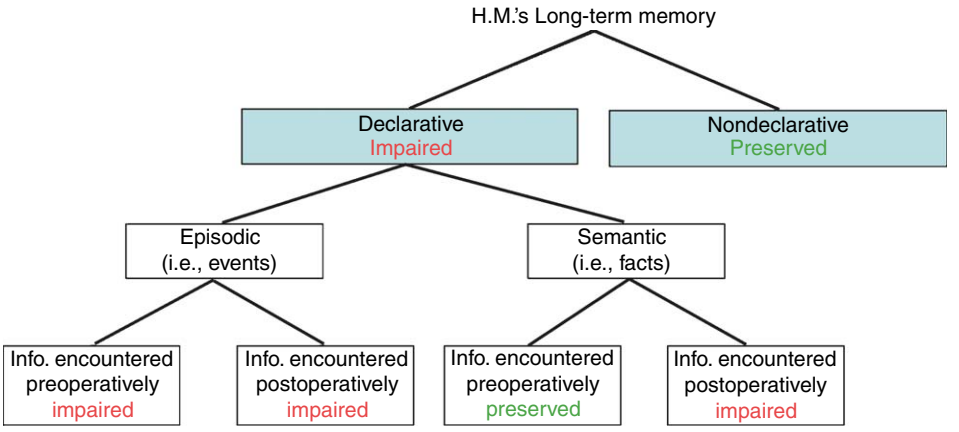

Figure 1 Pattern of spared and impaired learning following MTL resection in the amnesic patient H.M. Nondeclarative (implicit) learning is preserved in H.M., whereas declarative learning is markedly impaired. He does, however, show evidence of residual declarative learning. For example, he sometimes has demonstrated normal recognition memory performance (Freed et al., 1987; Freed and Corkin, 1988) and also has provided some evidence of new semantic learning following his operation (Corkin, 2002; O'Kane et al., 2004; Skotko et al., 2004).

structures in episodic memory. We focus on debates that have arisen from studies of patients with amnesia and from animal models of amnesia, but we also incorporate broader evidence from neuropsychology and neuroimaging.

In the first section, we describe a controversy regarding the extent to which MTL structures function together as an inseparable network that guides learning and memory versus the extent to which dissociations exist among the functioning of the different regions. At the heart of this debate is the question of whether the hippocampus performs specialized memory functions, or whether it carries out mnemonic functions redundant with those of the surrounding MTL cortices. Although some research has focused on examining whether the hippocampus plays a specialized role in spatial memory (e.g., Jarrard, 1995; O'Keefe, 1999; Aggleton and Brown, 2005; Eacott and Gaffan, 2005; O'Keefe and Burgess, 2005; *See also* Chapters 1.23, 1.33), we focus here on a controversy over the extent to which memory for interitem associations and individual items are differentially supported by the hippocampus proper and the surrounding medial temporal cortices, respectively.

In the second section, we outline a debate as to whether the perirhinal cortex plays a circumscribed role in object memory or a broader role in object perception and discrimination. According to some authors, perirhinal cortex is dedicated to memory and does not contribute to stimulus perception (e.g., Buffalo et al., 1999). In this view, stimulus perception is dependent entirely on earlier cortical areas that make up the ventral processing stream. In contrast, other researchers have provided evidence that the perirhinal cortex may not be dedicated exclusively to mnemonic processing but, rather, may support performance on some perceptual discrimination tasks as well (e.g., Eacott et al., 1994; Buckley and Gaffan, 1997; *See* Chapter 1.08).

In the third section, we discuss the pattern of retrograde amnesia following MTL damage. According to one account of memory consolidation (often referred to as the standard model; Alvarez and Squire, 1994; Squire and Alvarez, 1995; Squire and Zola, 1998; Squire et al., 2004), MTL structures play a time-limited role in declarative memory: They are essential for the initial storage and retrieval of semantic and episodic memory traces, but they become unnecessary once memory traces are established permanently in the neocortex. According to this model, following MTL lesions, semantic and episodic memory will be affected equally, and each will show a temporal gradient, with remote memories relatively preserved.

An alternative model of consolidation (termed the multiple trace model; Nadel and Moscovitch, 1997; Moscovitch and Nadel, 1998; Nadel et al., 2000; *See* Chapter 1.04) proposes that the MTL serves as a mnemonic index, or as a pointer, to the neocortical areas that store the sensory and affective qualities associated with episodic events. Each time a memory is retrieved, a new mnemonic index, or pointer, is created. According to this model, a pointer always is needed for retrieval of episodic detail; thus, MTL

structures provide lasting support during the retrieval of episodic memories. A temporal gradient could occur with partial MTL lesions, however, because remote memories tend to have more pointers than recent ones (because, on average, remote memories have been retrieved more often than recent memories). Thus, a partial MTL lesion is more likely to damage all pointers for a recent memory than for a remote memory. The multiple trace theory postulates that retrieval of semantic memories, unlike episodic memories, can occur without the MTL pointer. Because these memories are void of episodic detail, they may become consolidated and independent of the MTL.

Both models, therefore, make the same prediction for retrieval of semantic memories in amnesia: Semantic retrieval should show a temporal gradient, with better memory for remote than for recent facts. In contrast, the models make divergent predictions for the retrieval of autobiographical information. The standard model predicts that retrieval of remote memories should be preserved, whereas the multiple trace model predicts that all autobiographical retrieval should be impaired. We focus on the questions of whether amnesic patients are able to recall autobiographical memories from time periods prior to the onset of their MTL injury and, if so, whether the remote memories retrieved by amnesic patients are qualitatively the same as those retrieved by healthy individuals.

In each of these sections, we present key evidence supporting each viewpoint. We also speculate on the methodological considerations that may allow future research to help resolve these controversies. Although a consensus concerning these issues is still far in the future, the following sections highlight the contribution that studies of amnesia have made to conceptualizations of memory processes and MTL function.

1.14.2 Anatomy of the Medial Temporal Lobe

The MTL is composed of multiple structures: the amygdaloid complex, hippocampal formation (composed of the dentate gyrus, hippocampus, subicular complex, and entorhinal cortex), perirhinal cortex, and parahippocampal cortex (Suzuki and Amaral, 2003, 2004; **Figure 2**). The amygdala, an almond-shaped collection of nuclei, sits at the most anterior portion of the MTL, with direct connections to the hippocampus and surrounding cortices (Stefanacci et al., 1996). The hippocampus (so-named for its sea horse shape) is located posterior to the amygdala. Information flow through the hippocampal formation proceeds from the entorhinal cortex to the dentate gyrus through the CA fields of the hippocampus proper and then to the subiculum. The entorhinal cortex (Brodmann's areas 28 and 34), located in the anterior and medial portion of the temporal lobe (medial to the rhinal fissure), serves as the principal source of input into the hippocampus, via the perforant path (Amaral et al., 1984; Amaral and Insausti, 1990). Information from unimodal and polymodal association cortices enters the MTL mainly through the perirhinal and parahippocampal cortices. The perirhinal cortex (Brodmann's areas 35 and 36) is located in the anterior and medial portion of the ventral temporal lobe, lateral to the entorhinal cortex. Posterior to the perirhinal cortex lies the parahippocampal cortex (von Economo's areas TH and TF), lining the banks of the collateral sulcus (which separates the fusiform and parahippocampal gyri) (Van Hoesen, 1995; Amaral, 1999; Pruessner et al., 2002; Suzuki and Amaral, 2003). The perirhinal cortex receives prominent input from lateral inferotemporal cortex (unimodal visual areas) and from the polymodal parahippocampal cortex (for a detailed review of the anatomical connectivity of perirhinal cortex, see Lavenex and Amaral, 2000). The parahippocampal cortex, caudal to the perirhinal cortex, receives its strongest input from the polymodal dorsal visuospatial processing stream (Goldman-Rakic et al., 1984; Selemon and Goldman-Rakic, 1988; Cavada and Goldman-Rakic, 1989; Suzuki and Amaral, 1994). Both the perirhinal and parahippocampal cortices send strong projections to the entorhinal cortex (**Figure 2**).

1.14.3 Do Medial Temporal Lobe Structures Have Dissociable Roles?

Although H.M.'s MTL lesion is large, his resultant amnesia originally was believed to be the result of damage to the amygdala and the hippocampus (e.g., Mishkin, 1978). For this reason, early animal models of amnesia focused primarily on the role of these structures in declarative memory. Early work, using aspiration lesions, indicated that damage to the hippocampus alone was sufficient to produce severe deficits in declarative memory (e.g., Zola-Morgan et al., 1982; Zola-Morgan and Squire, 1986), lending credence to the idea that these structures were

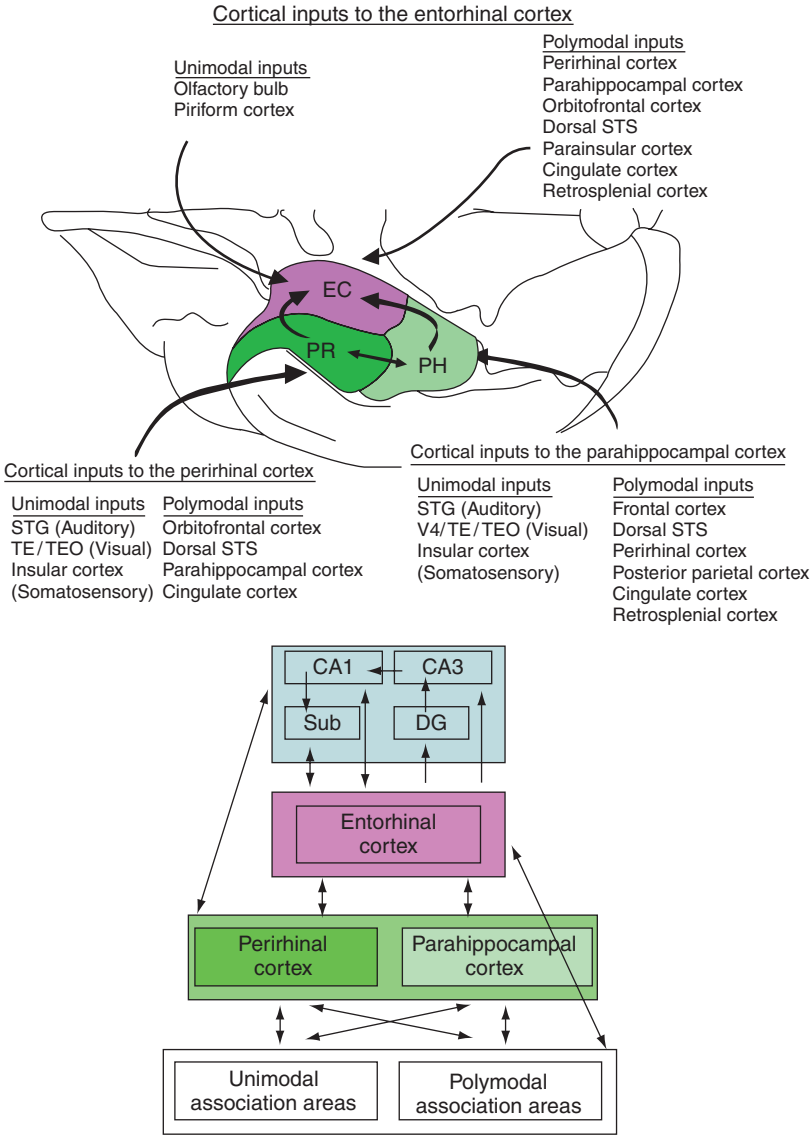

Figure 2 A schematic of MTL anatomy (top panel) and of projections within the medial temporal lobe (bottom panel). Colors reflect levels of integration within the MTL (bottom panel; green = first level of integration, pink = second level, blue = third level). Adapted from Lavenex P and Amaral DG (2000) Hippocampal-neocortical interaction: A hierarchy of associativity. *Hippocampus* 10: 420–430.

critical for declarative learning. It soon became apparent, however, that this view was too simplified: Several studies reported that recognition memory was impaired in animals with lesions that spared the amygdala or the hippocampus (e.g., Mahut et al., 1982; Murray and Mishkin, 1986; Zola-Morgan and Squire, 1986; Zola-Morgan et al., 1989). Researchers soon realized that part of the reason for the extensive declarative memory deficits following simultaneous aspiration lesions to the amygdala and hippocampus stemmed not from direct damage to those regions but, rather, from the resultant damage to the underlying rhinal cortex and to the efferents to the hippocampus. Subsequent animal research using selective lesioning techniques and electrophysiological methods has confirmed that other regions, including the perirhinal and parahippocampal cortices, also play an important role in declarative memory formation (Zola-Morgan et al., 1989; Otto and Eichenbaum, 1992; Meunier et al., 1993; Mumby and Pinel, 1994; Squire et al., 2004). Studies in monkeys and rats have shown that damage limited to perirhinal cortex, or

including perirhinal and entorhinal cortices, can lead to severe memory impairment on recognition memory tasks (Meunier et al., 1993; Eacott et al., 1994; Buffalo et al., 1999), and that such lesions also can exacerbate the memory deficits seen following lesions restricted to the hippocampus (Zola-Morgan et al., 1993; Wiig and Bilkey, 1995).

These results emphasize that MTL regions beyond the hippocampus play an essential role in declarative learning and memory. They do not, however, clarify the extent to which the different MTL structures make specialized contributions to learning and memory. It is clear that not all MTL structures support the same mnemonic functions. For example, although debate occurred for decades regarding the amygdala's role in memory, its focal role in emotion-related modulation of memory now has been well-established (Kensinger, 2004; Phelps, 2004; Phelps and LeDoux, 2005). In contrast, less consensus exists on the specialized contributions of other MTL structures to declarative memory.

In this section, we focus on a debate regarding the extent to which the hippocampus proper supports mnemonic functions that are independent of those mediated by surrounding neocortical regions. At the core of this debate is the question of whether recognition memory for individual items is dependent on the integrity of the hippocampus, or whether the hippocampus plays a specialized role in the recollection of interitem associations (relational memory), while memory for individual items (and intraitem features) can be mediated by adjacent cortical regions, such as perirhinal cortex.

1.14.3.1 Point: The Hippocampus Supports Mnemonic Functions That Are Independent of Those Mediated by Adjacent Neocortical Regions

If all MTL structures contribute equally to all forms of declarative learning, then it should follow that amnesic patients with MTL lesions should show similar magnitudes of impairment across a range of declarative memory tasks. Under certain encoding and retrieval conditions, however, amnesic patients show surprisingly good recognition memory coupled with poor recall ability (e.g., Johnson and Kim, 1985; Freed et al., 1987; Freed and Corkin, 1988; Green and Kopelman, 2002). For example, after studying a series of indoor and outdoor scenes, H.M. showed normal forced-choice recognition at delay intervals ranging from 10 min to 6 months (Freed et al., 1987; Freed and Corkin, 1988; **Figure 3**). In contrast, H.M.'s ability to recall items (or item locations) is at chance (e.g., Smith, 1988; reviewed in Corkin, 2002). Amnesic patients' rate of forgetting also differs based on the

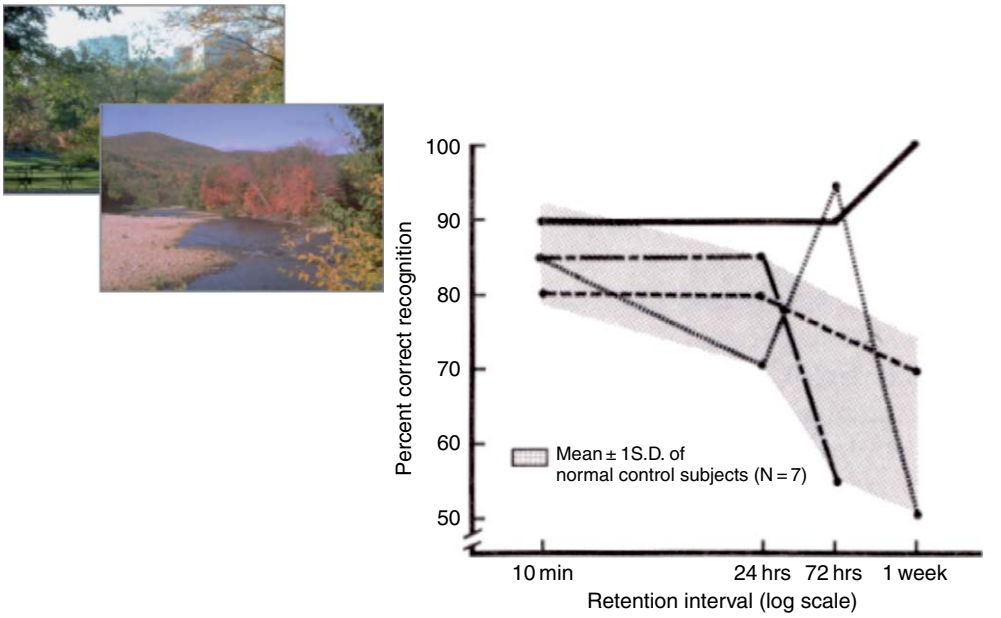

Figure 3 H.M.'s recognition memory performance. H.M. was within the normal range when asked to distinguish presented from nonpresented visual scenes. These results provide evidence of preserved learning despite his large MTL lesion. Modified from Freed DM, Corkin S, and Cohen NJ (1987) Forgetting in HM: A second look. *Neuropsychologia* 25: 461–471.

retrieval demands of the task. Recognition tasks often reveal normal rates of forgetting (Freed et al., 1987; Green and Kopelman, 2002), whereas recall tasks elicit accelerated forgetting (Green and Kopelman, 2002).

Direct comparisons between recall and recognition performance can be difficult to make, however. The two memory measures often are not matched in difficulty (recognition tasks typically are easier than recall tasks), and they always differ in their scales of measurement (with recognition tasks measuring percentage correct and recall assessing the number of items generated). To circumvent these problems, researchers often try to equate amnesic patients and control participants on recognition memory performance (e.g., by giving amnesic patients additional repetitions of studied stimuli, or by lengthening the delay after which the control participants' memory is tested), and then to assess whether, under these conditions of equated recognition, recall performance also is matched.

The initial reports using this approach revealed inconsistent results. Some investigations showed that when recognition was equated between amnesic patients and control participants, the patients' recall remained impaired (Hirst et al., 1986, 1988). Other studies, however, found that once patients' recognition memory was matched to that of control participants, recall memory was equated as well (Shimamura and Squire, 1988; Haist et al., 1992; MacAndrew et al., 1994; Kopelman and Stanhope, 1998). A study by Giovanello and Verfaellie (2001) has shed light on at least part of the reason for these inconsistencies: The relation between amnesic patients' recall and recognition performance depends, at least in part, on the method by which their recognition performance is matched to that of controls. In one experiment, Giovanello and Verfaellie (2001) tested amnesic and control participants after the same delay, but they provided amnesic patients with additional study exposures to equate their recognition memory. In a second experiment, amnesic patients' memory performance was matched with control participants' performance by testing the amnesic patients after a short delay and the control participants after a 24-h delay. These two methods for equating performance led to different patterns of results. In the first experiment, amnesic patients' recall remained impaired, even though their recognition memory was equated. In the second experiment, recall and recognition both were equated across the amnesic and control groups.

At first blush, these findings are perplexing: Why would changing the method used to match amnesic and control participants' memory performance alter the pattern of memory preservation in amnesic patients? To understand this pattern of results, consider that different processes can contribute to a correct endorsement on a recognition memory task (Mandler, 1980; Tulving, 1985; **Figure 4**). On the one hand, a participant can recollect information from the

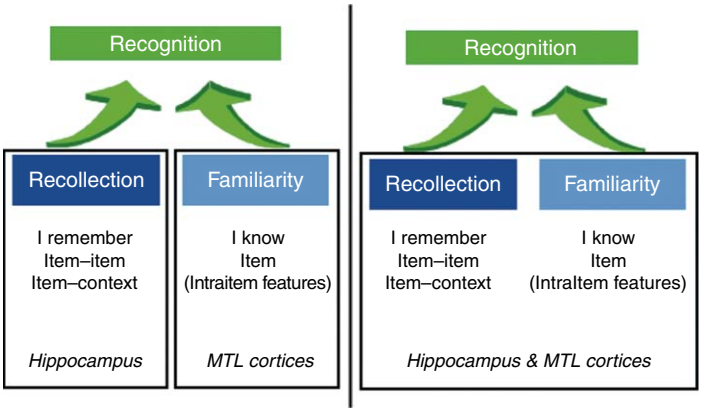

Figure 4 Processes contributing to recognition performance. When presented with an item on a recognition task, participants can use recollection to make their decision (i.e., they can determine that an item was studied because they remember something particular about the encoding episode for that item). Participants also can rely on stimulus familiarity: If a particular item seems more familiar than some other items on the list, it is likely that the enhanced familiarity stems from the fact that the item was presented on a recent study list. Debate exists as to whether these two processes are supported by different MTL circuits (with the hippocampus playing a critical role in recollection and the surrounding perirhinal and parahippocampal cortices being sufficient to support familiarity – left panel) or by the same MTL processes (with all regions of the MTL contributing to both recollection and familiarity – right panel).

study episode: Upon seeing a picture of a meadow on the recognition task, she may remember thinking about how peaceful the scene made her feel, she may recall sneezing while the picture was on the screen, or she may remember that she thought the picture of the meadow was juxtaposed with the prior picture of a crowded city street. Memory for any of this contextual information would allow the participant to confidently endorse the meadow as previously studied. On the other hand, a participant also can correctly endorse the meadow in the absence of any recollection, so long as she has a feeling of stimulus familiarity: If the meadow seems more familiar than other items that have appeared on the recognition task, it is likely that the enhanced familiarity has resulted from a recent encounter with the stimulus (i.e., that the meadow was present on the study list). In contrast, on a recall task, participants cannot rely on stimulus familiarity; they must generate the information themselves, and they therefore must be able to recollect the information and to attribute it to the study episode.

Keeping in mind that these two different processes can contribute to recognition performance, but that only recollective processes support accurate recall, let us return to the two different methods used to equate amnesic patients' performance. In the first experiment, Giovanello and Verfaellie (2001) equated recognition memory by altering the number of study repetitions (one for controls and many for amnesic patients) and by testing memory after a short delay. The fact that the two groups could be equated on recognition, but not on recall, can be explained by considering that control participants' recognition performance was likely to be supported primarily by recollective processes. The multiple item repetitions for the amnesic patients, in contrast, may have primarily boosted familiarity-based processes. Thus, while amnesic and control participants showed comparable recognition memory performance, that performance was supported by different processes in the two groups (more reliance on recollection in controls, and more reliance on familiarity in the amnesic patients). On a recall task, however, in which only recollection and not familiarity can support accurate retrieval, control participants performed better. In contrast, in the second experiment, in which Giovanello and Verfaellie (2001) equated amnesic and control participants' recognition performance by increasing the retention interval for the control participants, it is likely that the manipulation served primarily to decrease control participants' ability to rely on recollection. This reduction in recollection is probable because recollection is believed to fade quickly over a delay, while familiarity is more stable over time (Tulving, 1985; Gardiner and Java, 1991). Because control participants' reliance on recollection was reduced, the equated performance on the recognition task probably resulted from a true equating of processes (e.g., similar reliance on recollection and familiarity in the control participants and the amnesic patients). Because control participants' reliance on recollection was reduced to a level comparable to that of the amnesic patients, performance was equated not only on a recognition memory task but also on a recall task.

These results emphasize the importance of analyzing amnesic patients' performance not just in terms of the type of task used to assess memory (e.g., recall or recognition) but by considering the underlying processes as well. The evidence for a disproportionate impairment in recollection in the study by Giovanello and Verfaellie (2001) was indirect (i.e., the authors did not directly measure the contribution of recollection and familiarity to recognition task performance), but more recent investigations have tackled this question head-on.

In many of these experiments, researchers have relied on participants' self-reports as to what types of information contributed to their recognition response. With this type of assessment (referred to as the remember-know procedure; *See* Chapter 2.17), participants are asked to not only decide whether information was presented in a study list but also to indicate whether they believe the information was presented because they remember something about the context in which the item was presented (i.e., they recollect details from the study episode) or because they simply know that they studied the item (i.e., the item is familiar but they are unable to recollect any information about its presentation; Mandler, 1980; Tulving, 1985; Rajaram, 1993). Evidence using the remember–know paradigm and other dual-process procedures suggests that the familiarity-based contribution to recognition memory performance is preserved in amnesic patients, whereas the recollective-based component is drastically impaired (e.g., Bastin et al., 2004; King et al., 2004; Aggleton et al., 2005; but see Medved and Hirst, 2006, for evidence of vivid recollection in amnesic patients). Amnesic patients often give far fewer remember responses than control participants, and their distribution of remember responses across different conditions differs from that of control participants. In contrast, the distribution of know responses for amnesic patients tends to be more in line with that of control participants (e.g., Rajaram et al., 2002).

The remember–know paradigm, however, has limitations. The first is that it relies on participants' subjective reports. It is likely that amnesic patients' subjective sense of remembering may not be qualitatively similar to the sense of remembering experienced by control participants (see Maguire et al., 2001b; Rajaram et al., 2002, for further discussion). The second is that, when a participant endorses an item as remembered, it is not clear what types of information the participant has retrieved. Depending on instructions used by investigators, a remember response can signify retrieval of information ranging from a wide variety of contextual elements (e.g., remembering a feeling elicited by the stimulus, or remembering the item that preceded the stimulus) to memory for the exact features of the presented stimulus (e.g., remembering the font in which the word was written). It is likely that memory for these different types of information (e.g., item–context associations, item–item associations, and memory for intraitem features) is supported by different processes; the remember–know procedure does not provide an easy way in which to parse their distinct contributions.

To circumvent these issues, researchers have adopted paradigms that more directly compare memory for associations or relations with memory for isolated items. One commonly used paradigm asks participants to distinguish between studied associations (e.g., fork–bench, pig–limousine, often referred to as intact pairs), novel associations between previously studied items (e.g., fork–limousine, recombined pairs), and novel associations between unstudied items (e.g., canary–tool, novel pairs). The ability to distinguish intact from recombined pairs (a measure of associative memory) has been compared with the ability to distinguish either of those pairs from novel pairs (a measure of item memory). Cognitive studies in young adults have provided empirical support for a dissociation between these two types of memory measures, with associative recognition being tied to recollective processes and item memory more reliant on familiarity signals (e.g., Hockley and Consoli, 1999).

Amnesic patients often show profound impairment on associative memory measures, even under conditions in which memory for items is equated (e.g., Giovanello et al., 2003; Turriziani et al., 2004). Not only are these associative memory deficits apparent on tasks that directly ask participants whether items were studied together but they also are apparent using eye tracking measures to indirectly assess memory for item relations. Cohen and colleagues (Ryan et al., 2000; Ryan and Cohen, 2004) have found that control participants tend to look longer at components of scenes that have been moved, whereas amnesic patients do not show these effects. These data provide further evidence that amnesia may result in a fundamental deficit in processing the relations or associations among different stimuli.

The results discussed so far have suggested that amnesia does not always result in a declarative memory deficit that is equally pervasive across all memory measures. Rather, patients with amnesia are typically disproportionately impaired on recall tasks compared to recognition tasks, on tasks that require recollection as compared to those that can be supported by familiarity, and on tasks that rely on memory for associations as compared to those that can be supported by memory for items void of their context. Although these findings provide evidence for dissociations in the magnitude of mnemonic impairment based on the type of information retrieved, they do not speak to the precise regions within the MTL that may contribute differentially to different types of mnemonic functions.

Initial evidence for dissociations of function between the hippocampus proper and the surrounding MTL cortices came from animal models of amnesia. In a number of investigations, complete hippocampal removal had little to no effect on object recognition memory, even when memory was assessed after relatively long delays (Orbach et al., 1960; Stepien et al., 1960; Correll and Scoville, 1965; Meunier et al., 1993; Murray and Mishkin, 1998; Winters et al., 2004; Forwood et al., 2005). In fact, one study reported an inverse correlation between the amount of hippocampal damage and the magnitude of recognition memory impairment (Baxter and Murray, 2001). In contrast, lesions in perirhinal cortex can result in large decrements in object recognition memory (Mumby and Pinel, 1994; Brown and Aggleton, 2001; Mumby, 2001). Similar dissociations of function between the hippocampus and perirhinal cortex have been revealed in rats (Aggleton and Brown, 2005) by examining the expression of the immediate early gene *c-fos* as a marker of neural activity.

The advent of functional magnetic resonance imaging (fMRI) has made it possible to delineate the neural circuits that contribute to distinct memory processes in humans, and to examine the extent to which dissociations between the function of the hippocampus and perirhinal cortex explain dissociations in recollective and familiarity-based performance in

amnesic patients. A number of studies employing the remember–know procedure and associative learning paradigms have now provided evidence that the hippocampus proper supports the encoding and retrieval of recollective information, whereas perirhinal cortex mediates the encoding and retrieval of familiarity-based memory traces (Wan et al., 1999; Davachi and Wagner, 2002; Davachi et al., 2003; Giovanello et al., 2004; Ranganath et al., 2004; Kensinger and Schacter, 2006).

Although these studies suggest a dissociation in the contribution of the hippocampus and surrounding cortical regions in recollection- and familiarity-based processing, respectively, these neuroimaging studies cannot speak to the necessity of particular regions for these memory functions. To fill this void, several studies have investigated the degree to which lesion locus or extent affects the likelihood that amnesic patients are impaired specifically on the recollective or associative components of a memory task. If the hippocampal formation is disproportionately engaged during recollective or associative processing, compared to familiarity-based item processing, then amnesic patients with damage limited to the hippocampus should show sparing of item recognition relative to associative recognition. In fact, patients with damage limited to the hippocampus sometimes slow preserved familiarity-based responding (Aggleton et al., 2005) and relatively normal item recognition performance (Vargha-Khadem et al., 1997; Holdstock et al., 2002; Mayes et al., 2002), despite impaired free recall (Henke et al., 1999; Duzel et al., 2001; Holdstock et al., 2005). These findings are consistent with the hypothesis that familiarity-based item memory can be supported by cortical regions outside of the hippocampus proper (e.g., perirhinal and parahippocampal cortices), while the hippocampus is critical for recollective and associative-memory performance.

Even this associative/item dichotomy may be too broad, however. Evidence suggests that the hippocampus is not equally engaged in all forms of recollective or associative memory. Rather, it may play a selective role in the learning of arbitrary associations between stimuli (O'Reilly and Rudy, 2001; Ryan and Cohen, 2004). Meaningful and preestablished relations between stimuli, in contrast, may be processed more as intraitem features, and memory for those associations may be mediated by regions outside of the hippocampus proper (Aggleton and Brown, 1999). Thus, amnesic patients with extensive hippocampal damage are able to learn some stimulus pairings when those pairing are logical and build from preexisting knowledge (e.g., learning word pairs such as baby–cries or rose–red; Skotko et al., 2004). They show dramatic deficits, however, when attempting to learn stimulus associations that cannot build on such prior knowledge (e.g., apple–tent, balloon–fork; see Gilbert and Kesner, 2004, for similar results in rats with hippocampal lesions).

Evidence to support this conclusion comes from a study assessing memory for compound stimuli (e.g., pinpoint), which can be thought of as a class of nonarbitrary stimulus pairings. All amnesic patients showed a recognition advantage for these compound stimuli as compared to stimuli with no preexisting associations (Giovanello et al., 2006). Moreover, the advantage for the compound words was numerically greater for patients with lesions limited to the hippocampus than for patients with more widespread MTL damage. In other words, patients with circumscribed hippocampal lesions were able to take advantage of the preexisting associations of the compound stimuli to a greater degree than were patients whose lesions included the surrounding MTL cortices. This pattern of results is consistent with the hypothesis that regions outside of the hippocampus proper contribute to memory for nonarbitrary stimulus associations, whereas the hippocampus itself is essential for binding arbitrarily related stimuli together.

In summary, these findings provide strong evidence for dissociations of function between the hippocampus and surrounding cortical regions. In particular, they highlight instances in which the hippocampus proper plays a particular role in memory for recollective and associative information, allowing memory for an item to be bound to its context or to other items present during the encoding episode. This role of the hippocampus may be particularly critical when associations among items, or between an item and its context, do not hold preexisting significance but, rather, represent the arbitrary merging of previously unrelated stimuli.

1.14.3.2 Counterpoint: The Hippocampus and Surrounding Cortices Support Both Item and Relational Memory

Although the research described above provides compelling evidence for a dissociation of function between the hippocampus and surrounding cortical regions, other researchers argue that the hippocampus and surrounding cortices are broadly important

for all forms of declarative learning, ranging from those that can rely on judgments of stimulus familiarity to those that depend on forming associations between previously unrelated stimuli (e.g., Reed and Squire, 1999; Stark and Squire, 2001). According to this view, any single dichotomy (e.g., recollection vs. familiarity or associative vs. item memory) is too simplistic to capture the division of labor between the hippocampus and the adjacent cortical structures in the MTL, although dissociations in function between different MTL structures may exist (e.g., Stark and Squire, 2003). In this section, we describe some of the neuroimaging and neuropsychological evidence suggesting that the dichotomies described above may not always hold.

If the hippocampus performs separable functions from the surrounding MTL cortices, then it should be difficult, if not impossible, to find patients with lesions limited to the hippocampus who do not show disproportionate deficits on tasks that assess the types of memory that the hippocampus mediates. In other words, patients with circumscribed hippocampal damage always should be disproportionately impaired on tasks that assess recall compared to recognition memory, recollection compared to familiarity, and memory for associations compared to isolated items. While these dissociations often occur in patients with focal hippocampal lesions (Henke et al., 1999; Holdstock et al., 2002, 2005; Mayes et al., 2002), they are not always present: Such patients can be equally impaired on measures of recall and recognition (Reed and Squire, 1997; Manns and Squire, 1999; Cipolotti et al., 2001; Manns, et al., 2003), and they can show comparable deficits on memory assessments for single items and for item conjunctions (Stark et al., 2002; Stark and Squire, 2003). For example, Stark et al. (2002) equated item recognition between patients with discrete hippocampal damage and control participants and then examined whether associative recognition was matched as well. When item recognition was equated between groups by providing hippocampal patients with eight study exposures, no impairment in associative recognition was observed for the patient group (although ceiling effects in patients' item recognition may have masked a disproportionate impairment in associative recognition; see Kensinger and Giovanello, 2005, for further discussion).

Moreover, if the hippocampus plays little to no role in familiarity-based processing of single items, then lesions limited to the hippocampus proper should largely spare performance on tasks that can be supported by these familiarity-based processes. As discussed in the preceding section, familiarity-based processing often is spared in amnesic patients with focal hippocampal damage. Some reports, however, indicate that damage circumscribed to the hippocampus can lead to marked deficits in recognizing factual knowledge about events that occurred after the amnesia onset (Manns et al., 2003; see also Reed and Squire 1998; Kapur and Brooks 1999; Holdstock et al. 2002) and in endorsing items as previously encountered (Beason-Held et al., 1999; Zola et al., 2000; Stark and Squire, 2003). These findings violate the prediction that performance on tasks that can be supported by familiarity alone should be intact after hippocampal lesions.

The reason for the discrepant findings across studies is a topic of heated discussion. Although any number of factors may contribute (e.g., differences in the tasks used, differences in lesion location, reorganization of function, deafferentation of regions due to fiber tract damage; see Mayes et al., 2002, 2004; Holdstock et al., 2005 for further discussion), we focus here on a few possibilities that we believe are particularly viable.

One feasible contributor to the conflicting findings is that patients' lesions likely are not circumscribed to functionally monolithic regions. Rather, the lesions probably encroach on multiple subregions that subserve distinct processes. For example, considering the entire hippocampus as a single functional entity, and expecting damage to any location within the hippocampus to result in similar mnemonic deficits, is probably an oversimplification. In fact, recent neuroimaging evidence has suggested that not all regions of the hippocampus play equivalent roles in associative memory (e.g., Giovanello et al., 2004; Kohler et al., 2005). For example, Kohler and colleagues (2005) found that while a middle hippocampal region responded more to novel associations than to novel objects, the same was not true of all hippocampal regions (and see Henson, 2005, for discussion of whether there is an anterior–posterior gradient within the hippocampus).

Similarly, it is likely that collapsing all extrahippocampal medial temporal-lobe cortical regions into one functional category overlooks critical divisions of labor. For example, patient and neuroimaging studies have suggested that the parahippocampal cortex plays an important role in memory for spatial and topographical information (e.g., Bohbot et al., 1998; Epstein and Kanwisher, 1998; Kohler et al., 1998; Maguire et al., 1998; Epstein et al., 1999; Ploner et al., 1999, 2000; Barrash et al., 2000), whereas the

perirhinal cortex may play a more dominant role in the processing of object information (e.g., Aggleton and Brown, 2005; Buckley, 2005). Moreover, functional neuroimaging evidence suggests that the perirhinal cortex and parahippocampal gyrus may serve functionally distinct roles in familiarity-based and recollective-based retrieval, respectively. Thus, while perirhinal activity often corresponds with familiarity-based memory for isolated items or for intraitem features (Davachi et al. 2003; Dobbins et al. 2003; Henson et al. 2003; Kirwan and Stark 2004; Ranganath et al., 2004), activity in the posterior parahippocampal cortex often appears to relate to recollection and to memory for item context or item associations (Henke et al., 1999; Yonelinas et al., 2001; Davachi et al., 2003; Dobbins et al., 2003; Duzel et al., 2003; Kirwan and Stark, 2004; Ranganath et al., 2004).

It is also probable that differences between the role of the hippocampus proper and that of the surrounding cortices reflect gradations of specialization rather than complete dissociations. In other words, the function of adjacent MTL structures may overlap somewhat: Differences may exist in the proportion of particular neural networks within regions that subserve mnemonic functions, rather than absolute differences in the functions supported by the different structures. Electrophysiological studies back this interpretation. Although evidence indicates that neuronal activity in the hippocampus often provides a signal for conjunctive coding of items in a context (e.g., Wood et al., 2000), whereas perirhinal cortex neurons tend to respond in a stimulus-specific fashion (e.g., Suzuki et al., 1997; Young et al., 1997; Suzuki and Eichenbaum, 2000), one can find exceptions to these generalizations. For example, although most hippocampal cells respond based on stimulus-context conjunctions, stimulus-specific representations (i.e., responses to the stimulus regardless of its context) occasionally evoke hippocampal activity (e.g., Fried et al., 1997). Conversely, evidence suggests that at least in some instances, neural activity throughout the MTL cortices can correspond with memory for item associations (e.g., Buckmaster et al., 2004).

A study by Cipolotti et al. (2006) provided a strong warning that ignoring the types of stimuli for which memory is assessed leads to discrepant results regarding the role of the hippocampus in memory. These authors tested a patient with a focal hippocampal lesion on tasks assessing memory for a range of verbal, visual, and topographical information. Their results suggested that the hippocampus plays a role in both recollective- and familiarity-based processing of verbal and topographical stimuli but is not necessary for recollection and familiarity-based memory of human faces. Although future studies will be needed to confirm the generality of these findings, and to clarify whether they extend to patients with damage located anywhere in the hippocampus or whether they may have arisen due to the precise location of this patient's hippocampal lesion, the data urge caution in trying to compare results across multiple studies using different stimulus types.

In summary, the results presented here caution against adopting too simplistic a division of labor between the hippocampus and the MTL cortices. While it is likely that these regions do make independent contributions to declarative learning and memory, a consensus has yet to be reached regarding the nature of those contributions.

1.14.4 The Role of the Perirhinal Cortex in Object Memory and Object Perception

In addition to debates regarding the distribution of mnemonic function across MTL structures, disagreement exists regarding the extent to which MTL structures play an isolated role in memory. In this section, we focus on a controversy regarding the role of the perirhinal cortex in memory vs. perception. As discussed earlier in this chapter, in order for animal models of amnesia to recreate the dense anterograde memory loss demonstrated in patients such as H.M., damage has often extended outside of the hippocampus proper and into the perirhinal cortex (e.g., Orbach et al., 1960; Mishkin, 1978; Zola-Morgan and Squire, 1985; Zola-Morgan et al., 1993; Murray and Mishkin, 1998). These studies emphasize that the perirhinal cortex must play an influential role in memory.

An ongoing debate, however, regards the extent to which the perirhinal cortex is important specifically for visual memory and the extent to which the perirhinal cortex plays a broader role in visual discrimination and object perception. Perirhinal cortex has the characteristics, in terms of anatomical connections, to support memory and perception side by side (e.g., Suzuki, 1996). Although perirhinal cortex is often considered part of the hippocampal-based memory system, with strong connections to the hippocampus via the entorhinal cortex (Suzuki, 1996), perirhinal cortex is a polymodal area with strong connections to regions within the ventral visual processing stream that are

specialized for object identification (e.g., Burwell et al., 1995; Murray and Bussey, 1999; Goulet and Murray, 2001). Neurons in perirhinal cortex also have properties that could support both object memory and perception (e.g., large receptive fields that respond selectively to complex visual stimuli; Logothetis, 1998; Jagadeesh et al., 2001). In this section, we present evidence for each side of the debate: According to one view, the perirhinal cortex plays a role encompassing memory and perception (e.g., Eacott et al., 1994; Eacott and Heywood, 1995; Murray and Bussey, 1999; Buckley and Gaffan, 2000; Murray and Richmond, 2001; Bussey and Saksida, 2002); according to another view, the contribution of perirhinal cortex is limited to memory, with stimulus perception dependent entirely upon cortical areas earlier in the ventral visual processing stream (e.g., Squire and Zola-Morgan, 1991; Zola-Morgan et al., 1994; Buffalo et al., 1998; **Table 1**).

1.14.4.1 Point: The Perirhinal Cortex Supports Visual Perception

Perception refers to the process of acquiring, interpreting, and representing incoming sensory information. Memory, in contrast, refers to the retention and retrieval of these representations in the absence of the sensory information. A deficit restricted to memory, therefore, should be observed only when an individual is required to distinguish alternatives after they have been withdrawn from view. In contrast, a deficit in perception should be apparent when an individual is asked to distinguish objects in plain sight.

Some of the first evidence that perirhinal cortex may have a role in perception came from Eacott et al. (1994). They tested macaque monkeys on a matching-to-sample task. In this task, monkeys first learn that a particular object (e.g., a red square) is associated with a reward (the sample phase). They then are shown the rewarded object and a second object (e.g., a red square and a green circle), and the monkeys must choose the initially rewarded object (the match phase). Critically, Eacott et al. (1994) included simultaneous match-to-sample and delayed match-to-sample conditions. While deficits in the delayed condition could result either from perceptual or mnemonic impairments, deficits in the simultaneous condition should reflect perceptual difficulties (because the objects remain in view). They found that when there was a large perceptual load in the task (i.e., when they used many different types of stimuli across all of the trials), the monkeys with perirhinal lesions showed impairments even in the simultaneous condition. These results support the interpretation that perirhinal cortex mediates visual perception.

Further delineating the exact role of perirhinal cortex in visual perception, however, has proved challenging. For example, Eacott and colleagues' (1994) study further showed that perirhinal cortex is not needed for all forms of object perception. When perceptual load was relatively low (i.e., when only a small set of items was used across all of the trials), monkeys with perirhinal lesions showed a delay-dependent deficit: They were impaired relative to control monkeys at the long delay but performed normally at the shortest delay. This pattern of performance is consistent with a mnemonic, and not a perceptual, deficit.

Several additional studies, using discrimination of pairs of visual stimuli, showed inconsistent results. Damage to the perirhinal cortex can lead to impairments in visual discrimination under some conditions, but it does not lead to a pervasive deficit across all assessments of visual discrimination. Thus, Buckley and Gaffan (1997), like Eacott et al. (1994), reported that monkeys with perirhinal cortex lesions performed as well as control monkeys when learning a small number of concurrent visual discriminations (see also Aggleton et al., 1997; Thornton et al., 1997; Buffalo et al., 1999; Baxter and Murray, 2001) but

Table 1 Predictions made by the perception-and-memory view of perirhinal cortex, compared to the mnemonic-only view, based on the stimulus characteristics and delay interval used on tasks such as matching-to-sample or visual discrimination learning

		Perirhinal cortex necessary?	
Stimulus characteristics	*Delay*	*Perception view*	*Mnemonic-only view*
Few stimuli, distinguishable by single object features	No	No	No
	Yes	Yes	Yes
Stimuli distinguishable only by conjunctions of intra-object features	No	Yes	No
	Yes	Yes	Yes

were impaired when required to learn a large number of discriminations (see also Buckley and Gaffan, 1998).

At a broad level, these results suggest that activity in perirhinal cortex may enhance the specificity of an object's representation (i.e., the level or amount of visual detail). When the task includes relatively few stimuli, the representation for each stimulus does not have to be precise or specific for discrimination to be successful. In contrast, when the stimuli are numerous and potentially confusable, each one must be represented precisely to avoid stimulus confusion (see Murray and Bussey, 1999; Bussey and Saksida, 2002, for further discussion). By this view, perirhinal lesions selectively impair object discrimination on tasks that employ large stimulus sets.

A study by Eacott et al. (2001), however, suggested that the perirhinal cortex is not critical for representing all fine-grained discriminations between objects. In their study, Eacott and colleagues required rats to distinguish between squares and rectangles, and they modulated the difference in side length between the two shapes such that the rats had to maintain a precise representation of the shapes to distinguish the square from the rectangle. Even with perirhinal cortex lesions, the rats were able to perform the task successfully. Critically, successful performance of this task could be based on representation of a single object feature: edge length. It is likely that this single-feature representation can be supported by areas earlier in the visual processing stream, such as inferotemporal cortex (see Buckley et al., 1997), and does not require engagement of perirhinal cortex (see also Buckley et al., 1997, 2001). Rather, perirhinal cortex may become necessary only when the representation of feature conjunctions is required.

In an influential model (the perceptual-mnemonic/feature-conjunction model), Bussey, Murray, and Saksida (e.g., Murray and Bussey, 1999; Bussey and Saksida, 2002) have proposed that perirhinal cortex serves as the final processor in the ventral visual processing stream (Desimone and Ungerleider, 1986; Ungerleider and Haxby, 1994), coding for complex visual representations. Within this framework, the results described above can be understood by considering the degree of feature ambiguity present across the different stimuli. The greater the number of object pairs to be discriminated, the greater the likelihood that a particular object feature will be rewarded when it is part of one object but not when it is part of another object (i.e., the greater the feature ambiguity). Because of the increased probability that a feature will be present among multiple stimuli, the representation of conjunctions of complex features in perirhinal cortex will be critical for successful task performance. The preservation of function in the study by Eacott et al. (2001) can be explained by reliance on a precise representation of a single feature (edge length) rather than on a need to integrate multiple intraitem features. Thus, the role of perirhinal cortex may be best described as representing configural relations among features, or conjunctions of intraobject features.

To test this hypothesis directly, Eacott et al. (2001) designed a visual discrimination task in which combinations of features, rather than any single object feature, signaled the rewarded object. Performance on this task was compared to performance on a task in which visual discrimination among stimuli could occur based on single features. Rats with perirhinal cortex lesions were impaired only when successful performance required discrimination based on the configuration of features; when performance could rely on representation of single features, the perirhinal-lesioned rats performed normally. Bussey et al. (2002, 2003) have found similar results when assessing visual discrimination in nonhuman primates: Monkeys with perirhinal lesions were impaired on tasks that required disambiguating shared features, but not on tasks that could be solved by discrimination of single object features. These results are consistent with the conclusion that perirhinal cortex functions as part of the ventral visual processing stream and plays a critical role in feature integration (see Bussey et al., 2005).

Further corroborating evidence has come from a study demonstrating that the requirement for feature integration can exacerbate the mnemonic deficits demonstrated after perirhinal damage. In a spontaneous recognition task, Norman and Eacott (2004) used rats' natural tendencies to explore novel items as a means to assess their ability to remember which objects had been encountered previously. The features of the novel objects were manipulated so that some differed from familiar objects in single features, whereas others differed from familiar objects in the conjunction of features. The critical finding was that perirhinal-lesioned animals showed an exaggerated memory deficit for the feature-ambiguous stimuli compared to the feature-unique stimuli. In fact, even after relatively short delays, the perirhinal-lesioned animals were at chance in distinguishing between the novel and familiar feature-ambiguous objects (Norman and Eacott, 2004).

These findings have led to the proposal that perirhinal cortex represents the association between intraitem features (Gaffan, 1994) or the gestalt representation of a whole object (Murray and Bussey, 1999). These putative functions of perirhinal cortex are consistent with its location among high-order processing regions in the ventral visual stream. These regions tend to respond to the whole object rather than to the individual features that comprise the object (Baker et al., 2002). Two open questions are whether perirhinal cortex plays a role in configural learning of all intraitem features and whether its role is limited to intraitem feature integration or also extends to the association of features that are spatially or temporally separable (see Alvarado and Bachevalier, 2005, for evidence of dissociable roles of the perirhinal and parahippocampal cortices in object vs. temporal configural memory; see Lee et al., 2005a,b, for evidence of dissociable roles of the hippocampus and MTL cortices in spatial vs. object perception; see Shaw et al., 1990, for evidence that perirhinal cortex may be important for cross-modal object processing). These questions are closely tied to the debate, discussed in the first section of this chapter, regarding the extent to which the roles of perirhinal cortex and hippocampus can be dissociated (e.g., with perirhinal cortex representing intraitem feature integration and the hippocampus representing item–item and item–context relations).

1.14.4.2 Counterpoint: The Perirhinal Cortex Supports Memory but Not Perception

As already discussed, perirhinal cortex is not required for all object perception. Patients with MTL lesions that include perirhinal cortex are not impaired on simultaneous visual recognition memory tasks (Milner et al., 1968; Buffalo et al., 1998; Holdstock et al., 2000) or on a wide variety of visual perception tasks (Lee et al., 2005b). Where debate arises, however, is in whether perirhinal cortex serves any role in visual perception. Although the evidence described in the preceding section suggests that this area does play a fundamental role in perception, at least for some classes of stimuli, other researchers have questioned the validity of these claims.

One concern relates to the way in which researchers analyzed their data to arrive at the conclusion that perirhinal cortex is critical for visual perception. For example, in a reanalysis of the data presented by Buckley and Gaffan (1997), Hampton (2005) demonstrated that the conclusions reached differ depending on whether the measure of assessment is considered to be errors made per problem or total number of errors. Animals with perirhinal lesions appear disproportionately impaired on tasks with larger stimulus sets when performance is measured by the total number of errors. The number of errors per problem, however, remains stable across different set sizes. Although extensive discussion has probed the extent to which these differences in analyses can account for all of the discrepant findings (Buckley, 2005; Lee et al., 2005b), at the least, the debate emphasizes the difficulty inherent in comparing perceptual ability across tasks with differently sized stimulus sets.

Another complaint has been that the studies described in the prior section have not always cleanly teased apart the perceptual and mnemonic demands of the task (Levy et al., 2005). Part of this conflation has stemmed from the fact that most of the studies have assessed the role of perirhinal cortex in rats or in monkeys. Teasing apart perception from memory is difficult in these animals. For example, failure to correctly identify a rewarded target could stem not only from difficulties perceiving the target but also from difficulties remembering which item is rewarded (e.g., whether the novel object or the familiar object is rewarded). It is much easier to dissociate perceptual and mnemonic processes in humans because explicit reminders about the task instructions can be given (e.g., "which of these stimuli matches this target object?"), thereby eliminating any mnemonic load.

A number of studies, therefore, have assessed the performance of amnesic patients with damage to perirhinal cortex on perceptual discrimination tasks. Buffalo et al. (1998) and Holdstock et al. (2000) used a matching-to-sample paradigm to assess object perception and recognition memory in amnesic patients, including those with focal damage to the perirhinal cortex. In the study by Buffalo et al. (1998), participants viewed four visual designs and then, following a variable delay, indicated whether an image presented alone had been one of the four previously seen. The results revealed that at short delays (0–2 s), patients with perirhinal lesions performed well on the task, whereas they were impaired at longer delays (6 s or more).

Similar results were revealed in the study by Holdstock et al. (2000), in which performance was compared in simultaneous and delayed matching-to-sample tasks. In the simultaneous matching condition, participants viewed a probe (an abstract pattern) along with possible targets and were asked to indicate which target matched the probe. In the delay conditions, the

probe was shown and then removed from the screen. Following a delay (ranging from 0 to 30 s), participants saw the possible targets and were asked to select the one that matched the probe image. Holdstock and colleagues found that the patients with perirhinal lesions were impaired only at long delays (10 s or longer) and performed within the normal range with shorter delays (less than 5 s) and in the simultaneous matching condition. The fact that performance was impaired at longer delays but not at shorter ones suggests that perirhinal lesions primarily caused mnemonic deficits and not perceptual ones.

Further evidence in support of the conclusion that perirhinal damage does not impair perceptual ability comes from studies by Squire and colleagues. Stark and Squire (2000) tested three patients with MTL lesions that included all of the perirhinal cortex on the oddity task developed by Buckley and colleagues (Buckley and Gaffan, 1998, p. 15; Buckley et al., 2001). In this task, participants are shown five different views of the same object, and one view of a different object. Participants must indicate which object is the odd one. Obscuring the objects with a white-noise mask makes the object discrimination task quite difficult. Stark and Squire (2000) tested the amnesic participants on seven versions of the oddity task. Across each version, the patients performed as well as control participants.

Levy et al. (2005) also reported results suggesting that perirhinal lesions do not lead to perceptual deficits in humans. The authors tested two of the amnesic patients who had been assessed on the oddity tasks on a task that required discrimination of complex feature-ambiguous stimuli (using the stimulus manipulations of Bussey et al., 2003). Just as with the oddity task, these patients performed normally on similarity judgment tasks (indicating whether pairs of images were the same or different) and on simultaneous matching-to-sample tasks (indicating which of two blended images was closest to a target image). These results suggest that complex visual discrimination performance and discrimination between images that have high feature ambiguity can occur even in the absence of perirhinal cortex function.

One potential difficulty in interpreting the results of Levy et al. (2005) is that the scores obtained by the control participants were very close to ceiling. It is possible, therefore, that a mild deficit would be revealed in the patients if their perceptual abilities were assessed using tasks that resulted in poorer performance by everyone (see Lee et al., 2005, for further discussion). In the task used by Stark and Squire (2000), however, the control participants' performance was well below ceiling, providing suggestive evidence that ceiling effects may not fully explain the findings.

Taken together, these results indicate that on a range of tasks, monkeys with perirhinal lesions fail, but humans with perirhinal lesions succeed. A few viable explanations for these contrary findings come to mind. First, the monkeys may have had damage to regions outside of perirhinal cortex. Damage to lateral visual areas is known to produce visual perception deficits (e.g., Mishkin, 1982; Miyashita, 1993; Buffalo et al., 1999), and it is possible that, in at least some of the studies in nonhuman primates, the lesions encroached on these lateral visual areas (Buffalo et al., 1999). Previous studies showed that the extent of inadvertent damage to lateral temporal areas can correlate more strongly with a monkey's ability to learn concurrent object discriminations than the extent of intentional damage to perirhinal cortex (Buffalo et al., 1998). Second, the function of perirhinal cortex with regard to visual perception may be distinct in humans and in nonhuman primates, or other regions within the human ventral processing stream may serve redundant functions with the perirhinal cortex in terms of processing feature conjunctions. Third, even stronger demands for processing high-level feature conjunctions may be required to witness impairments in humans with perirhinal damage; perhaps, on the tasks used to date, engagement of other types of strategies by human participants (i.e., other than discrimination based on feature conjunctions) has increased the likelihood that regions beyond perirhinal cortex can support successful task performance. Related to this last point, human perirhinal cortex may subserve visual perception only for a subset of object stimuli. For example, Lee et al. (2005c) demonstrated that patients with MTL damage were impaired at discriminating scenes and faces, but were less impaired at discriminating single objects, and were unimpaired at discriminating art (see also Lee et al., 2005a, for importance of stimulus type). A challenge for future studies is to determine whether any of these explanations can account for the conflicting results.

1.14.5 Retrieval of Autobiographical Memories in Amnesia

So far in this chapter, we have focused on the role of MTL structures in acquiring new declarative memories. In addition, considerable debate exists regarding

their roles in retrieving remote memories. While the hallmark of bilateral MTL lesions is anterograde amnesia, this inability to form new memories typically is accompanied by difficulty retrieving memories from some time period prior to the onset of the amnesia (i.e., retrograde memory loss). As was first noted by the French psychologist Théodule Ribot in 1881 (Ribot, 1881), the retrograde memory loss often follows a temporal gradient: It is more pronounced for recently formed memories and is less pervasive for older memories (now referred to as Ribot's Law). Consistent with Ribot's law, initial studies reported that, following MTL damage, retrograde amnesia often was limited to only the few years prior to the injury, with more remote memories relatively preserved (e.g., Milner et al., 1968; Corkin, 1984).

These findings suggested that MTL structures were not required for permanent storage and retrieval of memories. Rather, the region seemed to play a time-limited role in memory storage and retrieval. Based on this evidence, the presence of consolidation processes were proposed: physiological changes that take place in the brain to stabilize memories and to make them resilient to disruption. Memory consolidation can be described on two levels. The first is a rapid, molecular-level consolidation during which the long-term conductivity of synapses is affected by experience with particular stimuli or pairings of stimuli and responses. The existence of this phase of consolidation is widely accepted and will not be considered further in this chapter (for more on molecular consolidation see McGaugh, 2000; Kandel, 2001; Lee et al., 2004). Memory consolidation can also be described at the system or network level. Broadly, this level of consolidation is believed to take place over the long term (days to decades), with MTL structures critical for mnemonic storage and retrieval only until the consolidation process is complete (e.g., Squire, 1992). Two primary models for this level of consolidation have been proposed: the standard model and the multiple trace model.

According to the standard model of consolidation, a prolonged process of system consolidation may last for a decade or more (e.g., Squire and Alvarez, 1995; Dudai, 2004). During the initial phases of this consolidation process, the MTL is required for the storage and recovery of a memory trace. Over time, however, these structures become unnecessary as neocortical activity becomes sufficient to support storage and retrieval of memory traces. This standard model, therefore, provides a mechanism to account for the temporal gradient of retrograde amnesia. Retrieval of recent events is impaired because the MTL is still required for their retrieval, whereas retrieval of remote events is preserved because the MTL is not essential for their retrieval.

According to this standard model of consolidation, the MTL is required during the consolidation period for all declarative memories (i.e., both episodic and semantic) and becomes unnecessary after consolidation processes have terminated. Thus, this model predicts that retrograde memory loss should show the same temporal gradient regardless of whether the retrieved memories are semantic or episodic in nature (Squire, 1992; Squire and Alvarez, 1995).

In contrast to the standard model of consolidation, the multiple trace model (Nadel and Moscovitch, 1997) proposes that the MTL serves as a pointer, or index, to the neocortical areas that store the representations of information present during an encoding episode (see also Teyler and DiScenna, 1986). Thus, activity in a network of MTL neurons provides a means to bind together the different pieces of information that were attended to during a particular experience. Each time a memory trace is activated (e.g., through reminiscence), another pointer is created. These new pointers bind together many of the same representations as the original pointer, but they also may include some additional representations (reflecting new associations made during the reminiscence) and may neglect others (those not activated during the reminiscence). Because the exact content retrieved about an episodic memory varies somewhat in the representations retrieved, over time each autobiographical event will become represented by multiple, distinct neuronal networks distributed throughout the MTL. Because remote autobiographical memories tend to be activated a greater number of times than more recent ones, the number of neuronal networks representing a remote autobiographical memory usually will be greater than the number of neural networks representing a recent autobiographical memory. Probabilistically, damage to a subset of MTL neurons, therefore, will be more likely to eliminate all of the networks associated with recent memories than to erase all traces of remote memories. The multiple trace model, in contrast to the standard model, explains the temporal gradient of retrograde memory loss not in terms of a change in the necessity of the MTL for retrieval of the memories but, rather, in terms of a change in the likelihood that all of the MTL traces representing a memory would be damaged as a result of brain injury. The multiple trace model does, however, postulate

that over time, semantic memories (factual knowledge void of context) can become represented solely in the neocortex. This shift can occur because, although these facts initially were acquired in specific contexts (e.g., we learned that the Eiffel Tower is in Paris by listening to our second grade teacher, we were reminded of it by reading a tour book, etc.), over time, the factual knowledge becomes extracted from the context in which it was learned. At the point where retrieval of this factual knowledge can occur without retrieval of its encoding context, MTL structures are no longer needed.

The standard model and the multiple trace model both predict that retrieval of remote semantic memories can occur in the absence of functional MTL structures. Indeed, abundant evidence shows that retrograde amnesia for semantic information tends to follow a temporal gradient (e.g., Kapur and Brooks, 1999; Fuji et al., 2000) and that retrieval of remote semantic knowledge often is preserved following extensive MTL damage (e.g., Kensinger et al., 2001; Schmolck et al., 2002). The two models, however, diverge in their predictions for whether MTL structures are always required for the retrieval of autobiographical memories (as proposed by the multiple trace model) or whether, over time, the role of those structures is eliminated such that retrieval of remote autobiographical memories can be supported by activity in other neocortical regions (as postulated by the standard model; **Figure 5**). In this section, we examine the evidence for and against the conclusion that retrieval of remote autobiographical memories requires the MTL.

1.14.5.1 Point: Retrieval of Remote Autobiographical Memories Does Not Require the Medial Temporal Lobe

If the retrieval of remote autobiographical memories can proceed in the absence of MTL function, then amnesic patients should show a temporal gradient in autobiographical memory (i.e., better memory for remote events than for recent events, in contrast to the pattern of results typically displayed by control participants) and relatively preserved memory for remote events. Both of these predictions have been upheld in a number of studies. Often, amnesic patients show a temporally graded retrograde amnesia for autobiographical memory, similar to the gradation shown for semantic knowledge (e.g., Reed and Squire, 1998; Kapur and Brooks, 1999). Particularly in individuals with damage limited to the hippocampus, memory for events sometimes is affected only for recent time points, within a decade of amnesia onset (Reed and Squire, 1998). In contrast, patients with more extensive temporal lobe damage (including the temporal neocortex) often show more extensive retrograde memory loss (Reed and Squire, 1998).

Further, amnesic patients can also show a preserved ability to retrieve remote autobiographical experiences. Several studies have reported that amnesic patients recollect detailed, autobiographical experiences from time points removed from their amnesia onset (e.g., Schnider et al., 1995; Rempel-Clower et al., 1996; Reed and Squire, 1998; Fujii et al., 1999; Kapur and Brooks, 1999; Bayley et al., 2003, 2005). Particularly in patients with damage limited to the hippocampus, the level of detail recalled about these remote life events has been reported to be indistinguishable from that recalled by healthy individuals (Reed and Squire, 1998). In contrast, patients with larger lesions extending into the temporal neocortex often show pervasive impairments in retrieving autobiographical memories from remote time periods (Bayley et al., 2005).

The fact that hippocampal damage disproportionately affects memory for recent events, while relatively sparing memory for remote events, is consistent with the standard model's proposal that the hippocampus plays a time-limited role in memory retrieval. The correspondence of more extensive damage of the temporal neocortex to disruption of retrieval of remote autobiographical memories is consistent with the proposal that retrieval of these remote events is dependent on networks distributed throughout the neocortex.

Additional support for these claims comes from comparing the performance of patients with progressive MTL damage (e.g., patients with mild Alzheimer's disease) to the performance of patients with progressive damage to neocortical regions (e.g., patients with semantic dementia). Patients with Alzheimer's disease tend to show a temporally graded retrograde amnesia, with memory for recent events more impaired than memory for remote events (Piolino et al., 2003). In fact, a deficit in retrieval of remote memories typically occurs only later in the disease process, once the neuropathological changes have begun to appear in the neocortex. In semantic dementia, the opposite pattern of results has been demonstrated: a relative preservation of memories for recent events and a disruption in memories for remote events. Because semantic dementia causes

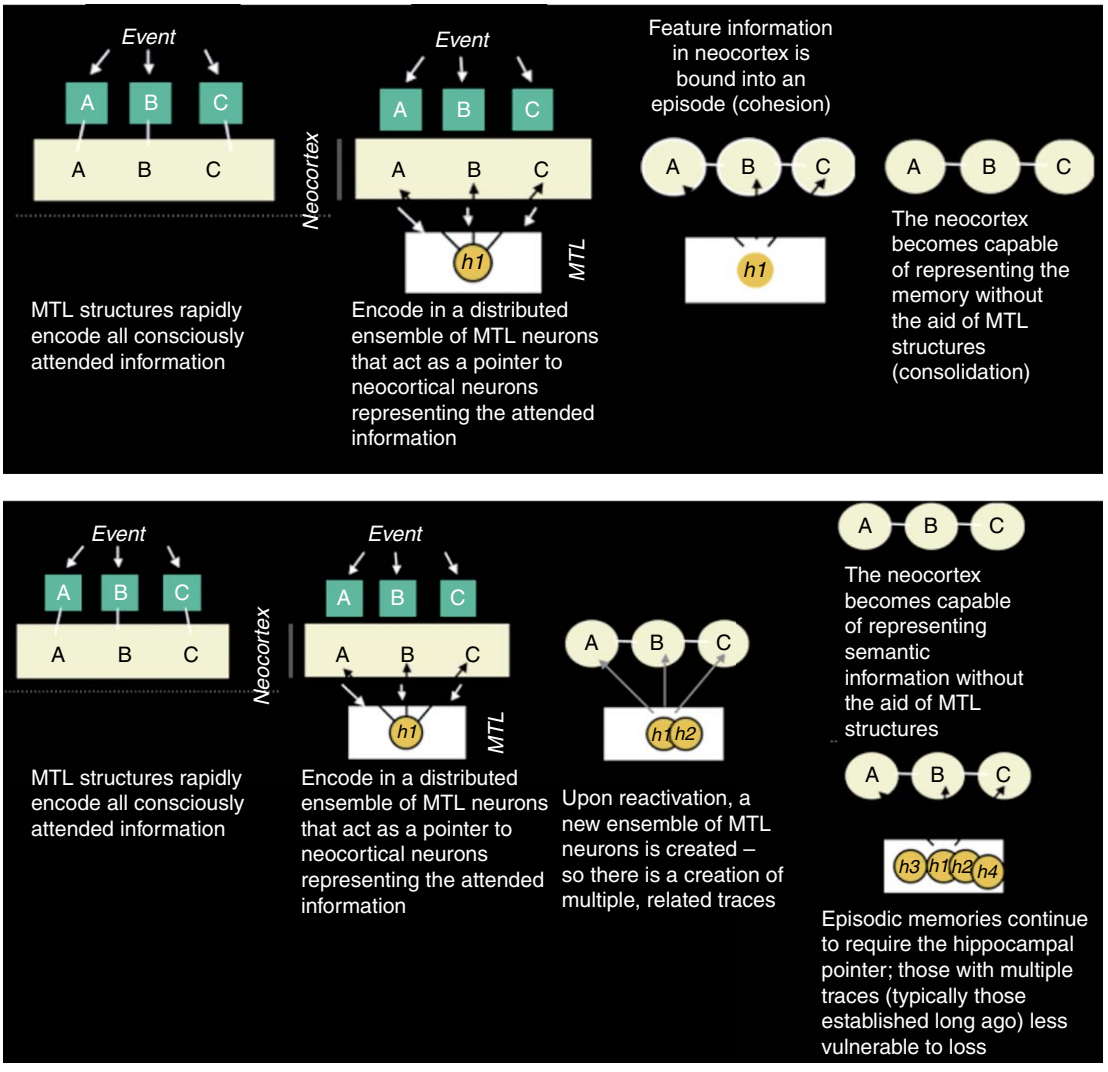

Figure 5 Phases of the consolidation process according to the standard model (top panel) and the multiple trace model (bottom panel). Adapted from Nadel L and Moscovitch M (1998) Hippocampal contributions to cortical plasticity. *Neuropharmacology* 37: 431–439.

progressive atrophy to the temporal neocortex, this pattern is consistent with the standard model's tenet that the hippocampus is needed for retrieval of recent memories but not for remote memories, while the temporal neocortex is critical for retrieval of remote memories (Murre et al., 2001; Nestor et al., 2002).

A study by Kopelman et al. (2003) reached a similar conclusion after assessing the correspondence between regional brain volume and autobiographical recall in 40 individuals with brain damage. They found that frontal lobe volume, and not MTL volume, accounted for individual differences in the retrieval of remote autobiographical memories. Corroborating evidence was revealed in a study by Eustache et al. (2004), in which resting-state glucose utilization in the hippocampus correlated with amnesic patients' ability to remember autobiographical events from recent time periods, while their ability to retrieve remote memories corresponded with glucose utilization in frontal cortex. Similar findings were reported in two functional neuroimaging studies of healthy volunteers. Piefke et al. (2003) found greater hippocampal activity during retrieval of recent autobiographical memories than during retrieval of remote memories; Takashima et al. (2006) found decreasing hippocampal activity (but increasing prefrontal activity) as a function of a memory's age (ranging from 0 to 3 months). These data are

consistent with the standard model's postulate that the hippocampus becomes less important as the age of a memory increases.

These findings all converge on the conclusion that MTL structures may not be required for retrieval of all autobiographical memories. While the function of MTL structures seems to be essential for retrieval of recently experienced events, remote memories appear to be retrieved in the absence of hippocampal function. Instead, retrieval of these events from one's past may rely on networks distributed throughout the neocortex.

1.14.5.2 Counterpoint: Medial Temporal Lobe Structures Are Required for Retrieval of Autobiographical Memories from All Time Periods

The story is not as straightforward as outlined above, however. A number of findings go against the claim that the MTL plays only a time-limited role in retrieval of autobiographical memories. For one, retrieval of remote autobiographical memories is not always spared in amnesia (e.g., Nadel and Moscovitch, 1997; Kopelman et al., 1999; Westmacott et al., 2001). For example, using family photos, Westmacott et al. (2001) found that the amnesic patient K.C. demonstrated a complete loss of memory for autobiographical episodes, even from remote time points (and see Rosenbaum et al., 2005, for similar findings). Steinvorth et al. (2005) similarly found that two amnesic patients (H.M. and W.R.) were severely impaired in retrieving remote autobiographical memories.

Second, amnesic patients often do not show a temporal gradient with regard to their autobiographical memories. This observation was made early on by Kinsbourne and Wood (1975), who suggested that amnesia affects autobiographical memories from recent and remote time points equally. This conclusion was corroborated in a series of studies by Warrington and colleagues, who demonstrated that amnesic patients often show a shallow temporal gradient (e.g., Warrington and McCarthy, 1988; Warrington, 1996). A few recent studies also have provided evidence of a flat temporal gradient for retrieval of autobiographical experiences (e.g., Cipolotti et al., 2001; Steinvorth et al., 2005).

How can one account for the discrepant findings in the amnesia literature, with some studies showing steep temporal gradients for autobiographical memory retrieval (with retrieval of remote memories relatively spared) and others showing shallower gradients (with retrieval of remote memories impaired)? One point of reconciliation relates to the specific locus of the amnesic patients' lesions. It is possible that some of the autobiographical retrieval deficits stem not from damage to the MTL but from damage to neocortical regions (see Squire et al., 2004, for more discussion). While extra-MTL damage should be considered, it does not appear to account for all discrepant findings. In at least some instances, damage specifically done to the MTL seems to correspond with difficulty retrieving remote autobiographical memories. Thus, even a patient with a lesion restricted to the hippocampal formation showed a flat temporal gradient and impaired retrieval of remote autobiographical memories (Cipolotti et al., 2001). This result suggests that flat temporal gradients cannot be ascribed merely to damage beyond the MTL. Further evidence suggesting a role of the MTL in retrieval of remote autobiographical memories came from a study examining whether the extent of MTL damage, as compared to damage to anterior and lateral temporal cortex, corresponded with the ability of Alzheimer's patients to retrieve autobiographical and semantic memories. Gilboa et al. (2005) found that while memory for semantic information was associated with damage to temporal neocortex, retrieval of autobiographical episodes was associated with the degree of MTL atrophy. Further, the strength of the association between MTL pathology and autobiographical memory retrieval was strong, even for childhood memories. These findings provide converging evidence that MTL regions remain important for autobiographical memory retrieval, regardless of the age of the memories being retrieved.

It is doubtful, therefore, that extra-MTL damage alone can account for all of the inconsistencies in the literature. Another possibility is that all regions within the MTL may not be equally important for retrieval of remote autobiographical memories. Squire and colleagues have argued that the hippocampus proper plays a critical time-limited role in retrieval of autobiographical memories (e.g., Squire, 1975, 1992; Squire et al., 1984). In their view, the surrounding MTL cortices may continue to be important for retrieval even of remote memories.

Because of the difficulties confirming that damage is circumscribed to the hippocampus and does not result in any functional damage to surrounding regions (e.g., through disruption of white matter fiber tracts), this hypothesis is difficult to address through testing of amnesic patients. Some evidence suggests that patients with damage limited to the

hippocampus show preserved retrieval of remote autobiographical memories (Levy et al., 2005), consistent with the claim that regions beyond the hippocampus are critical for retrieval of remote autobiographical experiences. Other studies, however, have reported impaired performance in patients with damage limited to the hippocampus (Cipolotti et al., 2001).

Neuroimaging studies in healthy individuals have provided one means to assess whether regions within the MTL are disproportionately active during retrieval of recent as compared to remote memories. As described in the previous section, some studies show that hippocampal activity is modulated by the age of the memory being retrieved (greater for recent than for remote memories; Piefke et al., 2003; Takashima et al., 2006). Increasing evidence, however, shows that hippocampal activity often is unrelated to the age of the retrieved memories. A number of studies have shown equivalent hippocampal activity during the retrieval of recent and remote autobiographical memories (Nadel et al., 2000; Maguire et al., 2001b; Ryan et al., 2001; Gilboa et al., 2004). One criticism of some of these studies is that the memories tested in the scanner were identified during a prescan interview; it is possible, therefore, that the true age of the memories was altered during this interview process. An fMRI study by Steinvorth et al. (2006) circumvented this problem. By assessing participants' memories for events written about in their diaries, or related by family members, these investigators measured brain activity associated with retrieval of memories that participants likely had not rehearsed recently. Although they found a large network of regions selective to autobiographical retrieval, the critical finding was that no MTL regions were more active during retrieval of recent autobiographical memories compared to remote ones. Although these studies cannot speak to the necessity of the regions, the fact that no MTL regions were less active during the retrieval of remote memories than during the retrieval of recent memories is inconsistent with the theory that the hippocampus plays a time-limited role in retrieval of autobiographical memories.

These results, therefore, suggest that differences in lesion location are unlikely to explain all of the contrary results within the amnesia literature. A more viable resolution may relate to a blurring of the contributions of semantic and episodic memory to autobiographical memory retrieval. Many of the studies that have assessed amnesic patients' ability to retrieve autobiographical memories have used procedures that do not differentiate memories that are semantic, or based on general knowledge about one's life, from those that are rich in contextual and temporal detail. Either of these types of information can allow one to recreate an autobiographical experience. For example, it is possible to remember one's sixth birthday party by reliving the tastes, sounds, and event locations. It also is possible to recall information about one's sixth birthday party by remembering the people present in a repeatedly viewed photograph, by repeating information often included in stories about the event, or by relying on general knowledge about the types of events that took place at most grade-school birthday parties.

Researchers have proposed that the ability to recall autobiographical information based on general knowledge relies on neocortical structures, just as do other forms of semantic memory (Nadel et al., 2000; Moscovitch et al., 2005). Thus, it is plausible that in studies that did not distinguish semantic from episodic contributions to autobiographical retrieval, amnesic patients appeared to have a preserved ability to retrieve autobiographical memories from remote time periods because those events had been rehearsed sufficiently to create a semantic memory, or because participants were able to rely on general knowledge about the event (Moscovitch et al., 2005).

The contribution of semantic and episodic memory to autobiographical retrieval has been assessed directly in studies that have asked participants to distinguish whether they vividly recollect a prior experience or simply know that the event has occurred. These studies have provided evidence that damage to MTL structures disrupts the ability to recall episodic details from events. A study with a patient with developmental damage to the hippocampus has clearly shown that such patients can retrieve autobiographical memories based not on episodic details but on semantic knowledge: The patient reported that there were some events from his life that he knew had happened, but that he could not recollect (Maguire et al., 2001a). Similar findings have been reported in a study of a patient who acquired MTL damage later in life (Hirano et al., 2002). In addition, Steinvorth and colleagues (2005) elicited memories for autobiographical events from two amnesic patients and from a number of age- and education-matched control participants. The investigators carefully scored the information generated by participants to distinguish recall of details based on semantic knowledge (e.g., the couch faced the television) from recall of details based on episodic knowledge (e.g., I felt the heat of the stove).

Neither patient could recall autobiographical memories with the same level of episodic detail as control participants. Their memories appeared to be constructed from semantic knowledge and were not associated with the feeling of being transported back in time (Steinvorth et al., 2005).

Further evidence to support the conclusion that many of the discrepancies in the literature relate to the amount of episodic detail remembered comes from comparing the findings of neuroimaging studies that reported greater hippocampal activity for recent than for remote memories with the findings from studies that found equivalent MTL activity regardless of a memory's age. In one study that demonstrated increased hippocampal activity for recent memories, those memories were associated with more episodic detail than were the remote memories (Piefke et al., 2003). The enhanced hippocampal activity, therefore, may relate not to the memory's age per se but, rather, to the amount of episodic detail retrieved. This hypothesis is consistent with studies that demonstrated greater hippocampal activity for memories retrieved with more episodic detail, both in patients with MTL damage (Maguire et al., 2001a) and in healthy individuals (e.g., Fink et al., 1996). In addition, a study by Addis et al. (2004) provided strong evidence that level of detail retrieved, rather than a memory's age, may be the strongest predictor of hippocampal engagement. Like Piefke et al. (2003), Addis and colleagues found that hippocampal activity was greater for recent memories than for remote ones. This finding, however, held only when the amount of episodic details recalled was not considered. Once level of detail was controlled, hippocampal activity no longer varied based on the age of the memories.

In another study that found greater hippocampal activation for recent than for remote memories, recognition memory was assessed over intervals ranging from 0 to 3 months (Takashima et al., 2006). As discussed earlier, two processes can contribute to recognition performance: episodic recollection or stimulus familiarity (Mandler, 1980; Tulving, 1985). Because recollection tends to decay over a delay faster than familiarity (Gardiner and Java, 1991), it is plausible that the decreasing hippocampal activity over time corresponded not with its reduced role in episodic recollection but with participants' increased reliance on stimulus familiarity (rather than on detailed recollection) after the delay. Support for this hypothesis is garnered from the fact that participants' performance after the delay was poor (corrected recognition performance was around 16%; Takashima et al., 2006).

These findings emphasize the need to assess not only the age of a memory but also the amount and quality of episodic detail retrieved about the memory. Future research will be needed to examine whether contradictions regarding amnesic patients' performance can be explained by considering the level of episodic (vs. semantic) detail retrieved. Recently developed interview techniques have emphasized the distinction between episodic and semantic details and have encouraged participants to generate as much information as possible about the event (e.g., to recall the sounds, colors, etc., that were present; Levine et al., 2002). These careful interview techniques make it possible to investigate the extent to which MTL damage (and damage to specific MTL regions, such as the hippocampus) disrupts the ability to recall episodic details from remote as well as recent time periods.

1.14.6 Conclusions

Since Scoville and Milner's landmark report on the amnesic patient H.M., a great deal has been learned about the types of memories that are preserved and impaired following MTL damage. As this chapter has highlighted, however, many open questions remain to be answered. Although resolution of the debates described here is a distant goal, this chapter has raised plausible hypotheses for the contradictions in the current literature and has provided a few pointers for further investigation. A common theme has been the need to examine structure–function correlations at a more fine-grained level than has been done to date. Future research will make great strides in elucidating the contribution of different MTL structures to human learning and memory if investigators examine the roles of distinct MTL structures, parse memory function into different categories based on retrieval demands and stimulus characteristics, and document the strategies that participants use for task performance.

1.15 The Nature of Infantile Amnesia

M. L. Howe, Lancaster University, Lancaster, UK

1.15.1 Introduction

Infantile amnesia, a term first used by Freud (1905/1953) over 100 years ago, refers to a unique memory phenomenon that occurs in humans and nonhumans alike. Essentially, infantile amnesia refers to a period very early in an organism's life when memories that are formed tend to be short-lived or inaccessible after a relatively short time frame. Historically, explanations have tended to fall into two camps. The first, or retrieval, camp holds that information that is stored early in life remains intact in storage and that infantile amnesia is the result of fluctuations in the retrievability of that information (Hoffding, 1891; Freud, 1914, 1938). The alternative, or storage, camp holds that memory storage is fragile early in life and that infantile amnesia is the direct result of this labile storage system (Kohler, 1929, 1941).

Modern theorists echo similar storage-failure and retrieval-failure conjectures about the nature of infantile amnesia. Proponents of this latter view argue that if storage is permanent and the inability to recall early experiences is simply a matter of retrieval failure, then such failures of remembering should be alleviated, given the appropriate reinstatement of retrieval cues (e.g., see Nash's (1987) discussion of the hypnotic age regression literature). This argument is fundamentally an encoding specificity one in which contextually dependent memories survive intact and can be recovered once the encoding context (internal and external) is reinstated. Of course it is difficult, if not impossible, to reinstate the context of infancy, and other data (reviewed later in this chapter) rule out a pure retrieval-based explanation in any event. Storage-based explanations have faired somewhat better. There is considerable evidence that although memory is much better in infancy than originally thought, storage in the immature organism is relatively fragile (Rovee-Collier et al., 2001). If storage is not permanent, particularly in the immature organism, then no matter what retrieval remedies are brought to bear, recall of early experiences may be impossible. Indeed, the general volatility of memory storage has been well documented over the years (e.g., Loftus and Loftus, 1980) and that it is somehow fundamentally different in infancy is equally well known (Hayne, 2004).

The issue concerning the fate of early memories is central to many theories of development, as most theories place special formative emphasis on experiences that occur early in life. This particular relevance of early experience was pivotal in Freudian theory as well as many subsequent theories of social, emotional, and personality development (e.g., see Ainsworth and Bowlby, 1991). Indeed, some early research demonstrated the profound effects of early experience (in this case, social isolation) on subsequent development (Skeels, 1966; Harlow et al., 1971). The question is whether memories of very early experiences that are alleged to result in aberrant adult outcomes are still available to consciousness or are lost to infantile amnesia, potentially exerting their effects without the person's awareness (also see Kagan, 1996).

In the nonhuman animal literature, infantile amnesia refers to the faster forgetting that is associated with immature organisms than with more mature members of the species. This more rapid forgetting in younger than older animals occurs even when levels of initial learning have been equated (see Campbell and Spear, 1972; Arnold and Spear, 1997). Much of the animal research on accelerated forgetting during infancy has been

conducted on the rat, with the early consensus being that young pups were more susceptible to interference effects in memory (Smith and Spear, 1981), a condition also thought to pertain to young humans (Kail, 2002).

Although increased susceptibility to interference effects is certainly one possible contributor to the frailty of early memory, it is by no means the sole factor. Indeed, depending upon encoding and testing conditions, young humans may be no more susceptible to interference than older children and adults (e.g., Howe, 2000; Rovee-Collier et al., 2001). As we will see, the waning of infantile amnesia is the result of changes to a number of basic memory processes, ones that emerge from correlated changes in cognitive structures. To see how, I review the latest research concerning neurobiological and behavioral underpinnings of infantile amnesia in human and nonhuman animal populations.

1.15.2 Neurobiological Factors

To begin, consider how neural maturation impacts memory. Because of the high degree of overlap between human and nonhuman animal species in the development, anatomy, and function of the hippocampus (and parahippocampal regions; e.g., Ferbinteanu et al., 2006; Manns and Eichenbaum, 2006), the results of this research will be considered together. Given space limitations, I present only a brief overview of the basics of the neural underpinnings of memory development and will touch on more specific aspects as needed (more detailed reviews can be found in Serres, 2001; Gogtay et al., 2006).

Nelson (1997, 2000) has argued that there are at least two memory systems that have different developmental trajectories. The earliest to emerge is implicit (or procedural) memory, a system that is capable of performing recognition tasks such as novelty preference, habituation, classical and operant conditioning, and visual expectancy tasks. The neurological substrates that are involved in implicit memory (e.g., the hippocampus, striatum, cerebellum, and olivary–cerebellar complex) are sufficiently developed very early in postnatal life to support this form of memory basically from birth (and perhaps before).

Explicit (or declarative) memory not only depends on hippocampal structures but is also thought to depend on inputs from elaborate networks of neocortex that converge on parahippocampal structures (e.g., entorhinal cortex; Serres, 2001). These diverse inputs are then organized into a cohesive memory trace in the hippocampus. Although some of the neural structures related to explicit or declarative memory develop early, others have a more protracted developmental course, with significant changes occurring at the end of the first postnatal year and the beginning of the second year (Serres, 2001). Of particular interest is the dentate gyrus of the hippocampus, because this serves as a critical link in the circuitry that connects the parahippocampal structures to the hippocampus (specifically to the CA3 and CA1 regions). Developments are also occurring in the frontal cortex and in the reciprocal connections between the neocortex and the hippocampus (Serres, 2001). Although neurogenesis in the dentate gyrus continues throughout life (e.g., Aimone et al., 2006), the network necessary to sustain explicit memory reaches functional maturity (in humans) late in the first year of life (Nelson, 1997, 2000; Serres, 2001). Although additional refinements occur throughout development, by the beginning of the second year of postnatal life, humans are capable of sustaining explicit or declarative recollection.

From this brief review, it would seem that the timing of these neurological changes (at least in humans) is at odds with the oft-cited empirical finding that the earliest autobiographical memories begin around the end of the second year of life (see Howe and Courage, 1993, 1997). As will become clear in later sections, neurobiological constraints may not be at the source of infantile amnesia at all. Although there are clear advances in neocortical structures that continue during early maturation, some of which might contribute, albeit indirectly, to the demise of infantile amnesia (see later discussion; Levine, 2004), I have argued previously (Howe and Courage, 1993, 1997; Howe, 2000, 2004), as has Bauer (2004), that neither age nor neurological developments control memory longevity after the basic neural 'hardware' has been laid down. Instead, the termination of infantile amnesia, like changes in other areas of memory, is controlled by alterations in the basic processes of encoding, storage, retention, and retrieval that drive memory across development and perhaps species. Although such changes may have obvious neurobiological correlates, their origins may have more to do with the development of an organism's knowledge (cognitive) structures than with additional neurobiological change by itself.

1.15.3 Behavioral and Cognitive Factors

1.15.3.1 Nonhuman Animal Populations

Research on behavioral and cognitive manifestations of infantile amnesia has focused on both faster forgetting in immature organisms and whether nonhuman animals possess autobiographical (or even episodic) memory in the first place. This latter question asks whether animals are 'stuck in time' (for a review, see Roberts, 2002). If so, then they cannot travel cognitively into the past and hence do not have what Tulving (1985, 1989, 1993) refers to as episodic memory. Tulving contrasts episodic memory and its concomitant autonoetic consciousness (personal awareness of remembering) with semantic memory and noetic consciousness in which organisms possess general information but do not experience a specific awareness of experiencing it in time. This distinction has also been linked to remember–know judgments, where remember judgments involve episodic memory because the organism remembers a particular experience having occurred in a past context, whereas know judgments involve a sense of familiarity but not a sense of personal, past experience. Although this sense of time also refers to planning for the future, the main point is whether nonhuman animals do possess the what, where, when, and perhaps who of past events. Tulving argues that, although nonhuman animals do have a well-developed knowledge of the world (e.g., general relationships between stimuli and events) derived from specific episodes, they do not code temporal information that allows them to travel back and reexperience the past episodes – that is, they have semantic memory but not episodic memory.

Clearly, it is unlikely that we will ever establish whether nonhuman animals (or preverbal humans) have autonoetic consciousness. This is because there are no agreed-upon behavioral markers of conscious experience (Griffiths et al., 1999). Hence, any model of episodic memory that requires conscious awareness must apply solely to language-using organisms. As Clayton et al. (2003a) point out, with the exception of putatively language-savvy apes and parrots, there is no litmus test that would establish that an organism was reexperiencing the past when remembering an episode.

Recognizing the futility of using phenomenological criteria in language-challenged organisms, researchers have focused on behavioral criteria in an attempt to establish that nonhuman animals (and preverbal humans) do have episodic-like memory. Specifically, there are three behavioral criteria that are consistent with Tulving's definition of episodic memory: (1) memory content, recollecting what happened where and when; (2) memory structure, having an integrated what-where-when representation; and (3) memory flexibility, deploying information in a flexible fashion (e.g., see Clayton et al., 2003a). Concerning the first criteria, the when of what-where-when seems to be particularly important in establishing that the memory is episodic. That is, a number of different episodes can all share what and where, but they cannot share when. Concerning the second criteria, what, where, and when cannot simply be linearly connected, but rather all three need to be in an integrated representation, so that retrieving any one retrieves the others. The third criteria simply states that, because episodic memories are declarative, they are by definition flexible (unlike nondeclarative memories, which are inflexible and inaccessible to consciousness). Therefore, animals should be able to flexibly deploy memories in new situations.

To date, episodic-like memories have been demonstrated in birds (e.g., western scrub jays, *Aphelocoma californica*; Clayton and Dickinson, 1998, 1999; Clayton et al., 2001, 2003c, 2005; Dally et al., 2006), rats (*Ratus norvegicus*; Eacott et al., 2005; Norman and Eacott, 2005), and gorillas (*Gorilla gorilla gorilla*; Schwartz et al., 2005). In this latter study, King, an adult male western lowland gorilla, remembered the order of past events as well as where the events occurred. Dally et al. (2006) have recently shown that western scrub jays remember not only the what-where-when of specific food caching episodes but also who (which other scrub jay) was watching them while they were hiding food, altering their recaching behavior accordingly. Episodic-like memories have also been demonstrated in pigeons (*Columba livia*; Zentall et al., 2001) and dolphins (*Tursiops truncates*; Mercado et al., 1998). Indeed, pigeons exhibited trace flexibility by accurately reporting whether they had recently been pecking when such reports were not anticipated, and dolphins too showed this flexibility by correctly reproducing actions recently performed (for a review, see Hampton and Schwartz, 2004).

Although some remain skeptical about whether these memories are episodic or even episodic-like (e.g., Roberts, 2002; Suddendorf and Busby, 2003a,b; but see Clayton et al., 2003b), questions concerning nonhuman animals' potential for autobiographical memory, at least as measured by behavioral criteria, remain an area of intense scientific debate and

research. Indeed, there are those who suggest that the anatomical details of the hippocampus and parahippocampal regions of the brain are conserved across (human and nonhuman) mammals (Manns and Eichenbaum, 2006). Moreover, these authors also claim that the functional role of these neural regions in declarative memory is also conserved across species. To the extent that the hippocampus and parahippocampal regions are critical for declarative, episodic memory (e.g., Tulving and Markowitsch, 1998; de Hoz and Wood, 2006), these across-species similarities are consistent with the claim that episodic (and perhaps autobiographical) memory may exist in a variety of mammalian species and is not special to humans. Perhaps the autonoetic component of human conscious recollection is epiphenomenal and is not a requirement of the memory itself. Indeed, Ferbinteanu et al. (2006) argue that autonoetic experience is a feature of human consciousness and not an aspect of episodic memory per se. Hence, episodic memory may exist in many species and can be measured behaviorally in human and nonhuman species alike. Certainly, as Manns and Eichenbaum (2006) point out, there are differences across species in the psychological properties of episodic memories (perhaps including autonoetic experiences), but these may be due to other differences in neocortical inputs to the hippocampus and parahippocampal regions, as well as the neocortical circuitry that mediates their outputs, determining their behavioral expression, rather than to differences between species in the hippocampal and parahippocampal regions themselves.

Although there may be some additional research needed before we can close the book on episodic memory in nonhuman animals, that these same organisms experience infantile amnesia is not contentious, although like episodic memory itself, the cause of this amnesia may not be the same across human and nonhuman animal species. Research by Richardson and colleagues (Richardson et al., 1983, 1986; Westbrook et al., 2002; Yap et al., 2005; Kim et al., 2006; Weber et al., 2006) with rat pups has shown more rapid forgetting in younger rats than older rats. More important, this research has shown that many of the behavioral markers indexing infantile amnesia in human infants are similar to those observed in nonhuman animals. For example, both human and nonhuman infants show faster forgetting than older members of the species and increased recollection following reinstatement treatments. This latter phenomenon was thought to rule out storage-failure hypotheses of infantile amnesia and instead favor retrieval failure mechanisms, because memories cannot be reactivated if they are not somehow present in storage. For example, the effects of infantile amnesia have been mitigated by injecting naloxone prior to training a fear response (Weber et al., 2006), indicating that central opioid receptors regulate retrieval of fear memories in rat pups. Similarly, in a recent article, Kim et al. (2006) have shown that, although younger rat pups retain fear conditioning for relatively short periods of time, administration of the gamma-aminobutyric $acid_A$ ($GABA_A$) receptor partial inverse agonist FG7142 alleviated infantile amnesia. It appears as though FG7142 facilitated the retrieval of a forgotten memory, showing for the first time that GABA receptors play a central role in the forgetting of fear memories from infancy.

Theoretically, these findings are critical to our thinking about infantile amnesia and memory continuity. Specifically, because GABA receptors play a role more generally in forgetting regardless of the age of the organism, perhaps forgetting early in life (infantile amnesia) and forgetting in adulthood simply represent quantitative variation rather than qualitative differences in forgetting mechanisms. Although certainly not conclusive, the fact that the same treatment that facilitates retrieval in adults also facilitates infant memory is more consistent with the memory-continuity hypothesis.

Of course, there is considerable evidence that storage factors play a role as well, because of the more rapid forgetting of information by more immature organisms. The longer an early memory has been in storage without reminders, the more likely it is to have decayed. Indeed, early memories that have been forgotten for longer periods of time are more difficult to recover than memories stored for shorter periods of time (e.g., Joh et al., 2002). Moreover, there is evidence that posttraining injections of pharmacological agents (glucose, epinephrine, norepinephrine) known to facilitate storage and consolidation in adult rats (Gold et al., 1982; Flint and Riccio, 1999) also mitigate the effects of infantile amnesia in rat pups. Thus, both storage and retrieval play roles in infantile amnesia, at least in nonhuman animals.

Finally, Richardson and his colleagues have shown that despite infantile amnesia, induction of fear responses in rat pups remains time-locked in memory. Specifically, for rats, fear is expressed in age-appropriate ways, ones that unfold with development (Yap et al., 2005). As it turns out, learned fear is expressed in terms of the age at which the animal was trained (time

of encoding), not at the age at which it was tested (Richardson et al., 2000; Richardson and Fan, 2002). Interestingly, these memories can be updated by subsequent experience. That is, memory updating can occur, and the expression of fear can be recalibrated to a more mature response, if a similar fear experience occurs at an older age (Yap et al., 2005). These results have implications for whether and how single versus multiple fear events (including acute versus chronic adverse experiences) occurring early in life may be remembered and expressed. Moreover, for language-using organisms, these results raise the question of whether experiences that have occurred before the vocabulary (receptive or productive) necessary to communicate those experiences can ever be expressed linguistically. If responses are truly time-locked at encoding, and language is not available at that time, then the answer to this question is no. I return to this point in the next section, when I consider behavioral and cognitive factors relevant to infantile amnesia human populations.

1.15.3.2 Human Populations

Like their nonhuman counterparts, studies of memory with preverbal human infants are difficult at the best of times. This is because memory tasks must be nonverbal in nature, in terms of both the task instructions and also the types of responses indexing remembering. Moreover, like nonhuman animals, preverbal human infants cannot provide us with an unambiguous indication of their conscious state during recollection. Despite these difficulties, like studies with nonhuman animals, experiments using a wide range of tasks have established beyond a reasonable doubt that human infants do possess declarative, episodic memory if not before the end of the first year of life, shortly thereafter.

Although a complete review of techniques and outcomes from infant memory research is beyond the scope of this chapter, comprehensive overviews are readily accessible (Rovee-Collier et al., 2001; Howe et al., 2003; Courage and Howe, 2004; Hayne, 2004). Instead, I will focus on several key paradigms and outcomes that illustrate the precocity of infant memory and auger well for our discussion of infantile amnesia. To begin, there are a variety of reports concerning memory for operantly conditioned events very early in life, including memory for *in utero* conditioning. For example, DeCasper and his associates have shown that newborn infants can recognize the prosodic characteristics of a story heard in the last trimester of their prenatal life and have determined the factors that affect this recognition memory (DeCasper and Fifer, 1980; Decasper and Prescott, 1984; DeCasper and Spence, 1986, 1991; Spence, 1996; Spence and Freeman, 1996).

Infants are also willing to imitate motor activities performed by an adult or peer. For example, Meltzoff and colleagues demonstrated that 6-week-olds reproduce various facial expressions and head movements modeled by an adult over a 24-h retention interval (Meltzoff and Moore, 1994). As infants mature, they can model more and more complex sequences over longer and longer delays (for a review, see Meltzoff, 1995). A strength of Meltzoff's work is that the activities performed were novel, were modeled without instruction, and were not performed by infants prior to the retention test. Thus, imitation was likely based on stored representations of previous experience and as such indexes recall (declarative memory) not recognition.

In all, experiments using conjugate reinforcement (Rovee-Collier et al., 2001), novelty preference (Courage and Howe, 1998; Courage et al., 2004), deferred imitation (Meltzoff, 1995; Hayne, 2004), elicited imitation (Bauer, 2004), and behavioral reenactment (McDonough and Mandler, 1994; Sheffield and Hudson, 1994) indicate that, like the findings for nonhuman animals: (1) when initial learning is equated, infant age and longevity of memory are positively correlated; (2) length of retention is affected by factors such as distribution of practice (spaced better than massed) and the match between proximal and distal cues at encoding and test; and (3) retention can be prolonged given appropriate reinstatement treatments. Thus, although fragile and short lasting, even very young infants can demonstrate declarative memory. As the neural structures that subserve declarative memory mature (see earlier sections in this chapter), declarative memories become longer lasting and less susceptible to decay and interference.

Although impressive, infants' encoding, storage, retention, and retrieval feats are still not as robust as those of children who have matured beyond the infantile amnesia threshold. Indeed, experiences before the age of 2 years appear to remain mysteriously 'time-locked' and inaccessible to conscious recall. Recollection, if any, is disjointed and fragmentary at best (Bruce et al., 2005) and may not be verbalizable (Simcock and Hayne, 2002). However, as has been known for a long time, at around the age of 2 years, memories become more stable and can be retrieved later in childhood and adulthood (Dudycha and

Dudycha, 1933; Kihlstrom and Harackiewicz, 1982; Usher and Neisser, 1993; Eacott and Crawley, 1998; Newcombe et al., 2000; Crawley and Eacott, 2006). Although often researchers will probe memories for specific, ostensibly significant events (e.g., birth of a sibling, death, traumatic experience), there does not appear to be any specific trend in the content of earliest memories. That is, although such recollections are not of mundane, everyday events (e.g., what one had for breakfast on the third day of December when one was 2 years old), neither do they have to be particularly traumatic (e.g., Bruce et al., 2005). Indeed, the recollections we have from around the age of two are often decontextualized segments of the past that are simple recollections of sensory experiences, behaviors and actions, or a feeling (Bruce et al., 2005).

As seen earlier in the neurobiological section, neurological changes can certainly drive many of the developments in memory that occur during the first postnatal year, but they cannot, by themselves, explain the changes in memory longevity observed in human episodic memory. Instead, we have to examine corresponding changes in cognitive development. Although many such changes exist around this transitional period (see Courage and Howe, 2002), the key development driving autobiographical memory is the onset of the cognitive self (Howe and Courage, 1993, 1997).

Briefly, consistent with trace-integrity theory (Howe, 2000), storage and retrieval lie on a single continuum, where traces consist of collections of primitive elements (e.g., features, nodes) that are integrated into a single cohesive (neural) structure in memory. The better integrated a trace is, the better it is retained over time and the less susceptible it is to interference. The less integrated a trace is, the more likely it is to recede into the background noise of other faded memories, losing its distinctiveness and hence its inherent memorability. Although these assumptions are consistent with most models of memory, it does organize a rather large literature on children's memory development more broadly and accounts for the offset of infantile amnesia and the onset of autobiographical memory, at least in humans. More specifically, as our proficiency with organizing information increases with changes in our knowledge structures, we are better able to group information in memory into cohesive structures that are more stable and relatively permanent. The key event relevant to autobiographical memory is the self – that is, you cannot have an autobiography until you have a self. As it turns out, there is considerable research that indicates that there is a dramatic shift in the development of the self that occurs around 18 to 24 months, one that results in the advent of the cognitive self (for a recent review, see Howe et al., in press). Although the specific details are not critical here, the main point is that, because a recognizable self contributes features that increase the cohesion of a memory trace, such traces are no longer event memories but memories of events that happened to me. That is, they are autobiographical.

Interestingly, it may be no coincidence that there exist corresponding neurological developments relevant to this expanding knowledge base of the self. Indeed, prefrontal areas related to autobiographical recall and the self are undergoing developmental change – for example, cortical gray matter volume increases until age four and then declines (synatogenesis followed by pruning; see Pfefferbaum et al., 1994). Functional neuroimaging studies have shown that portions of the anteromedial prefrontal cortex are involved in processing self-related information and autobiographical recall (see Levine, 2004). Although I would not argue that there is any direct link between these neurobiological changes and the offset of infantile amnesia, given that the mind is somehow a function of the brain (Levine, 2004), the cognitive advances that drive the onset of autobiographical memory may have their neural correlates in early changes in the prefrontal cortex.

Behavioral evidence has been accumulating over the past decade or so that also indicates that the self plays a key role in the onset of human autobiographical memory. For example, Harley and Reese (1999) found that the critical event related to the onset of autobiographical memory was the advent of the cognitive self (as measured by mirror self-recognition) and not performance on language measures, deferred imitation tests, or sociolinguistic measures (e.g., style of maternal reminiscing). More recently, Howe et al. (2003) reported that long-term retention of a unique event was also contingent on children having a cognitive self and not on other, related measures (e.g., language). Most recently, Prudhomme (2005) found that the cognitive self was essential for early declarative, autobiographical memory. Indeed, Prudhomme found that children with a cognitive self were not only better than those without a cognitive self on an elicited memory task, but they were also much more flexible when retrieving information.

Consistent with the theoretical approach advocated by Howe and Courage (Howe and Courage 1993, 1997; Howe et al., in press), this research makes clear that early autobiographical memory in

humans is contingent on cognitive advances, specifically the advent of the cognitive self. As children mature, the number of autobiographical events that can be retained increases due to a whole host of reasons related to memory development more generally, a discussion of which is beyond the mandate of this chapter (but see Howe, 2004; Howe et al., in press). However, an important question remains, namely what happens to memories from the infantile amnesia period. Although already acknowledged as being fragmentary at best, do they remain time-locked, or can they be later retrieved and recoded using newly acquired language skills? For humans, the period of infantile amnesia is also one in which language skills are relatively impoverished. Language acquisition was thought by many to herald the end of infantile amnesia (see Allport, 1937; Schachtel, 1947). Some current theories of infantile amnesia also emphasize the importance of language (see Harley and Reese, 1999). However, to the extent that infantile amnesia is similar in human and nonhuman animals, the role of language in the offset of infantile amnesia may be epiphenomenal. Indeed, the current evidence indicates that language does not play a causative role in the offset of infantile amnesia. However, language is one way in which humans rehearse, elaborate, preserve, and communicate memories, including autobiographical ones. So although it may not be germane to our nonhuman counterparts, it may be one of those neocortical inputs and outputs to the hippocampal and parahippocampal areas that varies across species and is important to later developments in autobiographical memory.

Curiously, although infants can recall past events behaviorally, there is little evidence that their memories are accessible to verbal report if they were laid down prior to the offset of infantile amnesia. Some studies that have shown verbal reports of early memories tested recall under conditions of high contextual support (e.g., Bauer and Wewerka, 1995, 1997). Other studies in which the degree of contextual support was much less have failed to produce verbal reports of early memories (Simcock and Hayne, 2002, 2003). Interestingly, in these latter studies, although children clearly had acquired the vocabulary to report the prior events, verbal ability was not related to memory performance. That is, children's sparse verbal reports of previous events were not due to poor memory per se, as these same children were able to accurately recognize photographs of the previous event as well as reproduce them behaviorally.

Simcock and Hayne's (2002, 2003) research provided considerably less contextual support than Bauer and Wewerka's (1995, 1997) studies. Could it be that contextual support is the key to 'helping' memories make the transition across the infantile amnesia barrier? More recent studies suggest this might be the case. For example, Bauer et al. (2004) found evidence of verbal reports of early memories only when event-related props, but not color photographs (as in the Simcock and Hayne studies), were provided as cues. Interestingly, verbal reports were not obtained from children who only experienced the events once. What this might indicate is that multiple exposures are necessary for events to cross the infantile amnesia threshold. Of course rehearsal is important in memory generally, and events that are repeated are better remembered than those that are not repeated.

More importantly, verbal evidence of memory was seen only in those children who were 20 months old at the time of the original experience and not those who were 13 or 16 months old at that time. Similar findings have been reported in other studies (e.g., Bauer et al., 1998, 2002) and are critical to the argument presented here concerning the importance of the cognitive self. Although language measures have been obtained in each of these studies (to insure adequate vocabulary to express the events), measures of the cognitive self have not been secured. However, it is clear from the vast literature on the development of the cognitive self (for a review, see Courage et al., 2004; Howe et al., in press) that the 13- and 16-month-olds who failed to exhibit later verbal recall were below this cutoff at the time the event was first experienced, whereas those who did evince verbal recall, the 20-month-olds, were above this cognitive self threshold. A similar finding has been reported by Morris and Baker-Ward (2007) using physical props (e.g., a bubble-making machine) to reinstate the encoding context in 2-year-olds; however, again, a test of the children's cognitive self was not administered.

1.15.4 Conclusions

Several conclusions emerge from this review of infantile amnesia. First, the recent literature on neural structures related to memory (particularly the hippocampus and parahippocampal regions) makes it clear that we share certain anatomical, functional, and developmental similarities with nonhuman animal species. Although there is clearly room for across-species variation in performance and

the manner in which memories are expressed, due to well-documented and substantial differences in neocortical inputs and outputs, the marked similarity in hippocampal (and parahippocampal) anatomy, function, and development is unmistakable.

Second, perhaps because of our common hippocampal (and parahippocampal) neuroanatomy, functionality, and developmental trajectory, we share with our nonhuman animal counterparts episodic or episodic-like memory, a memory like others that develops with maturation. Regardless of species, human and nonhuman animals alike can code the what, where, when, and even who of past events and use that information to guide behavior. Although the conscious, autonoetic component of recollecting autobiographical memories may be uniquely human, something that may arise given the considerable across-species differences in neocortical structures, that we share episodic memory with other species is not in doubt.

Third, and perhaps because of our common episodic memory capabilities, we also share with other species one of the limitations of early episodic memory, infantile amnesia. That is, there is faster forgetting of information than in more mature organisms, memories that are laid down are more susceptible to interference in younger than older members of the species, and for those species that recall past events, memories for early events are less accessible later in life than memories for events that occur when we are older. For humans, this infantile amnesia abates at around 2 years of age and is aided by the advent of the cognitive self. This perhaps uniquely human construct may have its roots in additional neural development in the prefrontal cortex. This is consistent with the neurobiological evidence reviewed in this chapter, as well as with the idea that across-species variation in memory (and infantile amnesia) is due to across-species variation in neocortical structures.

Because of this across-species similarity in episodic memory and infantile amnesia, it would seem to be intellectual folly to explain the end of infantile amnesia in uniquely human terms. For example, Hayne (2004) has argued that such similarities force a basic process explanation. That is, the waning of infantile amnesia must occur at the level of changes to encoding, storage, consolidation, or retrieval from episodic memory. To the extent that species-unique capacities play a role in the ebbing of infantile amnesia, they do so only inasmuch as they affect these basic processes.

This memory-continuity view has been favored by a number of early memory researchers (see Howe and Courage, 1993, 1997; Howe, 2000, 2004; Bauer, 2004, 2005; Howe et al., in press). For humans, the capacity to better organize information in memory is the key to most, if not all, memory advances in childhood. Advances in children's knowledge structures, whether they have to do with the self or other constructs (e.g., animals, vehicles), aid children's organization and storage of incoming information, making memory traces more integrated and hence more resistant to forgetting. As we have seen in this chapter, the neurological components necessary for declarative/episodic memory are in place and operating by the end of the first year of life if not before. What drives memory development are changes in knowledge (cognitive) structures that subserve encoding, storage, retention, and retrieval, making these basic processes more robust. For the offset of infantile amnesia and the onset of autobiographical memory, this knowledge structure is the cognitive self.

It is perhaps of more than passing interest to note that the cognitive self may be present in species other than humans. The quintessential test for the cognitive self is mirror self-recognition. Results of this test have been reported for a number of nonhuman species of fish, birds, and mammals (for a review, see Gallup, 1979). Although most creatures respond toward the image as if they were viewing a conspecific, nonhuman primates (given a period of exposure to mirrors) will respond to the contingent movement cues and use the reflective properties to locate objects. However, chimpanzees and orangutans demonstrate self-recognition like humans. Although speculative, it may be that the end of infantile amnesia in some other species is also heralded by the acquisition of the cognitive self. Regardless, the common ingredient that brings about the end of infantile amnesia is some change in the organisms' ability to encode, store, consolidate, retain, or retrieve event memories. Whether that is through the advent of new knowledge (cognitive) structures or some other (cognitive) mechanism is unknown. That the various species possess different neocortical structures that moderate hippocampal (and parahippocampal) functions may provide some insight as to what those mechanisms are that modulate basic episodic memory processing and end infantile amnesia. This is the grist for future research.

To close, I refer to another unresolved issue that needs further research, and that is: what is the fate of early memories? As we saw earlier, events that were experienced once were not subsequently recollected (at least not verbally) in Bauer et al.'s (2004) study, nor were events that took place earlier than 20 months

of age. Of course, these were not traumatic or life-changing experiences, but rather, innocuous laboratory-contrived events. However, there is converging evidence from adult participants that was also reviewed here that showed that recall of events, traumatic and otherwise, was limited by infantile amnesia across the first 2 years of life (e.g., Usher and Neisser, 1993; Eacott and Crawley, 1998). So the question remains, do memories for early events remain in storage despite our inability to bring them to consciousness during later childhood or adulthood?

Recall Kagan's (1996) discussion of the fate of early experience and how many theorists believe that, despite our inability to recollect early life events, they remain with us and shape our future behaviors. It is clear that early experience, by itself, does not determine future outcomes, as subsequent experience can alter that path. Even the bizarre behavior of 6-month-old isolated macaques was altered by placing them with younger female monkeys over a 4- to 5-month period (Suomi and Harlow, 1972). Indeed, there is a vast literature that shows that a strong form of early experiential determinism is not tenable (also see Howe, 2000). In light of this, there may be little reason to believe that these early experiences still exist in memory and have not been updated by more recent (and perhaps relevant) experiences.

However, recall from the discussion about neural development that in humans, at least, implicit memory precedes the development of explicit or declarative memory. Is it possible that implicit memories that have not been altered by subsequent experience (should such a thing exist) are still accessible implicitly and form the basis of our adult responses? Although there is some evidence that early implicit memories may still exist in humans (Newcombe et al., 2000), stronger evidence was presented earlier in this chapter for early fear responses in rats (e.g., Yap et al., 2005). If early postnatal fear responses are not altered by subsequent experience, then it is likely that earlier, immature conditioned responses might still predominate in the more mature organism. Because these response patterns are implicit, the organism would not be aware of the early experience, nor would it know why a particular response was occurring, something that may be akin to the apparent, sudden emergence of a phobic response. More importantly, implicit (as well as explicit) memories of early adverse experiences might be one source for later psychopathology in adulthood.

Unfortunately, here again, the evidence is wanting – however 'pleasing' such ideas may be, the literature is replete with examples that infirm rather than confirm such intuitions (for reviews, see Hardt and Rutter, 2004; Howe et al., 2006). What is not clear is how such memories are altered by subsequent experience and what the parameters are that drive such dynamic change in memory, regardless of species. Only subsequent research will clarify the fate of these early memories, particularly the ones that are laid down during the period of infantile amnesia. I suspect their fate is similar to that of early explicit memories and that they are as malleable and updatable as all memories throughout an organism's development.

1.16 Transmission of Acquired Information in Nonhuman Primates

J. Fischer, German Primate Center, Göttingen, Germany

1.16.1 Introduction

The development of human culture and technology largely rests on our ability to accumulate information about past experiences, store it, and transmit it to others, thus enabling a cumulative cultural evolution where innovations are based on previous innovations. Literally speaking, the ability to transmit acquired information spares us having to reinvent the wheel over and over again. What is the biological basis for this ability? Are any of these abilities shared with other species? Is there evidence for 'teaching' among animals? Do animals possess different cultures, and if so, how do they come about? Are animals informing each other about past experiences or events? These are the questions that I will address in the present article. My overview will focus on nonhuman primates because they are our closest living relatives, and thus, any comparative study will have to ask which of our abilities are shared with them; in addition, most of the evidence has indeed been collected on this taxon. To maintain a broad perspective, I will draw from studies on other animals whenever feasible.

The first part of this article will be devoted to the question of animal culture. I will begin with a discussion of the terminology used in this field and then review the evidence accumulated over the last five decades. The second part charts the communicative abilities of nonhuman primates, particularly in the vocal domain – one of the most important modes of information transmission in humans. This section will begin with the question of whether nonhuman primate signals refer to objects or events in the animals' environment, discuss the issue of vocal learning as well as the importance of auditory feedback, and

then review studies that addressed the issue of whether monkeys or apes intentionally provide information to others. The third part of this article turns to the mechanisms that give rise to the observed variations in behavior, including the question of teaching among animals. My review will conclude with a discussion of how communicative skills and the development of culture are intertwined. I will argue that, in both animal communication and animal culture, there is a fundamental difference between the sender (or actor) on the one hand, and the listener (or observer) on the other. It appears that animals are good at seeking information, processing it, and adjusting their behavior accordingly, but what they apparently do not do is to provide information with the intention to alter the knowledge state of others. To get cumulative cultural evolution off the ground, more is needed than social learning; among other things, an understanding of other individuals' knowledge states and intentions, as well as a symbol system to represent and transmit accumulated knowledge. To date, this appears to be found only in our own species.

1.16.2 Animal Culture

1.16.2.1 Definition

How one approaches the question of the evolution of culture depends very much on the framework used. An anthropocentric research program might begin with a definition of human culture and then go on to ask which aspects of this phenomenon are shared with animals. An ecological research program instead might begin with charting behavioral diversity and then go on to identify the factors that give rise to this variation. Both approaches would greatly benefit from a clear definition of the phenomenon under study; however, there is no single agreed definition to work with. One frequently cited definition (e.g., Goodall, 1973; Van Schaik et al., 2003; McGrew, 2004) is that by Edward Tylor, who described culture as "that complex whole which includes knowledge, belief, art, law, morals, custom, and any other capabilities and habits acquired by man as a member of society" (Tylor, 1871, p. 1). Early on, it became clear that this definition was of little use to people who studied animal behavioral diversity. In the 1950s, the Japanese primatologist Kinji Imanishi proposed a broader definition in which he described as cultural behaviors all flexible behavior patterns that were socially transmitted (cf. Jolly, 2001). Hans Kummer, one of the pioneers of primatological research, followed a similar line of argument. He suggested considering all behaviors as cultural that were socially transmitted and which remained in the populations ("If such social modification spreads and perpetuates a particular behavioral variant over many generations, then we have 'culture' in the broad sense in which a student of animals can use the term"; Kummer, 1971, p. 13). This view still resonates today, for instance in the definition by Laland and Janik, who describe as cultural all "group-typical behavior patterns, shared by members of animal communities, that are to some degree reliant on socially learned and transmitted information" (Laland and Janik, 2006, p. 542). The eminent cultural primatologist Bill McGrew took a somewhat different stance and defined culture as "the way we do things" (McGrew, 2004, p. 25), specifically referring to forms of behavior or artifacts that are standardized, or even stylized, and socially significant.

Not surprisingly, these broad definitions were later contested (Tomasello, 1994), and there is an ongoing and sometimes fierce debate about the terminology used when people chart and discuss behavioral diversity (Fragaszy and Perry, 2003). Andy Whiten argued that it is just an issue of definition whether or not we label the outcome of social learning as culture, while Kevin Laland and Vincent Janik find a broad definition simply more stimulating (Laland and Janik, 2006). The problem with a broad definition begins when people aim to study the evolution of human culture and implicitly operate with the same terminology for two possibly quite different phenomena. While some earlier researchers used the terms protoculture or preculture when they referred to animal behavioral diversity, this specification was at some point dropped. As a result, even proponents of a broad definition struggle with the distinction of their findings for animals versus for humans, and not surprisingly, our own species has recently been described as 'super-cultural' (Whiten, 2005, p. 54).

In addition, it is obviously logically flawed to herald observations of animal culture as signs for sharing the trait 'culture' with humans, as long as two different definitions are applied. For want of a better definition, I will in the following use the term animal culture to refer to behavioral variation among animals that appears to be socially mediated. I do not assume that animal culture and human culture are homologous, and I may note here that, in my view, human culture as a phenomenon is too complex and elusive to lend itself to a meaningful phylogenetic reconstruction. Instead, it seems more productive to

investigate the mechanisms that give rise to animal culture or human culture. In a second step, one may then identify which of these traits are shared among taxa, constituting either homologies or convergences that may have arisen to similar ecological pressures. This eventually leads to an understanding of which aspects constitute derived traits of the human lineage.

1.16.2.2 History

The interest in animal culture was sparked when Japanese researchers reported that Japanese macaques, *Macaca fuscata*, on the island of Koshima had begun to wash the sweet potatoes that had been fed to them to habituate them to the presence of human observers and lure them to the beach, where they could be more easily observed. One day, a young female named Imo waded into the water and dipped the potato into the water to get rid of the sand. This habit slowly spread through the group – 2 years later, four more monkeys were regularly washing their potatoes, and 1 additional year on, 11 out of the 30 group members had been observed to clean their food that way (Kawamura, 1959). At the end of the 1950s, the researchers observed another food processing technique that slowly spread trough the study group. Again, it was Imo who first threw wheat that had been spread on the beach into the water. The sticky sand was thus washed off, and she could scoop the clean grains out of the water. Both habits did not spread randomly within the group; subjects that interacted more frequently with one another tended to adopt this new behavior earlier than subjects with only infrequent contacts (Kawai, 1965). Kawai was the first to introduce the term 'precultural behavior' into the debate. In the Western world, the question of animal culture became a hot topic in the 1970s. At the fourth conference of the International Primatological Society in Nairobi in 1971, a workshop was devoted to the topic of "Precultural Primate Behavior." Jane Goodall, who had begun her studies of the Gombe chimpanzees, *Pan troglodytes*, in 1960, presented a paper entitled "Cultural Elements in a Chimpanzee Community" (Goodall, 1973), thus advancing this great ape species to center stage.

1.16.2.3 Recent Advances

In the last 15 years, the field of primatology has experienced an explosion of publications on the topic of cultural behavior among nonhuman primates. In his 1992 book, *Chimpanzee Material Culture*, Bill McGrew gave an overview on the differences in tool use in different chimpanzee populations (McGrew, 1992). West African chimpanzees, for instance, crack nuts using stones as hammers and other stones or roots as anvils (**Figure 1**). East African chimpanzees, in contrast, have never been observed to crack nuts, despite the fact that nuts occur in their habitat. Another behavior pattern is the so-called 'grooming hand clasp,' which was routinely observed at Mahale but absent at Gombe. There are also different variations of termite fishing. For instance, subjects at Taï use rather short sticks and insert them into termite mounds, and they pull the sticks through the mouth to harvest the termites, while subjects at Gombe pick up the termites with their hands (reviewed in McGrew, 2004). A comprehensive survey of the different variants of tool use and social behavior was initiated by Andy Whiten from the University of St. Andrews. Researchers who had observed wild chimpanzees for decades in seven different areas compiled a catalogue of behavioral patterns. They identified 39 different behavioral patterns which were either observed in only one or a few of the sites taken into account in this study and – importantly – could apparently not be related to the ecological conditions or genetic variation among subjects. Thus, the observation of behavioral variation could be well substantiated (Whiten et al., 1999). In the meantime, the interest in the so-called cultural variation has been extended to other species such as orangutans, *Pongo pygmaeus* (Van Schaik et al., 2003), and capuchin monkeys, *Cebus spp.* (Perry et al.,

Figure 1 Nut cracking in West African chimpanzees. Drawing by JF from a photograph taken by Roman Wittig, with permission.

2003; Fragaszy et al., 2004). However, the so-called 'ethnographic record' has recently been criticized by Laland and Janik (2006), who argue that it is logically impossible to rule out that some unknown ecological or genetic factor may account for the observed variation.

Cultural behavior (in the broad sense) is not restricted to the primate order. New Caledonian crows, *Corvus moneduloides*, for instance, manufacture tools from pandanus leaves (Hunt, 1996). With astonishing precision, the crows cut and tear the edges of barbed leaves to produce flat tools that are broad at one end and thin at the other, where they can be used for probing holes to harvest food. In addition, they make tools from a range of materials like tree twigs, small stems, and vines (Hunt, 1996). Hunt and Gray (2003) found that crows from different areas of New Caledonia produced leaf tools of different complexity. The authors concluded that different subpopulations apparently had developed varying degrees of expertise, indicative of a cumulative cultural transmission of the techniques used to manufacture these tools (Hunt and Gray, 2003). The crows' manufacturing skills were recently tested experimentally by Kacelnik and colleagues at Oxford University. Their studies indicate that social learning is not necessarily a prerequisite to develop the skill to manufacture hooks or choose the appropriate tool (Kenward et al., 2005; Weir et al., 2002, reviewed in Kacelnik et al., 2006), casting some doubt whether the observed variation in leaf production is indeed a sign of cumulative cultural evolution.

1.16.2.4 Dialects

Depending on the definition employed, dialects or regional variations in vocal behavior may be subsumed under the label of cultural variation. Several studies have suggested the existence of group-specific call characteristics in nonhuman primates that apparently could not be attributed to ecological or genetic variation (but see Laland and Janik, 2006). One of the earliest such reports came from Green (1975), who observed that three different populations of Japanese macaques produced acoustically different calls. Pygmy marmosets, *Cebuella pygmaea*, modified their trill vocalizations when placed with a new partner in such a way that the calls of both partners became more similar to each other than before pairing (Snowdon and Elowson, 1999). The alarm calls given by members of two populations of Barbary macaques, *M. sylvanus*, revealed significant variation between sites. Playback experiments in which calls from their own or the other population were broadcast suggested that this observed variation was perceptually salient (Fischer et al., 1998). Chimpanzees also reveal differences in the acoustic structure of their pant-hoots (e.g., Mitani et al., 1992; Crockford et al., 2004).

Since learning is not a prerequisite to develop the species-specific repertoire, it is not quite clear how group-specific calls come about. Possible mechanisms will be discussed below. In contrast, whenever learning from models is mandatory, such as in the acquisition of bird song, local variation is almost inevitable. Songbirds (of the temperate regions) learn their songs as nestlings, either from their father or other singing males in the neighborhood (*See* Chapter 1.17), and hence, specific local variation, which may initially occur as a result of a copying error, can be transmitted to subsequent generations. In addition, song elements copied from other species may be incorporated into the vocal repertoire of a species (Catchpole and Slater, 1995). Another example for a regional dialect is the song of killer whales or orcas. Orcas live in groups or pods of several matrilines, and their vocalizations reveal group-specific as well as population-specific signatures (Deecke et al., 2000; Riesch et al., 2006).

1.16.3 Primate Communication

1.16.3.1 Referential Signaling

Do monkeys or apes talk about things? Are there any indications that they refer to objects and events in the external world? Does their communication have a semantic quality? These questions experienced a boost when Tom Struhsaker reported that vervet monkeys, *Chlorocebus aethiops*, living in the Amboseli National Park in Kenya produce three acoustically distinct alarm calls and three different adaptive escape strategies in response to their three main predators: leopards, eagles, and snakes (Struhsaker, 1967). This led to the question of whether the vervets denote the predator type when they give a predator-specific alarm call. Playback experiments revealed that upon hearing an alarm call, the monkeys selected the appropriate response, even when there was no predator around. The authors concluded that the vervets denoted the predator type, or that they encoded the required response (Seyfarth et al., 1980). Either way, the alarm calls were deemed to be referential, because they apparently referred to either objects or escape strategies external to the

signaler herself. In due course, the question of semantic communication became a hot topic, and numerous studies were initiated that addressed the question of the meaning of animal signals (Zuberbühler, 2006).

While general theoretical accounts of communication (e.g., Shannon and Weaver, 1949) explicitly abstained from addressing the issue of signal meaning, such analyses as well as the work by John Smith (1977) stressed the importance of distinguishing between the role of the sender who generates the message and the recipient who interprets the signal. Accordingly, the problem with the initial conclusion (that callers may have denoted the predator type) was that the information provided in the signal was inferred from listeners' responses. The early studies on semantic or referential communication failed to differentiate between these two roles, and traces of this confusion can still be found today. Subsequent analyses, however, pointed out that, for such a seemingly referential communication system to function, signals simply have to be sufficiently specific (Macedonia and Evans, 1993). If this is the case, recipients can use these signals to predict subsequent events and choose their responses accordingly (Macedonia and Evans, 1993; Seyfarth and Cheney, 2003). Two sets of questions follow from this insight: first, how much control do primates have over their vocal production to produce specific sounds in specific situations; and second, how do primates (or other animals) attach meaning to sounds?

1.16.3.2 Learning

1.16.3.2.1 Vocal Production

Studies of the ontogeny of vocal production as well as the neurobiological foundations of vocal control in nonhuman primates suggest that the structure of primate vocalizations is largely innate. Unlike in most songbirds (*See* Chapter 1.17), exposure to species-specific calls is not a prerequisite for the proper development of the vocal repertoire (reviewed in Fischer, 2002). Nevertheless, developmental modifications occur. These can be mainly related to growth in body size. For instance, from the first week of life, rhesus macaque, *M. mulatta*, infants produced coo calls with a largely adult-like structure. With increasing age, however, the fundamental frequency dropped in pitch and the modulation of the fundamental frequency and the call amplitude decreased, while call duration slightly increased. Weight was the best predictor for almost all of the observed age-related changes (Hammerschmidt et al., 2000). Using a larger age range of subjects, Ey and colleagues analyzed the changes in the structure of contact barks in a cross-sectional study of 58 free-ranging Chacma baboons, *Papio hamadryas ursinus*. Baboon clear calls are tonal and harmonically rich (**Figure 2**). An acoustic analysis revealed that the duration of the calls and the mean fundamental frequency varied significantly with age. With increasing age, animals uttered longer calls with a lower fundamental frequency. These two variables also showed a significant interaction between age and sex, indicating that the profiles of age-related variations differed between the sexes (Ey et al., in press). The emergence of sexual differences corresponds to the onset of sexual dimorphism in body size and mass, suggesting that testosterone levels may play a role in driving changes in acoustic structure. In sum, there is ample evidence that primate vocalizations experience only minor structural changes during ontogeny. Most changes can be attributed to growth, and some also to hormonal changes during puberty, which may affect the usage and structure of certain signals.

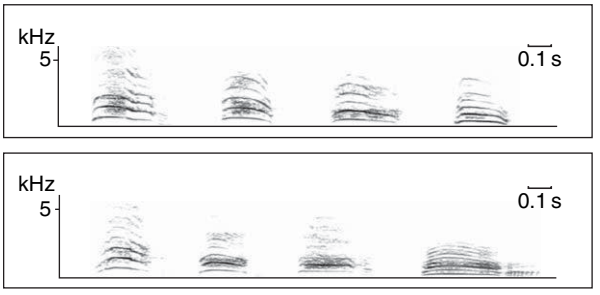

Figure 2 Spectrograms of Chacma baboon contact barks (frequency on the y-axis, time on the x-axis). The top row shows examples of calls recorded from females of different age classes (from left to right: infant, juvenile, adolescent, adult). The bottom row shows examples of male calls from the corresponding age classes.

1.16.3.2.2 Comprehension

The previous sections on modifications in the production and/or usage of calls showed that nonhuman primates apparently exhibit only little plasticity in their calls. In contrast, studies that examined the development of the comprehension of and correct responses to calls, indicated that subjects undergo pronounced changes in development. Most of the earlier work has focused on the development of vervet infants' responses to different alarm calls given to the main predators. Playback experiments showed that infants gradually develop the appropriate responses to alarm calls, and at an age of about 6 months, young vervets behaved like adults. Further evidence for a gradual development of responses comes from a study of infant baboons. Subjects developed the ability to discriminate between calls that fall along a graded acoustic continuum, as evidenced by the time spent looking toward the concealed speaker. At 2.5 months of age, infants did not respond at all to the playback of alarm or contact barks. At 4 months of age, they sometimes responded, but irrespective of the call type presented. By 6 months of age, infants reliably discriminated between typical variants of alarm and contact barks (Fischer et al., 2000). Further experiments showed that infants of 6 months and older exhibited a graded series of responses to intermediate call variants. They responded most strongly to typical alarm barks, less strongly to intermediate alarm calls, less strongly still to intermediate contact barks, and hardly at all to typical contact barks (Fischer et al., 2000). There appears to be some flexibility, because vervet infants who are exposed to specific alarm calls frequently develop the appropriate response earlier than infants who were rarely exposed to it (Hauser, 1988). Furthermore, a study of the development of maternal recognition showed that, from as early as 10 weeks of age, Barbary macaque infants responded significantly more strongly to playbacks of their mothers' calls than to playbacks of unrelated females from the same social group (Fischer, 2004). Apparently, infants are able to recognize their mothers by voice from this early age onward. Taken together, these findings corroborate the assumption that the structure of the vocalizations is largely innate, whereas call comprehension is based on learning (Seyfarth and Cheney, 1997). This asymmetry is shared with most other terrestrial mammals and taken to some extreme in the example of Rico, the domestic dog who was shown to be able to remember the names of over 200 toys. In addition, Rico was able to identify the referent of a new word by exclusion learning (Fischer et al., 2004; Kaminski et al., 2004).

How do infants learn to attach the correct meaning to sounds in their environment? To date, there is only indirect and partly contradictory evidence to what degree infant responses to calls are influenced by adult behavior. For instance, Seyfarth and Cheney (1986) reported that vervet infants were more likely to respond correctly to the different alarm calls when they had first looked at an adult. In contrast, infant baboons responded to intermediate alarm and contact barks which were typically ignored by adults, suggesting that in these situations, infants did not simply copy adult behavior (Fischer et al., 2000). In Barbary macaques, infant responses – looking toward the speaker – were not influenced by the behavior of their alloparental caretakers, that is, whether or not he or she looked toward the speaker (Fischer, 2004). Similarly, after playback of conspecific alarm calls, infant and juvenile Barbary macaques more frequently ran away or climbed into trees than did adults (Fischer et al., 1995; Fischer and Hammerschmidt, 2001). Apparently, social learning is not a prerequisite for the development of appropriate responses.

1.16.3.3 Neural Control of Vocalizations

The acoustic structure of nonhuman primate calls is determined by oscillation of the vocal folds and sometimes the vocal lip, articulatory gestures that influence the filtering characteristics of the vocal tract, and respiration (reviewed in Fitch and Hauser, 1995). Vocal behavior requires a coordination of all of these components, while vocal adjustment may take place at the level of laryngeal sound production, at the level of articulation, or both. Current evidence suggests that, in nonhuman primates, the anterior cingulate cortex serves to control the initiation of vocalizations, facilitating voluntary control over call emission and onset (Jürgens, 2002, for a review; Hammerschmidt and Fischer, in press). The periaqueductal grey (PAG) appears to serve as a relay station (Jürgens, 1998). Electrical stimulation of the PAG yields natural sounding, species-specific vocalizations. In a study with squirrel monkeys, most of the neurons in the PAG fired only before the start of vocalizations and did not show any vocalization-correlated activity (Düsterhöft et al., 2000). Recent retrograde tracing studies (Dujardin and Jürgens, 2005, 2006) revealed that vocalization-eliciting sites of the PAG receive widespread input from cortical and subcortical areas

of the forebrain, large parts of the midbrain, as well as the pons and medulla oblongata. The actual motor patterns appear to be generated in a discrete area in the reticular formation just before the olivary complex. Neurons in this area increased their activity just before and during vocalizations and showed significant correlations with the syllable structure of these vocalizations (Hage and Jürgens, 2006a,b).

1.16.3.4 Auditory Feedback

While the structure of primate vocalizations appears strongly genetically determined, some experimental studies suggest an influence of auditory feedback on vocal output. For instance, Japanese macaques' coo calls produced in response to a playback coo were more similar to the playback coo than to spontaneous coos (Sugiura, 1998). Common marmosets, *Callithrix jacchus*, increase their sound level as well as their call duration in response to increased levels of white noise in their environment (Brumm et al., 2004). Cotton-top tamarins, *Saguinus oedipus*, uttered shorter combination long calls with fewer pulses when they were exposed to white noise. In contrast, when they were exposed to modified real-time versions of their own vocal output, their calls became louder and had longer interpulse intervals (Egnor et al., 2006). It seems likely that most of these adjustments are mediated in the lower brainstem (Hage et al., 2006).

A study by Eliades and Wang (2003) on common marmosets showed that self-initiated vocalizations led to the suppression of the majority of auditory cortical neurons, while a smaller population showed an increased firing rate after the onset of the call, probably as a result of auditory feedback. Furthermore, exposure to modified self-generated vocalizations over longer periods of time may alter the response properties of neurons in the primary auditory cortex of common marmosets (Cheung et al., 2005). Whether the modulation of the auditory system is achieved via forward or inverse control, or a combination of both, needs to be investigated. In any case, this line of research eventually may help us to understand how vocal production and perception are integrated and how response priming or other related mechanisms may account for the emergence of group-specific calls.

In conclusion, there are apparently two sources that contribute to the adjustment of vocal output: one socially mediated and probably effective over longer periods, leading to group-specific calls, and the other an immediate adjustment to perturbations of auditory feedback. Whatever the details of small-scale adjustments of vocal output, learning is not a prerequisite for the development of the species-specific acoustic structure. To date, there is no reliable evidence that nonhuman primates incorporate novel sounds into their repertoire. In contrast, marine mammals such as bottlenose dolphins, *Tursiops truncatus*, were found to be able to imitate the whistles of other conspecifics (Janik, 2000); parrots, *Psittacus erithacus*, can be taught to imitate human speech sounds (Pepperberg, 2000); mocking birds mimic all sorts of sounds in their environment; and there is even an odd anecdote of Hoover, the harbor seal who was reported to be talking, albeit with a heavy Bostonian accent (cf. Fitch, 2000). That is, flexible vocal production has evolved several times independently, but we do not appear to share it with our closest living relatives (Fischer, 2003; Egnor and Hauser, 2004).

1.16.3.5 Gestures

Possibly as a consequence of the frustration with the lack of elaboration in the vocal production of nonhuman primates, researchers have become more interested in the gestural communication of apes, and recently also monkeys. The reasoning is that, while primates lack voluntary control over their vocal output, they do have excellent voluntary control over their hands. Therefore, it has been hypothesized that human speech possibly evolved via a proto-sign language (Corballis, 2002; Arbib, 2005). In addition, the brain area in monkeys (area F5) that controls manual movements is supposed to be homologous to Broca's area, which is involved in speech production, further fueling the interest in this modality of communication.

In this context, it is important to distinguish between enculturated subjects raised by humans, captive animals, and wild animals. One enculturated ape, the chimpanzee Lana, was taught to use certain gestures like 'open' and 'more,' which she used in a range of different contexts (Kellogg, 1968). Detailed studies of the signaling behavior of chimpanzees, bonobos, *Pan paniscus*, gorillas, *Gorilla gorilla*, and siamangs, *Symphalangus syndactylus*, in captivity, in contrast, did not provide any evidence that gestures referred to certain objects or events in the subjects' environment (see chapters in Call and Tomasello, in press). The majority of flexibly used gestures occurred in the play context – a context that by its definition is characterized by highly variable behaviors. The evidence for gestural communication among wild subjects is still somewhat sketchy. Recently, a study of the gesturing

behavior of wild chimpanzees indicated that subjects used one specific gesture referentially (Pika and Mitani, 2006). Specifically, during grooming, groomees frequently used a "loud and exaggerated scratching movement" (Pika and Mitani, 2006, R191) on a part of their bodies. In 64% of all observed cases, the groomer then groomed that particular spot. The authors concluded that the exaggerated scratch constitutes a communicative signal. It seems equally likely, however, that the sequence of events is an example of either local enhancement (see following) and/or 'ontogenetic ritualization' (Tomasello, 2004), where both parties of the dyad learn about the consequences of certain actions.

1.16.3.6 Intentional Signaling

One important issue for the present purpose is the question of whether the usage of nonhuman primate vocal or gestural signals can be considered as intentional. In the domain of animal communication, researchers frequently invoke the definition of Daniel Dennett (1971). Dennett described different stages of intentionality, where zero-order intentionality would apply to simple expressions of emotion or fixed action patterns given in response to sign stimuli. First-order intentionality describes communicative acts employed in order to alter the behavior of the recipient. This does not necessarily imply that the signaler is conscious of her own behavior or mental state (Bruner, 1981), in the sense that the sender knows that she does have such an intention. Second-order intentionality would apply to cases where the sender intends to alter the knowledge state of the other, and not necessarily his or her immediate behavior. For second-order intentionality to apply, the sender must know that the receiver's mental state can be different from her own mental state. So far, there is no convincing evidence for second (or higher) order intentional communication in the animal realm (Seyfarth and Cheney, 2003), so most of the studies simply ask whether primates use signals with the intention to alter their group mates' behavior. Tomasello et al. (1997) listed a set of diagnostics of intentionality: (1) 'means-end dissociation' (Bruner, 1981), i.e., different signals are used to achieve the same goal while the same signal may be used to accomplish different goals; (2) 'persistence of the goal,' i.e., the sender continues to use the same signal or enhances his signaling behavior if the desired behavior cannot be achieved; (3) sensitivity to the social context, i.e., intentional signals should not only be addressed to a recipient, but the sender should also take into account his attentional state; (4) flexibility, i.e., signals may be combined (relatively) freely. While these criteria appear all quite straightforward, it is not a trivial task to operationalize them. How, for instance, does one determine the 'goal' of the sender? The goal must be inferred from the recipients' response, opening up the same problem as mentioned for the identification of message content in the vocal domain. Hesler and Fischer (2007) used an alternative approach and aimed to identify the function of a signal by examining the contingency between signal use and responses in others. However, this approach does not give any insight into the sender's intention either. Despite its intuitive appeal, therefore, the identification of the signaler's goal remains rather elusive. This aside, it appears that apes choose appropriate signal modalities according to the state of the receiver (see chapters in Call and Tomasello, in press). Moreover, they meet the criterion of means–end dissociation in the sense that they use different signals to achieve the same 'goal' or may use the same signal to achieve different 'goals.' This ability is not restricted to apes. Despite the fact that great and small apes produce a larger diversity of manual postures than monkeys, Barbary macaques also fulfill the above-mentioned criteria (Hesler and Fischer, 2007). One difference between apes and monkeys may be that, while there is some flexibility in signal usage in monkeys, it is nevertheless quite predictable. In other words, certain patterns are frequently combined with certain other patterns (e.g., rounded open mouth threat with head bob and ground slap, but not with 'present hindquarters'). Tomasello (in press) maintains that nonhuman primate gestural communication shows much more flexibility than primate vocal communication. He supposes that this might be the case because gestures are used in "less evolutionarily urgent activities." However, except for alarm calls, the immediate survival value of most vocalizations is not very obvious either. In addition, gestural signals may be simply more variable and flexible because they have more degrees of freedom: movements can be described in terms of space and time (i.e., four dimensions), while vocalizations vary – depending on the definition – in two (amplitude and time) or three (amplitude, frequency, and time) dimensions only.

Moreover, the Barbary macaques' vocal communication also fulfills the criteria for intentional signaling listed earlier: the monkeys use the same call type in different contexts, while in one context, different call types may be uttered; if a pant is not

sufficient to threaten a group member, subjects may begin to scream; when they approach another group member, they use vocal signals if the recipient is not looking at them, while they tend to use facial expressions if they do, and they may combine different call types in one call bout (Hesler and Fischer, 2007). To summarize, at least for Barbary macaques there seems to be no substantial difference between the vocal and nonvocal domain in terms of the criteria listed. In light of the view that most communicative acts serve to either decrease or increase the distance between social partners, this may not be so surprising. In conclusion, despite a high degree of voluntary control over their hands, there is no convincing evidence that manual gestures or other nonverbal signals are used (by wild apes or monkeys) to communicate about things or provide information to others (*See* Chapter 1.15 for nonverbal communication in humans). This finding suggests that a lack of voluntary control over the vocal apparatus is only one of the constraints that prevent a more elaborate communication among our closest living relatives.

1.16.4 Social Learning

So far we have seen that a variety of animal species have developed a certain degree of behavioral traditions. Apparently, vocal or gestural communication plays no particular role when such traditions are established or maintained (except when these traditions consider the signal repertoire itself). Nevertheless, the information transmission is socially mediated. Research during the last two decades has identified different social learning mechanisms that encompass a wide range of different forms with varying degrees of cognitive complexity. The common denominator is that the behavior of one subject facilitates or influences the behavior of another subject (see Heyes and Galef, 1996; Perry and Fragaszy, 2003, for comprehensive reviews). Note that the terminology is not always used consistently (Hurley and Chater, 2005).

1.16.4.1 Social Facilitation, Stimulus, and Local Enhancement

Social facilitation is invoked when an individual's learning is affected by the activity of another animal. Animals typically pay a lot of attention to what others, particularly their group mates, are doing. This may lead to stimulus enhancement, i.e., an increase in salience of stimuli others are paying attention to, as well as local enhancement, i.e., the subject learns something about the contingencies of a specific local situation simply because it is near an individual who does something particular (Heyes, 2001). Therefore, the potato-washing behavior of Japanese macaques can be viewed as a consequence of local enhancement: subjects who were closely associated with Imo also spent more time near water and near potatoes. Hence, they may simply have individually learned how delicious potatoes tasted that had been dipped in seawater.

1.16.4.2 Emulation

Emulation has been defined as a form of social learning when the subject learns – through observation – something about the consequences of a certain action. It does not imply an understanding of the causal relationship underlying action and outcome, nor does it require an understanding of the agent's intention (Hurley and Chater, 2005). For instance, if an animal observes another subject that is manipulating a bolt at a box and then sees that the box can be opened, they associate the action (manipulating) with the outcome (opening). In other words, the animal may understand that manipulating the bolt leads to opening (the end of the action). Emulation does not require that the animal understands or follows the exact procedure (the means) of the action, nor does it entail an understanding of the other subject's intention.

1.16.4.3 Copying

Within the framework of the means–ends structure, copying would be the rendition of some other individuals' behavior with no understanding of what it is good for. In this sense, one follows the exact procedure of the model, but also follows any dysfunctional (or accidental) aspects of it. Copying has been invoked in a large array of situations, including mate choice where females may prefer males that have already mated successfully, bird song learning where songsters dutifully produce exact renditions of song models heard earlier, or the acquisition of food preferences (see Dugatkin, 1996; Zentall, 1996).

1.16.4.4 Imitation

Edward Thorndike was the first to note that most animals learn by trial and error, and not by imitation (*See* Chapters 1.06 and 1.10 for operant learning).

Indeed, thorough analyses of imitation led to the view that this capacity should be viewed as a relatively complex ability that requires an understanding of the means as well as the end of an action (Hurley and Chater, 2005). Researchers interested in imitation distinguish between perceptually opaque and perceptually transparent imitation. The former, for instance, applies to imitating someone else's facial expression, where one cannot see one's own face. Most phenomena discussed earlier, in contrast, should be viewed as perceptually transparent, because they involve hand movements and vocalizations (Heyes and Ray, 2000). For the present purposes, I will therefore not discuss models put forward to address the opacity problem.

Horner and Whiten initiated a series of experimental tests to assess the transmission of acquired knowledge in captive chimpanzees and human children. Subjects watched a human demonstrator first stab a stick into a hole at the top of an opaque box, then remove the stick and insert it into a second hole at the front panel to obtain a food reward (**Figure 3**). Both the chimpanzees (aged 2–6 years) and the children (aged about 4 years) followed this sequence of actions. However, when presented with a transparent box which revealed that sticking the tool into the top hole was inefficient, the chimpanzees switched from copying to a more goal-oriented emulation and simply used the stick to gather the reward. In contrast, the children continued to follow the demonstrated procedure of first inserting the stick into the top and then into the front hole. The authors viewed this result as evidence for the strong conformity bias of our own species (Horner and Whiten, 2005).

In a second set of experiments, Whiten and colleagues examined whether a novel technique would spread in a group of chimpanzees (Whiten et al., 2005). They first trained two female chimpanzees, each from a different social group, to use one of two different techniques (poke vs. lift) to obtain a food reward (**Figure 4**). After reintroducing the females into their groups, all but two of their group members adopted the specific strategy used by the model. Interestingly, some chimps in the lift group accidentally discovered the other technique as well. However, when retested, these chimps continued to use the originally seeded technique nevertheless, which led the authors to the conclusion that chimps show a conformity bias as well (Whiten et al., 2005).

What are the requirements to achieve the somewhat simpler case of transparent imitation? Associationist models propose that the capacity to imitate derives from the experience of simultaneously observing and executing that action in the past. Transformational theories, in contrast, suggest that an observed action is transformed into a sensory representation that is then used as an internal model for the motor program (see Heyes and Ray, 2000; Brass and Heyes, 2005, for detailed discussions). At a somewhat different level, two competing frameworks have been put forward to explain how imitation may be achieved: the sensorimotor and the ideomotor frameworks (see Prinz, 2005, for a review). In the sensorimotor model, perception and action are subserved by two distinct representational structures. Rule-based mappings connect the two. According to this model, an observer who perceives a given action needs some way of translating this into

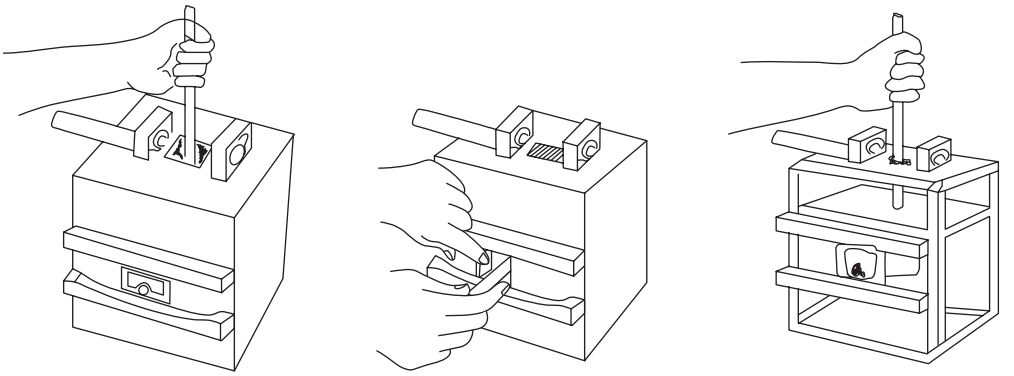

Figure 3 Opaque and transparent boxes used in the experiments with chimpanzees and children. Subjects first saw a familiar human stab a stick tool into the top and then into the front hole to recover food. In a second condition, the transparent box revealed that the first move (stabbing from the top) had no effect. In this second condition, chimpanzees switched from copying the sequence to emulation, while children continued to follow the human model. Adapted from Whiten A (2005) The second inheritance system of chimpanzees and humans. *Nature* 437: 52–55, with permission from Macmillan Publishers Ltd: NATURE.

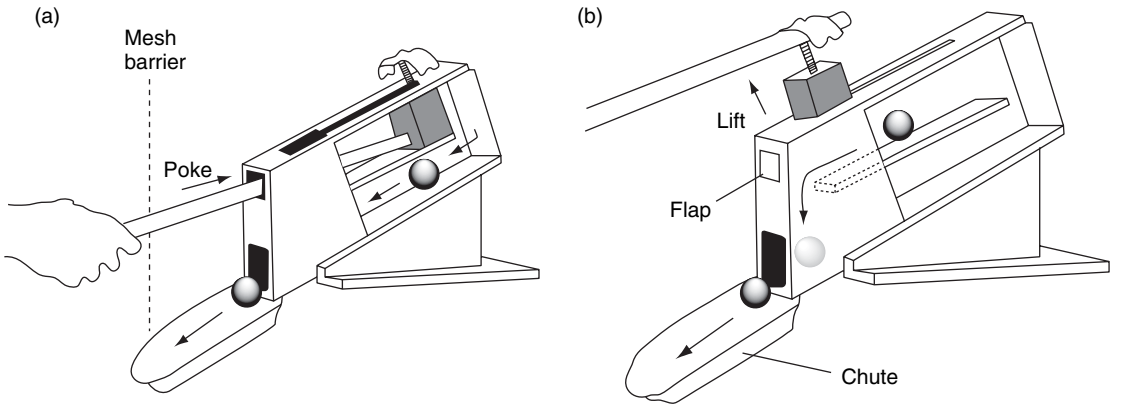

Figure 4 Two techniques for gaining food: (a) in the poke method, the stick tool is inserted into the apparatus and used to push (an invisible) blockage back along a ramp so that the food falls down and rolls forward underneath; (b) in the lift method, the stick tool is passed under hooks, allowing the blockage to be lifted and the food to roll forward. Redrawn version, adapted from Whiten A, Horner V, and De Waal FBM (2005) Conformity to cultural norms of tool use in chimpanzees. *Nature* 437: 737–740, with permission from Macmillan Publishers Ltd: NATURE.

her own motor planning. Feedback on the consequences of one's own movements can be used to correct the execution of that plan. This is generally compatible with the transformational model mentioned earlier. According to the ideomotor (common coding) framework, in contrast, perception and action are represented by the same system. This has two effects: first, to predict an ongoing action's perceivable consequences; second, to select a certain act in order to achieve certain effects (Prinz, 2005). Thus, both forward (predicting the outcome) and inverse models (using feedback) may play a role in imitation. Effectively, an understanding of imitation is part of understanding motor control and simulation and also bears on the issue of how mental state attribution is conceptualized.

While there is now some evidence that chimpanzees may be able to imitate, human children are 'imitation machines' (Tomasello, 1999, p. 159), and they have a strong tendency to imitate inefficient actions like pushing a light switch with the head instead of with the hand, or using rakes the wrong way around if the demonstrator did so. Thus, it appears that, to human children, imitation is rewarding per se. While imitation is difficult to distinguish phenomenologically from copying, true imitation requires an understanding of someone else's intention. That is, not only does the observer need to understand the goal (turning on the light) but also needs to assume that it matters to the demonstrator how the light is turned on. Thus, a certain form of perspective taking seems to be required to achieve full-fledged imitation (Tomasello, 1999).

1.16.4.5 Gaze Following

There are several studies showing that nonhuman primates follow the gaze of others regularly (reviewed in Tomasello and Call, 2006), while fewer studies systematically examined the ontogeny of gaze following in nonhuman primates. Tomasello and colleagues (2001) investigated the age at which rhesus macaque and chimpanzee infants began to follow the gaze of the human experimenter. In rhesus macaques, subjects followed the gaze of the experimenter at 5.5 months of age. Barbary macaque infants up to an age of 10 weeks did not follow the gaze of others (Fischer, 2004), but a more systematic study of the development of gaze following among nonhuman primates is still lacking.

1.16.4.6 Teaching

An assessment of teaching entails a change in perspective; all of the aforementioned social learning mechanisms tried to explain the behavior of observer or information seeker. An investigation of teaching, in contrast, focuses on the subject that provides the information. In an influential article, Caro and Hauser (1992) formulated the following criteria for the occurrence of teaching:

> An individual actor A can be said to teach if it modifies its behavior only in the presence of a naïve observer, B, at some cost or at least without obtaining an immediate benefit for itself. A's behavior thereby encourages or punishes B's behavior, or provides B with experience, or sets an example

> for B. As a result, B acquires knowledge or learns a skill earlier in life or more rapidly or efficiently than it might otherwise do, or that it would not learn at all. (Caro and Hauser, 1992, p. 153)

This rather broad definition does not assume instruction; instead the authors argue that teaching does not depend on higher-order intentionality or attribution of mental states. Nevertheless, evidence for teaching in animals remains equivocal. In a recent study, Thornton and McAuliffe (2006) investigated the transfer of skills in free-ranging meerkats, *Suricata suricatta*. After emerging from the burrow, meerkat pups spend much of their time following helpers who capture and process prey for them. Helpers killed or disabled prey more frequently when pups were young, while they fed mostly intact prey to older pups. The authors also conducted an experiment where they presented live scorpions to helpers who then removed the sting and fed the pup (all of which then also bit into the scorpion). In contrast, only half of the pups bit into the prey when no helper was around (Thornton and McAuliffe, 2006). While the helpers' behavior conforms with the criteria listed above and, thus, can be defined as a form of teaching, it is questionable whether it helps us to understand different forms of information transmission. For instance, helpers may have learned that young pups cannot handle intact prey, so they have to disable or kill it. In addition, the outcome of the experiment can easily be explained by social facilitation. To date, there is no convincing evidence for active punishment or encouragement. Obviously, however, socially living animals do provide each other with experiences that they might not have if they lived alone, so this criterion does not help much to distinguish teaching from other forms of social learning, such as social facilitation. In other words, despite some superficial similarity of the observed meerkat helper behavior and the expected outcome of teaching (in the more canonical sense of the word), it is probably a good idea to consider the form of information transmission (active or passive) when teaching is investigated.

The same needs to be said about the acquisition of the diverse cultural behavior of chimpanzees or other primates. There is to date no indication that older animals correct or help youngsters to acquire a certain skill, e.g., nut cracking. Observations of the ontogenetic development of nut cracking in chimpanzees indicated that youngsters had a strong interest in their mothers' nut cracking activities. Nevertheless, they needed to develop that ability through trial-and-error learning (Matsuzawa et al., 2001). The young chimpanzees' attention was drawn to hammer, anvil, and nut, but they could not acquire the appropriate technique through observation alone. There is no record that mothers ever corrected or punished youngsters' incorrect behavior. Therefore, it seems more plausible that the acquisition of nut cracking can be explained through a combination of social facilitation, emulation, and trial-and-error learning.

1.16.5 Conclusions

There is now convergent evidence to support the notion of a strong asymmetry between animals' intentional abilities to transmit versus to acquire information, and this is true for communication as well as social learning. Despite the fact that the structure of primate vocalizations appears fixed from birth, primate calls nevertheless provide rich information about sender attributes such as size, age, sex, hormonal levels, and also motivational state. Specific relations between motivational state and certain contextual situations allow listeners to use signals as predictors of upcoming events. There is, however, no conclusive evidence that signalers have the intention to provide this information to others. While nonvocal signals such as gestures and postures show a higher degree of variability (particularly in apes), there is no convincing evidence that gestures are used to intentionally communicate about objects or events, either. Similarly, the behavioral diversity observed among nonhuman primates can largely be attributed to social learning mechanisms where observers pay attention to and are influenced by the actors' behavior (social facilitation and goal emulation), but there is no evidence for teaching or instruction. Apparently, nonhuman primates lack the ability to attribute knowledge states to each other.

Social learning is clearly a prerequisite for the development of human culture, but it does not explain its complexity. One of the hallmarks of human culture is its rich symbolic structure (Jablonka and Lamb, 2005; *See also* Chapter 1.38). Moreover, cumulative cultural evolution (Boyd and Richerson, 2005) requires a system to represent and transmit knowledge. One such system is human speech: speech encompasses external reference as well as temporal and spatial transcendence. Once such a symbolic communication system is in place, it is possible to transmit information and knowledge

without forcing the individuals to reenact each action every time information needs to be conveyed. Speech generally and writing in particular can be used to compress information transmission, store acquired knowledge, and drive technological development. In addition, the symbolic nature of speech allows for an increasing complexity of other human symbol systems. In conclusion, while both animals and humans share a number of social learning mechanisms, humans in addition are apt imitators, attribute knowledge to others, and are in command of a complex communication system. All of these contribute to the rich symbolic structure that characterizes human cultures. Future research should be devoted to the question of how mental state attribution and information transfer are linked, and how both of these are related to the formation of a symbol system.

1.17 Bird Song Learning

P. Marler, University of California at Davis, Davis, CA, USA

1.17.1 Introduction

All birds have a repertoire of calls for communication about danger, food, sex, and group movements, and their calls are used for many other purposes as well. Within this repertoire of a dozen or more sound signals, a distinction can be made between calls, which are usually brief and often monosyllabic, and song, which is a more extended pattern of sound, sometimes raucous, often tonal and melodic, and not infrequently a source of pleasure for human listeners (Catchpole and Slater, 1995). Defined in this way, virtually all birds have something that we can call a song, whether it be the crow of the cock or the music of nightingales. In close to half of all 9000 species of birds, the song is learned. Most of the 4000 or so probable learner species come from just one of the 27 orders into which taxonomists classify living birds. Excluded are waders, chicken-like birds, woodpeckers, cuckoos, doves, hawks, owls, and all marine and freshwater birds. The only groups that qualify are parrots, hummingbirds, and above all the very populous suborder of the Passeriforms known as the oscines, characterized by the complexity of their vocal organs and by their distinctive forebrain circuitry expressly evolved to sustain song learning. Parrots and perhaps hummingbirds seem to have independently achieved the same end with equivalent but neuroanatomically distinct brain circuitry (e.g., Striedter, 1994).

Songs are usually, though not always, a male, androgen-dependent prerogative. In species that are learners, the associated brain circuitry is often sexually dimorphic, and there is an extensive literature on the extent and functional significance of this dimorphism and its developmental basis (Nottebohm and Arnold, 1976; DeVoogd, 1991; Arnold, 1990; Vicario, 1991; Brenowitz and Kroodsma, 1996). A larger song system in male brains clearly implies a greater commitment to song learning, and the correlation between the size of song system nuclei, the presence of song, and song repertoire size extends not only to comparisons between the sexes but also between species, subspecies, and even individuals (Nottebohm et al., 1981; Canady et al., 1984; DeVoogd et al., 1993).

Unlike calls, which are occasionally learned but are typically innate, oscine songs always develop abnormally if a young male is reared out of hearing of adults. A common consequence of dependence on learning is the emergence of local song dialects, often varying on much the same geographic scale as dialects in human speech (Baker and Cunningham, 1985). Their distinctiveness depends on such factors as patterns of dispersal from the birthplace and the timing of song learning. When dialects are well defined, it seems to be a general rule that songs like a bird's own dialect are especially potent as vocal signals, both to territorial males and to females

ready to mate. A bird's dialect may or may not correspond to that which prevails in the natal area.

Many analogies can be struck between song learning and the acquisition of human speech (Doupe and Kuhl, 1999). There is no nonhuman primate in which vocal patterns are culturally transmitted from generation to generation. Aside from cetaceans, which also engage in vocal learning, birds provide the most valuable animal model we have for studying the behavioral, hormonal, and neural basis of vocal plasticity (Konishi, 1985; Arnold, 1990; Marler, 1991; Nottebohm, 1993; Zeigler and Marler, 2004).

1.17.2 The Physiology of Song Learning

1.17.2.1 Special Brain Mechanisms

Although many important issues remain unexplored, much has been learned over the past 30 years about the specialized neural mechanisms that mediate avian vocal plasticity since the song system was discovered in the canary brain (Nottebohm et al., 1976; *See also* Chapter 3.23). There are two main functional requirements for controlling song production. Appropriate configurations of the articulators must be set up, primarily the syrinx and the postsyringeal vocal tract. Also, the required pattern of air flow must be generated to set the articulators vibrating. These controls are required whether a song is learned or innate, and as might be predicted, some of the circuitry responsible is relatively conservative, located in the midbrain and the brain stem (Wild, 1994). The added requirements for songs to be learned are met by two major circuits in the forebrain, one to sustain the actual learning process, the so-called anterior forebrain pathway, and the other, the motor pathway, for control of the production of learned songs (Nottebohm, 1993; **Figure 1**). Disruption of the motor pathway always results in the distortion and even the elimination of learned songs, whereas the anterior forebrain pathway seems to be redundant except during actual song development. As with innate songs, the motor pathway must have access both to the vocal tract and the syringeal musculature, mapped in one part of the motor pathway and also to the respiratory system, mapped in another part, both in the robust nucleus of the archistriatum, or RA (Vicario, 1991). Demands on the motor pathway circuit are complicated by the existence of two semiindependent vibrators in the songbird syrinx, requiring precise coordination, since both participate in the production of learned songs (Greenewalt, 1968; Suthers, 1990).

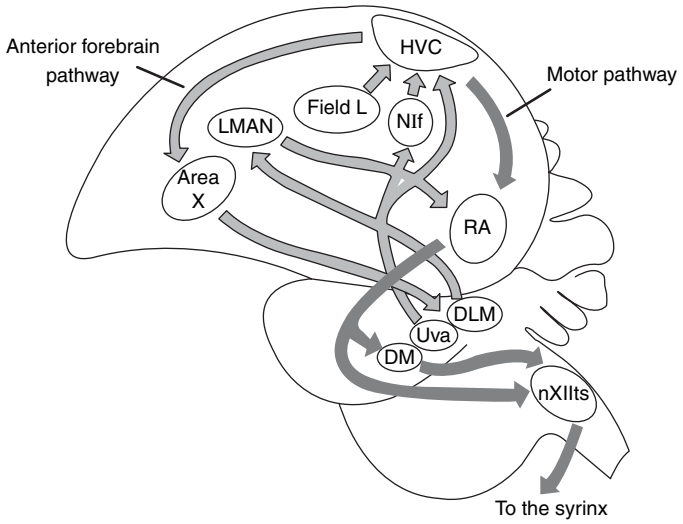

Figure 1 A diagram of the two major circuits in the song system of the oscine brain. One is for control of movements of the vocal apparatus in learned songs (motor pathway), the other for song learning (anterior forebrain pathway). There is a fork in the motor pathway from RA (robust nucleus of the arcopallium) to the hypoglossal nucleus in the brainstem, and to the vocal apparatus (nXIIts). One branch goes directly, the other passes through DM (dorsal medial nucleus) in the midbrain, thought to be involved in the control of respiration. A different circuit for the production of innate songs, involving the midbrain nucleus ICO (intercollicular complex), is not shown. Inputs to the higher vocal center (HVC, no formal name) include field L, the primary auditory forebrain area. Another auditory projection area close by that also projects to HVC. NCM (caudal medial mesopallium) is not shown (see text). Also labeled is LMAN (lateral magnocellular nucleus of the anterior nidopallium).

The hearing of birds has been extensively studied in relation to their vocal behavior (Dooling, 1982). Many parts of the song system are responsive to song stimulation. Strangely, one of the strongest stimuli, especially in the higher vocal center (HVC) of adult males, but also elsewhere, is the bird's own individually distinctive crystallized song (Margoliash, 1986). This finding has promoted the plausible speculation that adult males of some species use auditory feedback from their own song as a yardstick to calibrate the potency of songs of others when they hear them, especially those of conspecific neighbors and strangers.

Attunement of a male's song system to his own individual song, including all of its personal quirks, only emerges as songs crystallize (Doupe, 1993). Unfortunately, little attention has been paid to responsiveness of the brain of young birds to song stimuli prior to the production of plastic and crystallized song. Patterns of auditory responsiveness of the song bird brain during the earliest memorization phase of song learning remain almost unexplored (but see Whaling et al., 1995). Behavioral tests at this age demonstrate innate responsiveness to many features of song, especially those of the bird's own species (Nelson and Marler, 1993; Whaling et al., 1997). Details of the process of song memorization are consistent with involvement of the set of innate auditory predispositions that each species deploys, serving as a guide to the process of selective song learning. The neural mechanisms responsible still await neurophysiological investigation, and until they are elucidated, a full understanding of the physiological basis of song learning will continue to elude us. At present we do not know how songs are memorized by a young male, nor where they are stored in the brain in preparation for the guidance of song production.

One remarkable feature of the bird brain is the continuing development of new neurons in many parts of the brain, both in infancy and in adulthood, including the song system (Goldman and Nottebohm, 1983). Although it is not clear what relevance neurogenesis has to song learning, there are many fascinating hints, including the demonstration, in something of a technical tour de force, that some new neurons are actually inserted into the song system and become active there (Paton and Nottebohm, 1984; Alvarez-Buylla et al., 1990). It may be that neuronal turnover in the motor pathway prepares the way for the song plasticity that some birds such as the canary (Nottebohm and Nottebohm, 1978) display in adulthood.

Another place to look for song-related activity is in the forebrain auditory circuits concerned with the perceptual processing of song stimuli. One of these (caudal medial mesopallium, NCM) has been identified as the site of gene activation in response to conspecific stimulation and as a location where experience-dependent changes in electrophysiological responsiveness to song stimuli are occurring (Mello et al., 1992; Mello and Clayton, 1994). Circuits extrinsic to the song system may prove to be more involved in song learning than has been thought.

1.17.3 Sensitive Periods for Learning

In song development, as in the ontogeny of other kinds of behavior, the rapidity and precision with which learning takes place varies from one stage of the life cycle to another. All song birds seem to share a similar sequence of stages in the process of learning to sing. First is the acquisition phase often restricted to a short period, when a bird hears songs and commits some of them to memory. After storage for a period that ranges in duration from days to months, depending on the species, songs are recalled from memory, and imitations begin to emerge. Renditions are relatively faithful to the original model in some species, but others depart from it quite radically, with vocal inventiveness playing a significant role.

The separation in time between the acquisition or sensory phase and the production or sensorimotor phase, ending with the production of crystallized, adult song, is a significant one. In many birds, the sequence occurs just once, often in early adolescence. In such cases, adult song patterns remain fixed thereafter, their production waxing and waning with the passing of each breeding season. In other species, the sequence recurs repeatedly during adulthood, so that song patterns may continue to change. Even close relatives, such as canaries and sparrows, can differ in this respect.

Several species of sparrows have a sensitive period for song acquisition beginning at about 2 weeks of age, soon after they leave the nest, and ending 6–8 weeks later (Nelson et al., 1995). The precise duration varies, even in different populations of the same species (**Figure 2**). Sensitive periods for learning are not fixed but are changeable, within limits, depending on such things as the strength of song stimulation; access to a live, interactive tutor (Baptista and Petrinovich, 1986); and physiological factors, such as hormonal states, that vary with the season.

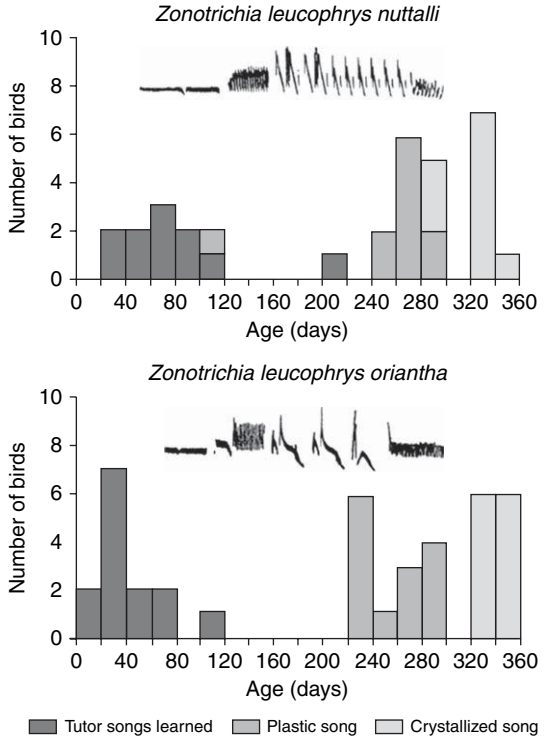

Figure 2 The timing of song production and song acquisition from constantly changing programs of tape recordings throughout the first year of life in male white-crowned sparrows raised in the laboratory. The birds represent two populations: one resident year-round on the coast (subspecies nuttalli), the other migratory in the high Sierras (oriantha). The migratory birds began acquiring song earlier (peaking at 33 days vs. 52 days), and the acquisition period was significantly shorter. A representative song of each is shown. Both are about 2 s in duration. From: Nelson DA, Marler P, and Palleroni A (1995) A comparative approach to vocal learning: Intra-specific variation in the learning process. *Anim. Behav.* 50: 83–97.

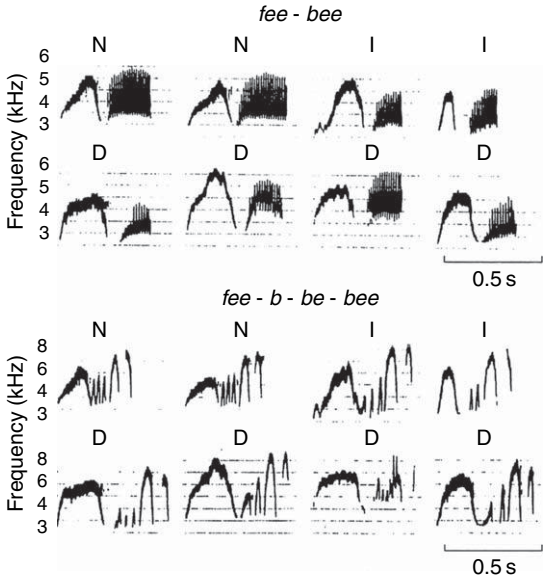

Figure 3 Within the passeriform perching birds, the oscine songbirds all have learned songs, but the suboscines, which lack the special song-system brain circuitry, do not. Here are examples of the innate song of a suboscine passerine, the eastern phoebe. Some developed normally in the wild (N), some in isolation (I), and some after deafening (D). Two song types are represented, the fee-bee and the fee-b-be-bee. Unlike oscines, whose songs are drastically modified by isolation or deafening, both isolated and deafened phoebes developed normal songs. From Kroodsma DE and Konishi M (1991) A suboscine bird (Eastern phoebe, *Sayornis phoebe*) develops normal song without auditory feedback. *Anim. Behav*. 42: 477–487.

Closure of the acquisition period can sometimes be delayed if songs of the bird's own species are withheld (Kroodsma and Pickert, 1980), as though termination of the sensory phase is delayed until adequate song stimulation has been experienced. If young are hatched late in the season and singing has already ceased for that year, the sensitive period may be extended until the following spring in some species, though this delay does not occur in all cases.

1.17.4 Vocal Development

1.17.4.1 The Ontogeny of Learned Song

In contrast with song learners, nonlearners develop normal song when raised in isolation, even after deafening (Kroodsma, 1984; Kroodsma and Konishi, 1991). This is true of a male dove, a cockerel, and even of those passerines that are nonoscines, such as the New World flycatchers (**Figure 3**). In such cases, when a young bird starts to sing, its very first efforts are clearly identifiable as immature versions of what will ultimately be normal adult song. Early attempts may be noisy and fragmented, but there is a clear linear progression in the development of innate songs.

In birds that learn their songs, the developmental progression is quite different. They begin with the unique vocal pattern called subsong, a quiet, variable warbling that can begin as early as 3 or 4 weeks of age. It is reminiscent of the early babbling stage of speech development (Locke, 1993). Typically it seems to bear no resemblance to mature song, although we know less about its structure and function than any other aspect of song development. As defined, there are no imitations in subsong. In song learners, there is a kind of vocal metamorphosis between subsong and later stages of song development. The amorphous structure and noisy spectral organization of subsong are consistent

with a role in the acquisition of the general motor skills of singing, in coping with the complexities of the oscine syrinx, and also in honing the ability to guide the voice by the ear, a prerequisite for vocal imitation (Thorpe, 1961; Nottebohm, 1972; Marler and Peters, 1982b). Duration of the subsong period varies greatly, even within a species, depending on individual histories. In deaf birds and social isolates, it may last for weeks, but a bird with adequate tutoring in youth may progress rapidly from subsong to the next phase, plastic song, in a few days.

In plastic song, signs of mature song structure first appear. Previously memorized song patterns emerge and begin to stabilize, first gradually, then rapidly, until adult, crystallized song is achieved, and the young male is ready to launch a full season of mature singing (**Figure 4**).

1.17.4.2 Overproduction, Attrition, and Action-Based Learning

Song learning has been traditionally viewed as memory based. Songs are acquired and memorized and then used later to guide motor development by auditory feedback, with no practice at the time of memorization. Another kind of vocal plasticity, involving only working memory, and with a key role for motor practice, occurs during the plastic song phase.

Several learner species overproduce during plastic song, generating more than they need for mature song, and discarding excess plastic songs as the time for song crystallization approaches (**Figure 5**). Some overproduced songs are invented, but many are imitated, and the richness of early song experience is one factor in determining the extent of the overproduced repertoire (Nelson et al., 1996). However, overproduction and attrition also occur in birds tutored and raised in individual isolation in the laboratory (Marler and Peters, 1982a). In this case, the decision about which songs to discard seems to be random, whereas in nature it is guided by social experience.

The attrition phase in which overproduced songs are discarded from the repertoire coincides with the efforts of young male sparrows to establish their first territory. As it competes with adults, those songs of the young bird that match song types of older rivals, even if only approximately, are most effective in eliciting counter singing and perhaps in territorial defense (Beecher, 1996). Young males tend to retain and crystallize those plastic songs that are the closest match to those of their rivals, and to discard the rest.

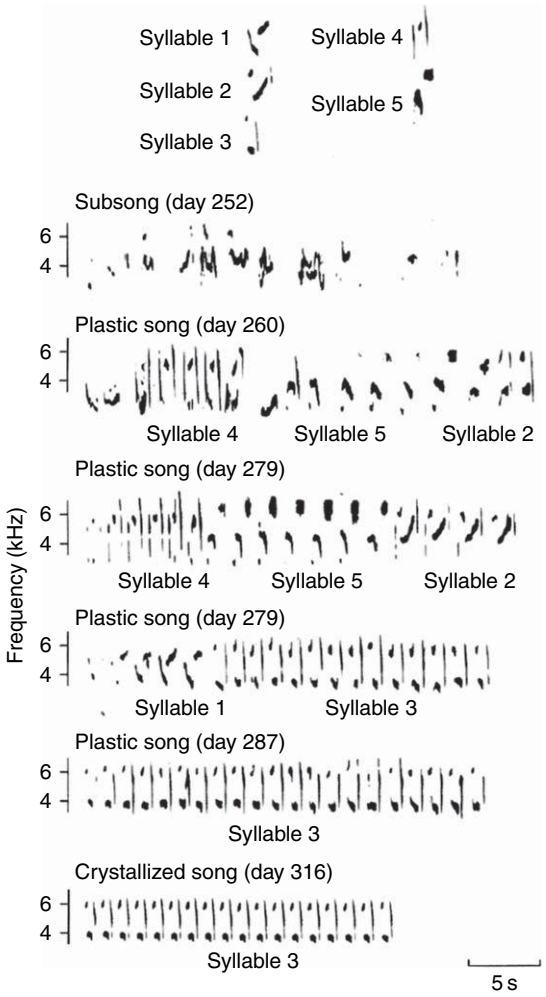

Figure 4 Development of the song of a male swamp sparrow raised in the laboratory and tutored with tape recordings of song from 20–60 days of age. Some of his training song syllables are shown at the bottom right. The first emergence of imitations can be seen in his plastic song from day 260, 200 days after the end of tutoring. His mature song crystallized around 300 days of age (see **Figure 5**).

Effects of male-to-male territorial interactions, either real or simulated, on song attrition have been described in several species of sparrows (Nelson, 1992; Nelson and Marler, 1994). In another species, the brown-headed cowbird, responses of females serve to shape male decisions about which overproduced songs to retain (West and King, 1988). The process by which a repertoire of varied motor patterns is selectively winnowed, with the selection process based on social feedback, has been termed action-based learning (Marler and Nelson, 1993). There are probably parallels with the development of other kinds of motor behavior, including play.

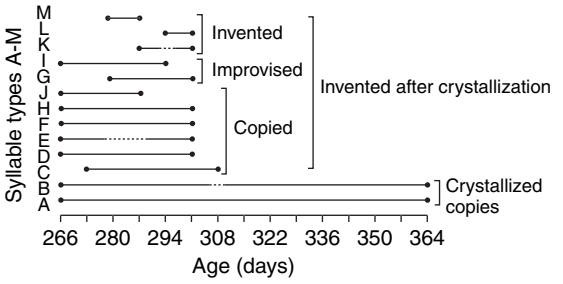

Figure 5 A diagram of song development in the same male swamp sparrow shown in **Figure 4**. In addition to the eight tape-recorded songs he imitated, he invented three more and modified two by improvisation. His crystallized adult repertoire of two song types is typical for this species.

Use-dependent processes of selective attrition may be widespread in the development of many kinds of behavioral activities. The actions that are discarded from the repertoire may themselves have functional significance. For example, songs that are practiced in youth and then rejected may provide a potential memory bank for the future, perhaps consulted in assessing the songs of others. In species that retain vocal plasticity into adulthood, discarded songs may be redeployed as the basis for producing new songs later in life.

The life-cycle timetable for action-based learning is different from that for memory-based learning. Action-based learning has the potential to recur whenever, for whatever reason; progression through a phase of variable action patterns is then followed by use-dependent winnowing of the variants. A mechanism is required for selective reinforcement of certain motor variants over others. Unlike memory-based learning, highly specialized brain mechanisms such as the oscine song system are not required. As a consequence, action-based learning is likely to have a wide phylogenetic distribution. For example, although nonhuman primates seem to be incapable of memory-based vocal learning, they do have a limited degree of vocal plasticity, possibly mediated by action-based learning.

1.17.4.3 Effects of Isolation and Deafness

Regardless of the opportunity to learn, certain aspects of the normal singing behavior of the species will always develop in oscines. When sparrows are raised in isolation, for example, the note structure and tonal quality of their songs is aberrant, but aspects of basic song syntax develop normally (**Figure 6**). Certain song features of the species are produced despite their absence from the tutoring songs a male has experienced, but with the important proviso that hearing must be intact.

The singing patterns of a hearing male oscine raised in isolation and of a male deafened early in life and raised in isolation are quite different. Typically, deaf male songs are highly degraded and variable, lacking most of the few normal features that an intact male can develop in isolation (Konishi, 1965). Songs of early-deafened males are not completely amorphous. This is true even when the critical step has been taken to be sure that there has been no song practice prior to deafening. This step

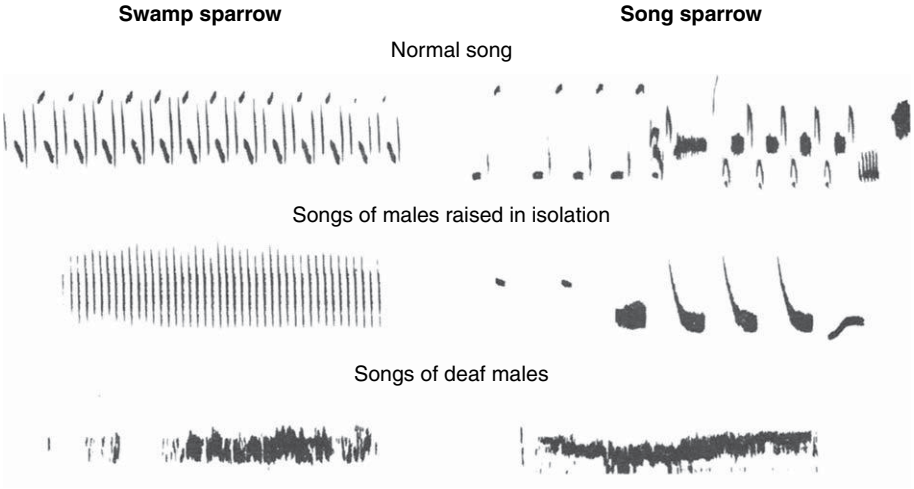

Figure 6 Normal songs of swamp and song sparrows compared with those developed by males raised in social isolation and by males deafened early in life. The simplicity of the note structure of the isolate songs is typical for sparrows. The high degree of species specificity, so evident in normal song, is largely erased from the songs of deaf males.

was lacking in some of the earliest studies. The emergence of some elements of species-specific song syntax in males deafened very early in life seems to implicate innate motor programs in song development. The highly abnormal song patterns characteristic of deaf birds develop both if a male becomes deaf before tutoring and if he is deafened after the tutoring but before singing has developed. There seems to be no internal brain circuitry that makes memorized songs directly available to guide vocal development. To transform a memorized song into a produced song, the bird must be able to hear its own voice. We can infer that some aspects of song production are guided by auditory templates for song, located in the brain, with specifications that vary from species to species (Konishi, 1965; Marler and Sherman, 1983). Neurobiologists have yet to demonstrate where these templates are located and how they operate (but see Whaling et al., 1997).

Like ornithologists, wild birds rely heavily on song for species identification. Each bird has its own distinctive way of singing, and this is recognized by other species members. Songs of early-deafened song birds, on the other hand, are often indistinguishable between species and are largely, though as noted not entirely, lacking in species specificity (**Figure 6**). Songs of males raised in isolation but with hearing intact fall somewhere between. They retain some species-typical features, and they lack others.

When tape-recorded songs are played to wild territorial males or to females in hormonally induced estrus, experienced birds of both sexes respond strongly to normal song of their species but completely disregard deaf songs as social signals (Searcy et al., 1985; Searcy and Marler, 1987). Similarly, songs of other species elicit none of the strong aggressive responses of territorial males, or the courtship of estradiol-primed females, that conspecific song evokes. But those of social isolates do retain a minimal level of effectiveness. Thus the efficacy of bird song as a social signal is augmented during development both by learning and by ontogenetic involvement of innate auditory templates that encode certain species-specific features of normal song.

1.17.4.4 Learning Preferences

Learning theorists once believed that any stimulus could be learned, given appropriate conditions; differences in stimulus potency, although present, were regarded as unimportant enough to be ignored in theorizing about the mechanisms underlying learning. We now know that innate predispositions play crucial roles in the adaptiveness of natural learning processes, and song learning in birds provides many illustrations of this principle. While birds are capable of learning a multiplicity of different sounds, including those of many other species (**Figure 7**), other-species mimicry is relatively rare in the wild (Kroodsma and Baylis, 1982). Leaving aside mimics, which only account for about 15% of songbirds, it is adaptive for most song birds to avoid other-species songs as models for learning.

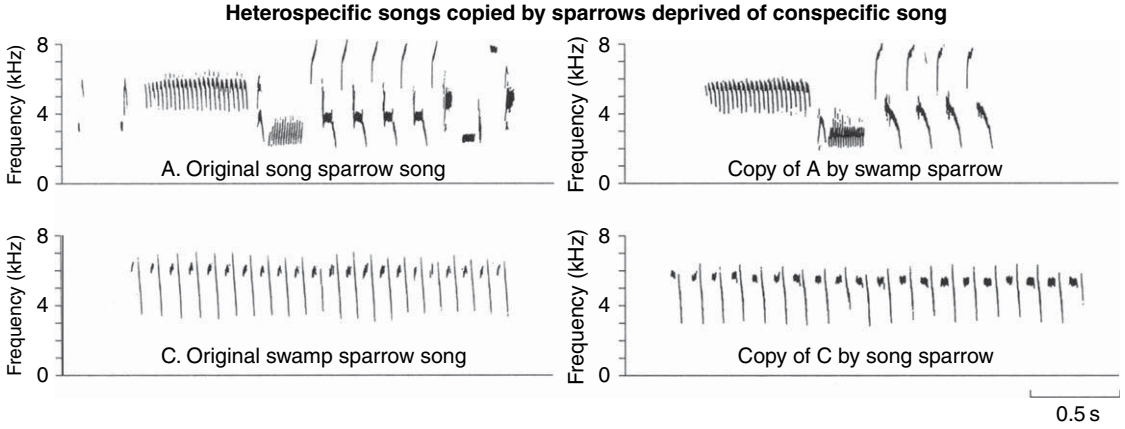

Figure 7 Although sparrows typically reject each other's songs as models for learning, they will sometimes accept them if given no other choice. Here male swamp and song sparrows learned a tape-recorded song of the other species when given no conspecific songs to listen to. Evidently the vocal apparatus is able to articulate the sounds of the other species song.

If males of two different species, such as swamp and song sparrows, are brought into the laboratory and exposed to identical tape recordings that include both species' songs, each displays a clear preference for song of its own kind, even if it has never been heard before (Marler and Peters, 1988, 1989). This preference does not arise from an inability to produce the other species song. An alien song that a male rejects, when given a choice, may become acceptable if it is the only option (**Figure 7**), especially when it is presented in a highly interactive situation by a live tutor caged nearby (Baptista and Petrinovich, 1986). But given a choice, there is typically a preference for conspecific song.

1.17.5 The Role of Innate Knowledge in Song Development

The view of the brain as a *tabula rasa*, a blank slate, all too long a basis for the thinking of learning theorists, is patently absurd. Whatever the task, every brain brings to bear a set of neurally based predispositions, each with its own evolutionary and experiential history, about how to proceed most efficiently in dealing with a given set of learning problems. Some of these predispositions are generic and pan-specific, and others are highly singular and even species specific, as with the innate processes that the human infant brings to bear on the development of speech behavior and language. Such is the case with birdsong.

The young bird embarks on the process of developing song armed with innate predispositions about how best to proceed. Some are generic, such as the widely shared tendency of songbirds to sing tonal sounds, evident even when they render imitations of sounds that were not originally strictly tonal (Nowicki et al., 1992). Others are species specific. When sparrows learn to sing, they favor conspecific song. They do so on the basis of not a single ethological sign stimulus but a range of song features. Naive young birds, recently fledged, are highly discriminating with regard to the song stimuli they find most potent, as revealed by their tendency to give more begging calls to them in response to playback (Nelson and Marler, 1993). By playing experimentally modified songs to young birds, innate responsiveness has been demonstrated to a range of conspecific song attributes. It is clear from their behavior that young birds possess extensive foreknowledge about the song of their species before they embark on the process of learning to sing. The evidence indicates that they know much more than you might guess solely on the basis of the songs that a male produces when raised in social isolation. They behave as though auditory experience that matches their innate knowledge is required before that knowledge can be fully brought to bear on song development (Marler, 1984).

One way to view song learning is as a process of validation by use of a subset of innate knowledge, drawn from a more extensive library encoded in the brain that details the rules for the singing behavior for each species (Marler and Nelson, 1992). This innate library is shared by all species members. The species-universal rules encoded there are sufficiently flexible to provide almost infinite opportunities for differences in individual behavior as a function of personal experience, and yet firm enough to restrict the development of excessive divergence between individuals.

There are analogies with the rules for orderly musical composition that each human culture possesses, encompassing the potential for an infinite number of different melodies (Jackendoff, 1994). The genetic underpinnings of the immune system provide another parallel, with the major histocompatibility complex providing enough alleles for a vast number of possible combinations. The imposition of limitations is important because it ensures that, however individualistic a bird's singing behavior may be, it still conforms closely enough to species-universal rules that obstacles to communication with others are minimized.

In addition to predispositions evident in the sensory phase of song memorization, others are manifest during motor development. The emergence of some species-specific basics in the song syntax of early-deafened males has already been noted. A bird tricked into learning heterospecific songs may only reject them in late stages of plastic song as species-specific syntax emerges (Marler and Peters, 1989). When young sparrows were tutored using experimentally modified songs with abnormally high syllable repetition rates, they imitated the songs but reorganized them in invented patterns that conformed more closely to the temporal organization of their normal species song (Podos, 1996). Again there is great flexibility in these motor predispositions, but even though songs with abnormal temporal organization can be taught, there is an underlying tendency to conform to species-specific norms. The individual and population differences that characterize learned birdsongs are all-pervasive, but they rarely confuse experienced bird watchers in identifying the species

responsible. With their genetic fitness at stake, the birds themselves are hardly likely to be any less perceptive.

1.17.6 Reinforcement and the Speed of Vocal Learning

Some of the distinctive features of song learning recur in other cases of developmental plasticity. It is not uncommon for developing behavioral and neural systems to exhibit sensitive phases, when the potential for plasticity is unusually great. Completion of one developmental stage is often a necessary precursor for embarking on the next.

Unlike some other widely studied forms of learning, no external reinforcement is required in song learning, even though social stimulation may augment the acquisition process. It suffices that the bird be exposed to an appropriate set of stimuli at the appointed stage of development for acquisition to occur. At the height of the sensitive period, learning can take place with great rapidity. Sometimes remarkably few exposures to a bird's own species song are sufficient. In sparrows, some acquisition can occur from 30 repetitions of a conspecific song. European blackbirds have learned from 15–20 song presentations on a single day.

The virtuoso performer in this regard is the nightingale, which can learn a sequence of song types accurately after 20 presentations – some males with as few as five. The virtuosity of nightingales is such that they can learn strings of up to 60 different songs and reproduce them in the original order. The sequencing is only retained in subsets of three to seven songs, however. After producing such a matched sequence, birds in one experiment then switched to another subset, beginning at a different point. These birds behaved as though they divide a string of many songs into manageable subsets of up to seven songs, using a strategy for memorizing long sequences reminiscent of that used by humans in memorizing strings of words (Hultsch and Todt, 1989, 1992, 2004). This is one of many avian accomplishments reminiscent of aspects of human speech behavior.

1.17.7 Song Development as a Creative Process

Perhaps most mysterious and intriguing of all is the ability of songbirds to invent new sounds. They achieve this in several different ways. Some birds first imitate the components of songs they have heard and then, as plastic song progresses, recombine them to create new sequences. In this way, parts can be exchanged within a song, between different songs, and even between songs that have been acquired many months apart (**Figure 8**). Rather than remaining faithful to the structure of imitated sounds, some birds find the temptation to improvise irresistible, especially during plastic song, so that songs originally imitated eventually become so changed as to be unrecognizable.

Not uncommonly, birds invent new sound patterns that they themselves have never heard. This is frequent in birds raised in isolation, with the result that, although the songs of isolates are abnormally simple in some respects, they are also extremely diverse. The act of producing novel and distinctively patterned sound seems to be itself reinforcing, attesting to the strong and deep-rooted commitment of many song birds to vocal inventiveness.

The drive to invention is stronger in some species than others. Certain birds remain quite rigidly faithful to their tutors, adding just sufficient individuality to personalize their song, and no more. Adherence to their models makes them especially tractable as subjects for laboratory investigation of song learning. Perhaps for this reason, the more imaginative songsters tend to be underrepresented in the roster of favored subjects for scientific study. The huge individual repertoires that males of some bird species possess, sometime with hundreds of song types,

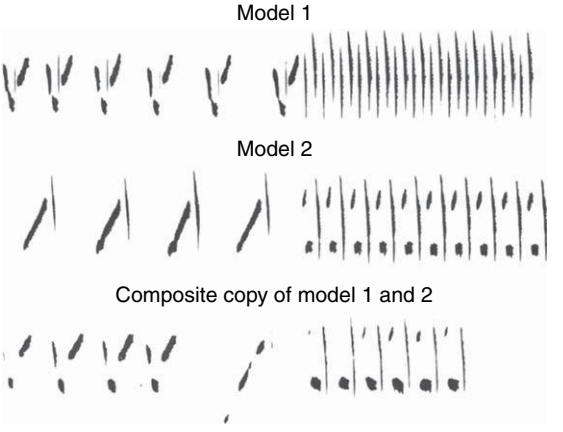

Figure 8 An example of a bird that created a new song by recombination. A captive male song sparrow was given only artificial songs to learn made up of two-parted swamp sparrow songs. He created a three-part song, approximating normal song sparrow syntax by combining parts of two different models.

built up by reiteration of these processes of imitation, segmentation, recombination, improvisation, and invention are barely manageable as subjects for scientific study. But for anyone interested in esthetic theory, the birds with large repertoires that give human listeners so much pleasure, such as mockingbirds and their relatives, the Australian lyre-bird, and certain thrushes, are unrivaled as subjects of choice. Utilitarian concerns are only one aspect of our fascination with birdsongs. If we are looking for animal models of the creative impulse, birdsong is one of the few that comes close to human standards.

1.17.8 Conclusions

As more bird species are studied, we find that each has achieved its own special solutions to the problems of developing a song. Songsters participate in a system of social communication that relies upon signals learned from others. Some species learn readily from song stimulation alone, and often remarkably few song stimuli are necessary, as though the brain is primed to be especially responsive to songs of a bird's own kind. Other species take longer to learn and require social stimulation.

Despite the possession of extensive innate foreknowledge about songs of their species, and a strong inclination to favor them if given a choice, they can be persuaded under special circumstances to learn songs of others. Certain species engage in the process of between-species mimicry naturally and create a species-specific song by imposing distinctive temporal patterning on the imitations as they are rendered. Some birds are faithful to the song they imitate, and others use imitations as a basis for improvisation, retaining certain features of the tutor and changing others.

The diversity of these patterns of behavioral development is made possible because, along with the oscine song system, the brain of each bird species brings to bear its own distinctive set of properties and predispositions to the task of learning to sing. The challenge for the neurobiologist is to understand not only the basic brain mechanisms that underlie the generic learning abilities of all song birds but also the more subtle, singular means by which a given species adds its own unique flavor to the process of developing a song, adapted to a particular set of social, ecological, and phylogenetic circumstances.

1.18 Adaptive Specializations and Generality of the Laws of Classical and Instrumental Conditioning

M. Domjan, University of Texas at Austin, Austin, TX, USA

1.18.1 Introduction

How general are the laws of classical and instrumental conditioning? Empirical observations invariably involve a particular species and responses and stimuli arranged in a particular fashion. But the findings would be of little interest if they were only applicable to the specific circumstances of their discovery. Scientists strive for generality. A specific experiment is of import only because we assume that it illustrates truths about the world that go beyond the circumstances of that experiment.

Early investigators of classical and instrumental conditioning were quick to assume that the behavior changes they were discovering in the laboratory represented general laws or principles of learning applicable to a variety of species and circumstances. Thorndike, for example, formulated the Law of Effect to characterize how instrumental behavior is acquired (Thorndike, 1898, 1911). Pavlov provided principles of classical conditioning, including delayed conditioning, inhibition of delay, extinction, and spontaneous recovery (Pavlov, 1927). Skinner characterized general principles of shaping and schedules of reinforcement for operant conditioning. Hull, Guthrie, and Tolman followed suit in formulating general theories of learning which were not restricted to a particular species, response, or stimulus (Bower and Hilgard, 1981).

Formulations that ignore the species and the particular stimuli or responses that are involved in a conditioning experiment have continued to dominate learning theory in the latter part of the twentieth century. These include theories offered by Rescorla and Wagner (1972), Mackintosh (1975), and Pearce and Hall (1980), and more recently the sometimes opponent processes (SOP) theory and affective emotional SOP (AESOP) (Wagner, 1981; Wagner and Brandon, 1989), the comparator hypothesis (Miller and Matzel, 1988), the temporal coding hypothesis (Savastano and Miller, 1998), and Rate Expectancy Theory (Gallistel and Gibbon, 2000). (*See also* Chapters 1.06, 1.10, 1.12.)

The assumption of generality has shaped not only our theories but also the range of experimental preparations that we use to study classical and

instrumental conditioning. If conditioning is in fact a general process, then we should be able to discover the laws of conditioning regardless of what species or situation we examine. This rationale, explicitly stated by Skinner, encouraged investigators to select experimental preparations based primarily on convenience. At the behavioral level, investigators have settled on a small number of experimental paradigms that have gained wide usage. These include pigeons key pecking for food as the reinforcer, rats pressing a lever for food or water, and the conditioned suppression or conditioned freezing procedure for studying classical conditioning.

The assumption that the laws of learning are general and widely applicable has also provided the fundamental justification for studies of the neurobiology of learning. Although such studies may be conducted in a hippocampal slice preparation or in a marine mollusk, the experiments are assumed to reveal general principles of neural plasticity that can be extended to intact vertebrates. The present chapter will review challenges to the generality of Pavlovian and instrumental conditioning at the behavioral level and discuss theoretical efforts to incorporate these challenges into a revised general theory of conditioning (*See also* Chapters 1.17, 1.20, 1.22). The exposition will focus on studies of conditioning in vertebrate species. However, the issues raised are also relevant to studies of learning in nonvertebrate species such as the honey bee (e.g., Menzel, 1990, 1999) (*See also* Chapters 1.27, 1.29).

1.18.2 Biological Constraints on Learning

Although the general-process perspective predominated theories of conditioning through much of the twentieth century, there were serious kinks in its armor. The first prominent challenges were actually provided by Thorndike, who studied learning in 15 different puzzle boxes and found some significant differences among them. In most of the puzzle boxes, the instrumental response was manipulating a latch or pulling a string to escape and get a piece of food. However, in some of the boxes, the required response was a self care behavior (e.g., grooming or yawning). Learning did not proceed smoothly in these boxes. The instrumental response initially increased, but the gain was not sustained. The yawn or scratch became perfunctory and not as genuine as spontaneous occurrences of these behaviors. Thorndike proposed the concept of *belongingness* to characterize these failed instances of the Law of Effect. According to this concept, an instrumental response has to 'belong with' the reinforcer to show robust acquisition.

It is to Thorndike's great credit that he reported failures in instrumental conditioning and violations of his Law of Effect, along with the successes. However, the failures did not attract much attention for nearly half a century. That is not to say that learning psychologists were always successful in designing instrumental conditioning procedures. Rather, the number of common experimental paradigms quickly narrowed to three that investigators could rely on to produce orderly data (lever-pressing in rats, key pecking in pigeons, and running in a runway in rats), and the importance of 'belongingness' effects took a back seat to efficient data collection. Subsequent analyses suggested that the development of these standard conditioning paradigms required considerable tuning that helped to match the procedure to the animal's behavioral predilections (Timberlake, 1990, 2001b).

Potential problems with general principles of shaping and instrumental reinforcement only became evident when investigators stepped outside the scope of conventional procedures. Two of Skinner's graduate students ventured far from standard laboratory procedures in their efforts to create displays for amusement parks and shopping malls showing ducks, chickens, raccoons, rabbits, and pigs doing various entertaining things for food reinforcement (Breland and Breland, 1961). If the instrumental response was releasing an object or token for food (e.g., having a pig put a coin in a piggy bank), initial acquisition was followed by a serious deterioration in performance. The pig, for example, would root the coin on the ground, and the raccoon would rub the coins together or 'dunk' it into the coin slot instead of releasing it. These responses resembled the natural behavior of these animals in situations involving feeding. Therefore, Breland and Breland characterized these as instances of 'instinctive drift.'

The failures of the Law of Effect and the shortcomings of Skinnerian principles that were highlighted by the Brelands were soon followed by analogous examples in avoidance conditioning. Bolles (1970) reported that freezing and running were much easier to condition as avoidance responses than rearing, lever-pressing, or pecking a response key. Unexpected

failures of learning also appeared in the area of stimulus control. Foree and LoLordo (1973) found that pigeons were less likely to use visual cues than auditory cues as discriminative stimuli for avoidance behavior. Garcia and Koelling (1966) found that rats could not associate audiovisual cues with illness or taste cues with foot shock.

These dramatic failures or constraints on learning were obtained at the same time that investigators discovered examples of remarkably rapid learning. Tastes could be associated with illness in a single trial, even if there was a long delay between the two events (Garcia et al., 1966). Pigeons could learn to peck a key-light paired with food (Brown and Jenkins, 1968), even if the pecking behavior was not required to obtain the food (Williams and Williams, 1969). Freezing and running were readily acquired as avoidance responses (Bolles, 1970), and audiovisual cues were readily associated with foot-shock even though they could not be associated with poisoning (Garcia and Koelling, 1966).

1.18.2.1 Empirical Analyses

Although initial theoretical efforts to explain biological constraints and adaptive specializations in classical and instrumental conditioning did not provide much insight into these phenomena, empirical analyses were more informative. In general, these served to confirm the validity of the initial findings and suggested ways in which problematic phenomena might be incorporated into general process theory (Domjan, 1983).

1.18.2.1.1 Constraints on the conditioning of token-release behavior

As noted earlier, one of the major problematic findings was that animals required to deposit a token for food or water reinforcement often refused to release the token (Breland and Breland, 1961). This behavior was initially puzzling because holding onto the token was not required for reinforcement and actually negated reinforcer delivery. Although the finding was puzzling from the perspective of instrumental conditioning, it could be easily explained once investigators considered the role of Pavlovian contingencies in the procedure. Requiring contact with the token before the delivery of food resulted in pairings of the token with the food reinforcer. Such stimulus–reinforcer pairings served to condition appetitive properties to the token stimulus, and the subsequent reluctance of the animal to relinquish the token was a reflection of this Pavlovian conditioned appetitive behavior (Boakes et al., 1978). Consistent with this interpretation, Pavlovian pairings of a token stimulus with food are sufficient to generate contact and handling of the token (Timberlake et al., 1982; see also Timberlake and Washburne, 1989).

1.18.2.1.2 Constraints on the conditioning of self-care responses

Thorndike (1911) was the first of several investigators who noted that grooming responses such as scratching and yawning are difficult to increase with instrumental conditioning. Subsequent experiments with the golden hamster suggested that this constraint on learning was also due to the Pavlovian conditioning that inevitably accompanies an instrumental training procedure. Hamsters show a suppression of grooming in anticipation of daily feedings (Shettlesworth, 1975), and grooming occurs as an interim rather than a terminal response with periodic food deliveries (Anderson and Shettlesworth, 1977). Thus, Pavlovian processes tend to suppress rather than facilitate grooming. Another factor that might be responsible for constraints on the conditioning of grooming responses is lack of necessary support stimulation. Pearce et al. (1978) found that scratching in rats can be conditioned more easily as an instrumental response if the rats wear a collar that provides tactile stimulation. Scratching appears to be easier to condition in primates (Anderson et al., 1990), perhaps because primates are better able to discriminate instances of scratching (Morgan and Nicholas, 1979).

1.18.2.1.3 Constraints on the conditioning of avoidance learning

Avoidance behavior appears to be even more heavily constrained than positively reinforced behavior. The limitations operate both on the types of responses that can be learned to prevent aversive stimulation and the types of stimuli that can serve as cues for avoidance behavior. Rats readily learn to avoid aversive stimulation if the instrumental response is running in a wheel, jumping out of a shock box, or remaining still (Maatsch, 1959; Bolles, 1969; Brener and Goesling, 1970). However, they have difficultly learning to rear or press a lever to avoid shock (D'Amato and Schiff, 1964; Bolles, 1969). Pigeons have a much harder time learning to peck a response key to avoid shock (Schwartz, 1974) than they have learning to press a treadle (Foree and LoLordo, 1970).

Avoidance procedures typically provide a signal for the impending aversive stimulus, and responding during the signal cancels the scheduled shock and turns off the signal. Auditory cues tend to become conditioned more readily as warning signals than visual cues (Foree and LoLordo, 1973; Jacobs and LoLordo, 1977), whereas visual cues are more easily conditioned as signals for food. Subsequent research has shown that selective association effects can also be obtained with a single reinforcer (food or shock). In these studies, the stimulus control acquired by the auditory or visual element of a compound stimulus depended on whether the compound signaled the presence or absence of the reinforcer (Weiss et al., 1993; Panlilio and Weiss, 2005).

Initial efforts to understand biological constraints on avoidance learning emphasized the concept of species-specific defense reactions (SSDRs). Bolles (1970, 1971) proposed that, in an aversive situation, the organism's repertoire is severely limited to a set of instinctive defensive behaviors (SSDRs) that include freezing, fleeing, and aggression. Which of these responses predominates was assumed to depend on environmental factors. In the absence of an escape route, freezing was presumed to predominate. If there is a potential escape route, fleeing may be the predominant SSDR. Responses such as lever-pressing or key-pecking are never likely to be acquired as avoidance behaviors because they are not related to an SSDR.

The SSDR hypothesis was important because it emphasized for the first time that to understand avoidance behavior we first have to consider the instinctive defensive behavioral repertoire of the organism. However, the details of the SSDR hypothesis turned out to be incorrect. Studies showed that the predominant SSDR for rats was freezing whether or not a prominent escape route was available (see Fanselow and Lester, 1988). These observations led to a reformulation of the SSDR hypothesis that introduced the concept of predatory imminence (Fanselow and Lester, 1988). This revised theory assumes that which of a range of possible defensive behaviors occurs depends on the perceived imminence of danger or predation. A low level of perceived danger (or predatory imminence) may reduce the amount of time a rat spends foraging but does not generate a targeted defensive action. In contrast, a high level of perceived danger elicits freezing. When the danger (or predator) is actually encountered, a defensive circa strike response is elicited. Differences in how rapidly subjects learn various avoidance responses are explained by reference to timing of expected danger and the instinctive responses that are elicited by a particular level of predatory imminence.

1.18.2.1.4 Long-delay taste-aversion learning

Another prominent phenomenon that encouraged consideration of adaptive specializations of learning is long-delay taste-aversion learning. This effect was originally discovered during the course of research on the biological effects of exposure to X-rays. Garcia and colleagues found that rats exposed to irradiation after drinking a saccharin solution subsequently showed a strong aversion to the saccharin flavor (Garcia et al., 1966; see also Smith and Roll, 1967). This type of learning was considered to be an exception to general process learning theory because it occurred in a single trial even if the irradiation (unconditioned stimulus, US) was presented several hours after the taste (conditioned stimulus, CS) exposure. Since this type of learning occurred rapidly over a long CS-US interval, it could hardly be considered a 'constraint' or limitation on learning. Furthermore, one could hardly argue that rats evolved to learn about exposure to irradiation. However, long-delay aversion learning helped explain how animals avoid nutritionally inadequate and poisonous foods and thereby end up eating a healthy diet. Therefore, taste-aversion learning became treated as an example of an adaptive specialization of learning that plays an important role in food selection (Rozin and Kalat, 1971).

Taste-aversion learning remains unique in permitting a delay of several hours between the CS and the US. Nevertheless, efforts to understand the basis for long-delay taste-aversion learning have identified a number of important factors. One factor concerns the nature of the taste stimulus and how it is encountered. In traditional classical conditioning procedures, the subject does not have to do anything to obtain either the CS or the US. In fact, the lack of a response contingency is considered to be a defining feature of classical conditioning. In contrast, taste stimuli are usually encountered as a result of licking a drinking tube. The licking behavior controls exposure to the CS and also provides nongustatory orosensory stimulation. The licking contingency and orosensory stimulation are important for taste-aversion learning. If a flavored solution is passed over the tongue without licking (through a cannula or while the subject is paralyzed with curare), the

strength of the taste aversion is significantly attenuated (Domjan and Wilson, 1972a; Domjan, 1973).

Another factor that contributes to long-delay taste-aversion learning is that the stimuli that subjects are likely to encounter during the delay period are not readily associable with illness and therefore do not provide concurrent interference (Revusky, 1977). In the typical long-delay taste-aversion experiment, subjects are given a novel flavor to drink and are then injected with a toxin several hours later. During the interval between the taste and illness, the subjects inevitably encounter various visual, auditory, and tactile cues. However, these are not likely to interfere with conditioning of the target flavor because nongustatory stimuli are less likely to become associated with toxicosis (see following section). Consistent with this idea, introduction of other flavors during the delay interval disrupts learning an aversion to the target flavor (Kalat and Rozin, 1971; Revusky, 1977). The concurrent interference hypothesis is challenged in explaining long-delay aversion learning to the tactile or other nongustatory aspects of ingested food (e.g., Revusky and Parker, 1976; Domjan and Hanlon, 1982; Domjan et al., 1982), since these should be disrupted by other tactile stimuli encountered during the delay interval. However, these other tactile cues are not accompanied by orosensory stimuli related to eating and drinking, and therefore they may not be as available for association with illness.

1.18.2.1.5 Selective associations

Although novel tastes readily become associated with illness, novel auditory or visual cues do not. In contrast, auditory and visual cues readily become associated with foot-shock, whereas taste cues do not. These cue-consequence specificity effects were first clearly demonstrated by Garcia and Koelling (1966) and attracted a great deal of attention because they were entirely contrary to general-process learning theory as it was known at the time. Initial efforts to analyze the effect focused on various methodological issues to rule out potential artifacts. To properly compare learning about taste and audiovisual cues, the two types of stimuli have to be presented in the same manner. Garcia and Koelling (1966) equated the method of CS presentation by having rats lick a drinking tube that produced both the taste and the audiovisual stimuli. In a subsequent study, Domjan and Wilson (1972b) equated the method of stimulus presentation by having both types of CSs presented independent of behavior. Similar results were obtained with both approaches.

Another methodological concern was that shock and illness may have different nonassociative effects, and those might be responsible for cue-consequence specificity effects. That possibility was ruled out in a study in which rats were given both shock and illness unconditioned stimuli, but only one of the USs was paired with a CS (Miller and Domjan, 1981). Despite exposure to both USs, when taste and a visual cue were paired with illness only a taste aversion developed, and when the CSs were paired with shock, an aversion only to the visual cue occurred.

In all of the initial experiments, aversions were measured in terms of suppression of drinking, and some critics were concerned that this response measure was differentially sensitive to certain CS-US combinations. To evaluate that possibility, Miller (1984) recorded a variety of responses in a cue-consequence specificity experiment (freezing, rearing, grooming, chin-wiping, head shaking, gaping, and drinking). He found that a taste paired with illness elicited increased gaping, head-shaking, and chin-wiping, and an auditory cue that had been paired with shock elicited increased freezing and decreased rearing and grooming. No evidence of learning in any response measure was found if the taste had been paired with shock or the auditory cue had been paired with shock.

The aforementioned studies served to substantiate the cue-consequence specificity effect but did not prove that the phenomenon was due to adaptive specializations resulting from evolutionary selection. Because the experiments were conducted with adult rats, one could argue that their previous experiences resulted in selective associations in adulthood. During normal ontogenetic experience, tastes are correlated with interoceptive malaise, and telereceptive cues are correlated with cutaneous pain. Perhaps these historical experiences produce the cue-consequence specificity effect. This experiential hypothesis was evaluated by conducting conditioning 1 day after birth. Despite the young age of these subjects, the cue-consequence specificity effect was replicated (Gemberling and Domjan, 1982).

1.18.3 Theoretical Analyses

1.18.3.1 Biological Constraints

The examples of conditioning that were unexpected on the basis of general learning processes were initially characterized as *biological constraints* on learning (Shettlesworth, 1972; Hinde and Stevenson-Hinde,

1973). The term 'biological' was intended to capture the notion that these examples were the result of natural selection. The term 'constraint' was used because investigators found limitations on what animals could learn particularly noteworthy. However, beyond pointing out the relevance of the subject's evolutionary history, the concept of a biological constraint does little to further our understanding of these unusual learning phenomena and does little to help us discover new ones (Domjan and Galef, 1983). The various forms of learning that were identified as biologically constrained had little in common other than the fact that they were unexpected on the basis of extant general process theory. Thus, considering them in a single category did not help to identify their underlying processes. Furthermore, it is unlikely that these constraints on learning were specifically selected for. Rather, they were probably the consequence of the selection of other forms of conditioning that were especially useful for the organism and increased its reproductive fitness. Thus, constraints on learning may be epiphenomena that result from the selection of forms of conditioning that are especially effective in foraging for food or avoiding predation.

1.18.3.2 Adaptive Specializations

Characterizations of special forms of Pavlovian and instrumental conditioning as adaptive specializations also emphasized the evolutionary origins of these learning phenomena. But in this case the focus was on instances of more rapid or robust conditioning than on slow and laborious learning (Rozin and Kalat, 1971). Taste-aversion learning was frequently discussed as an adaptive specialization, since it occurs with long delays between taste and illness, can be acquired in just one trial, and is specific to taste cues. One could easily imagine how this kind of learning might have evolved, since it seems ideally suited to solve many of the challenges that omnivores face in selecting a healthy diet (Rozin and Kalat, 1971). Rapid acquisition of freezing behavior in aversive conditioning probably also evolved as a specialization of the defensive behavior system.

Although the adaptive specialization approach is more promising than the constraints approach, labeling something as an adaptive specialization is just a promissory note that requires demonstrating exactly how the conditioning process increases reproductive fitness. The promissory note has not been paid in the case of taste-aversion learning. The justification is more convincing with conditioned freezing, since animals that freeze are less likely to be detected by a predator (Arduino and Gould, 1984; Suarez and Gallup, 1981). The only direct evidence of learning increasing reproductive fitness comes from studies of sexual conditioning (Hollis et al., 1997; Adkins-Regan and MacKillop, 2003; Mahometa and Domjan, 2005; Matthews et al., in press). However, those experiments employed conventional CSs, and the authors did not argue that the increase in reproductive fitness reflected an adaptive specialization in learning. Other examples of sexual conditioning (to be described later) involved species-typical CSs and may be more accurately characterized as representing adaptive specializations.

1.18.3.3 Preparedness

Biological constraints and adaptive specializations were proposed as alternatives to a general process account of conditioning phenomena. However, they did not dissuade investigators from looking for ways to incorporate unusual forms of learning into a more general conception. The first serious proposal along those lines was the concept of preparedness proposed by Seligman (1970; see also Seligman and Hager, 1972).

According to the concept of preparedness, tasks were considered to differ in the extent to which they were compatible or incompatible with the evolutionary history of the organism. Preparedness was defined as "the degree of input necessary to produce a specified output" in a learning procedure (Seligman, 1970, p. 407). Forms of learning that occurred quickly with relatively little input were said to be highly prepared. In contrast, forms of learning that required extensive training and input were said to be unprepared or contraprepared. Thus, the concept of preparedness enabled ordering various examples of learning along a continuum of preparedness. This continuum in turn served to integrate examples of biological constraints and adaptive specializations of learning without treating either category as an exception to general principles of learning. The proposal was to supplement general process theory with the continuum of preparedness that would then help characterize all forms of learning.

The concept of preparedness provided a convenient way to talk about instances of learning that were particularly easy or difficult to learn. However, the concept did little to advance our understanding or learning processes (Domjan and Galef, 1983). As first

proposed, the concept was basically circular. Measures of the rate of learning were used to identify different levels of preparedness, at the same that preparedness was intended to explain differences in learning rate (Schwartz, 1974). Second, a common metric was not available to measure input or training across widely disparate learning tasks such as taste-aversion learning and language acquisition. Third, even if a common metric could be found, behaviors that are learned at similar rates may not share other characteristics, such as rates of extinction or sensitivity to temporal contiguity. Despite these shortcomings, the goal of defining a continuum of learning effects that differ in biological preparedness remains laudable.

1.18.3.4 Behavior Systems and Learning

One of the most systematic efforts to integrate specialized forms of learning into a general theory is the behavior systems approach. This approach provides a general framework for characterizing how evolutionary influences determine the specific behavioral outcomes of laboratory conditioning procedures. Its starting point is that behavior is organized into functional systems that evolved to deal with specific tasks.

Functional systems of behavior have been entertained by a variety of investigators. Garcia and colleagues, for example, invoked functional systems in their efforts to explain differences between taste-aversion learning and fear conditioning (Garcia et al., 1974). According to them, organisms evolved specialized behavioral and neural mechanisms to deal with interoceptive information provided by the taste of food and its postingestive consequences. The interoceptive system operates on a time scale that facilitates the association of interoceptive CSs and USs, and this is responsible for long-delayed taste-aversion learning. In contrast, different behavioral and neural mechanisms, operating on shorter time scales, are involved in organizing responses to external cues and their consequences, such distal visual and auditory input that may lead to cutaneous pain. According to Garcia et al. (1974), selective associations reflect differences in the systems that are designed to deal with the *milieu interne* as contrasted with the *milieu externe*.

The behavior systems approach is also consistent with how Bolles (1970, 1971) characterized constraints on avoidance conditioning. As was noted earlier, Bolles proposed that aversive situations activate the defensive behavior system, which constrains the response repertoire of the organism to species-specific defense reactions. This idea was subsequently fleshed out with the suggestion that the defensive behavior system is also characterized by differential sensitivity to auditory cues (Foree and LoLordo, 1973) and is organized along a temporal dimension dictated by perceptions of the imminence of danger (Fanselow and Lester, 1988).

The concept of behavior systems and how they shape the behavioral outcomes of conditioning were spelled out in greatest detail by Timberlake and his associates (e.g., Timberlake, 2001a; Timberlake and Lucas, 1989). Although Timberlake focused on the feeding system in his empirical and theoretical work, he proposed a general framework for conceptualizing behavior systems and their role in learning. According to this framework, behavior is organized into functional systems, each designed to accomplish a major biological goal (feeding, predatory defense, reproduction). Within each system, behavior is organized in terms of a hierarchy of control mechanisms. The first level consists of response modes, each of which contains a number of response modules.

Response modes have a linear temporal organization, with one mode reliably following another. For example, in the feeding system, the general search mode is followed by the focal search mode, which in turn is followed by the food/handling/consumption mode. The same linear order holds whether the sequence moves forward to ingestion of food or backward in the event that food is not found. That is, if the food/handling/consumption mode is not successful, the organism returns to the focal search mode rather than the general search mode. Most importantly for predictions of learning effects, each response mode and module is characterized by unique stimulus sensitivities and response propensities. In the focal search mode, for example, animals are more attuned to details of their environment as they look for food in a particular location. Once the food has been obtained, the response repertoire shifts to food handling behaviors, controlled by features of the food object itself.

The behavior systems approach helps us understand biological constraints on conditioning because it assumes that the ease of learning a particular task depends on the extent to which the task is consistent with the behavior system that is activated by that conditioning procedure. Food deprivation and periodic deliveries of food, for example, strongly activate the feeding system, increasing the probability of

responses and stimulus sensitivities associated with that system. If a conditioning procedure requires an instrumental response, such as grooming, that is incompatible with the feeding modes and modules, that response will be difficult to reinforce with food. Responses more relevant to the feeding behavior system will emerge with food deprivation and food reinforcement, whether these are specifically reinforced or not. The emergence of these relevant behaviors is what Breland and Breland (1961) characterized as 'instinctive drift.'

1.18.4 Natural Learning Paradigms

All approaches to studying adaptive specializations in learning assume that specialized learning effects are the products of evolution. It is important to keep in mind that evolutionary selection is an interaction between selection processes and the ecology of the organism. Adaptation is not a progression to an ideal and does not occur in a vacuum. Rather, it occurs in the particular ecology and microenvironment inhabited by the species. Natural learning paradigms focus on that microenvironment.

General theories of conditioning are invariably couched in terms of abstract stimulus and response elements (conditioned and unconditioned stimuli or instrumental responses and reinforcers). An important assumption of general process theory is that these elements are unrelated before a conditioning procedure is introduced. In fact, this initial independence has been incorporated into the definitions of the stimulus and response elements. For example, a CS is defined as being 'arbitrary' or 'neutral' before its pairings with a US (Bower and Hilgard, 1981; Staddon, 1983; Shettleworth, 1998; Papini, 2002). These terms are used to signify that the CS has no inherent relation to a US prior to the introduction of a conditioning procedure.

The lack of an initial relation between CS and US may accurately characterize laboratory procedures for Pavlovian conditioning, but such independence cannot be true for naturally occurring instances of conditioning. If a CS and US were truly unrelated to each other in nature, they would not coincide with sufficient regularity to become associated. An arbitrary or neutral CS may be paired with a US once in a while by chance, but even if such pairings occurred, they would be preceded and followed by individual encounters with the stimuli, which would undermine their subsequent association (Benedict and Ayres, 1971; Rescorla, 2000). For a CS to be reliably paired with a US outside the laboratory, the CS has to be a natural precursor of the US or a stimulus that reliably occurs in the causal chain of events that leads to the US. Thus, in natural learning paradigms, the CS has to have an inherent or preexisting relation to the US before the onset of learning. Such an inherent relation is required for the CS to be reliably paired with the US so that an association can develop.

The fact that learning outside the laboratory depends on preexisting relations between events has been recognized for some time (Dickinson, 1980; Staddon, 1988). Being able to predict events of biological significance enables organisms to cope with those events more successfully (Domjan, 2005), and the best predictors of biologically significant events are "the causes of these events, or at least detectable indices of these causes" (Dickinson, 1980) – not arbitrary or neutral stimuli.

Interestingly, the first demonstrations of classical conditioning in Pavlov's laboratory involved a procedure that could readily occur in nature (Boakes, 1984). Studying how salivation may be elicited by various substances such as dry food, Stephan Vul'fson, one of Pavlov's students, observed that the dry food elicited salivation the first time it was placed in a dog's mouth. After several tests with the dry food, the sight of the food also started to elicit salivation. In this initial demonstration, the CS was the sight of the food and the US was the food in the mouth. Notice, that the CS was not arbitrary or initially unrelated to the US. Rather, the CS was a telereceptive feature of the food object.

Much of the early literature on adaptive specializations and biological constraints on learning involved learning situations that resembled natural learning paradigms. Long-delay taste-aversion learning is a prime example. Such learning probably evolved to discourage the ingestion of poisonous foods or substances with little nutritional value (Rozin and Kalat, 1971; Rzoska, 1953). An omnivore, such as a rat, that eats a varied diet has to learn to avoid eating foods that make it sick. Given that illness is usually a delayed consequence of eating something poisonous, the learning mechanism has to operate with a long delay between the taste and the consequent malaise. Note that the CS flavor is not arbitrary, neutral, or unrelated to the consequent poisoning. Rather, the taste is a feature of the poisonous food itself. Thus, it is inevitably encountered during the chain of events that results in food-induced illness.

Learning can occur to natural precursors of the US in a variety of response systems. In interacting with a sexually receptive female, for example, a male rat first encounters the odors of the female. Sexually naive males do not have a preference for the odor of estrous females. However, a preference develops with copulatory experience (Carr et al., 1965; Ågmo, 1999), presumably because of the pairings of the odor with sexual reinforcement.

Naturalistic learning can also occur in nursing situations, where tactile cues provided to an infant by the mother typically precede nursing and can come to elicit conditioned orientation and suckling responses (Blass, 1990). Cues that precede a nursing episode are also reliable precursors of the suckling stimulation that elicits oxytocin release and the milk let-down reflex on the part of the mother. Oxytocin release and the milk let-down reflex are initially unconditioned responses to suckling. However, they can also come to be elicited as anticipatory conditioned responses to prenursing tactile and olfactory cues provided by the nursing infant (Fuchs et al., 1987; Tancin et al., 2001).

Learning no doubt also occurs to stimuli that are encountered during the course of territorial and predator–prey interactions. Although predators have evolved strategies for surprising their prey, these improvements in offense have been accompanied by the evolution of detection and defensive tactics on the part of potential prey species. Cues that precede predatory attack are not arbitrary but are related to the visual, olfactory, or auditory features of a predator that can be detected at a distance before the attack. Learning to associate these cues with the subsequent predatory encounter can improve the effectiveness of defensive behavior (Hollis, 1990). Furthermore, fear is acquired more readily to ecologically relevant cues, such as the sight of a snake, than to ecologically irrelevant cues, such as the sight of flowers (Öhman and Mineka, 2001).

Repeated drug administration by drug addicts has also been described as a natural learning paradigm in which cues related to drug administration come to be associated with the drug effects and come to elicit conditioned physiological responses in anticipation of the impending drug delivery (Siegel et al., 2000). Consistent with this model, one approach to alleviating the symptoms of drug addiction involves repeated presentations of the drug administration cues without the drug, so as to extinguish the drug-conditioned responses (Siegel and Ramos, 2002).

Siegel and his associates have extended the conditioning analysis of drug addition to learning about different components of a drug effect (Kim et al., 1999). This analysis focuses on the fact that drug effects are typically long lasting and have distinct onset properties. One cannot experience the enduring effects of a drug without first encountering its onset properties. Therefore, the early physiological effects of a drug can serve as a CS for later drug effects and can come to control conditioned anticipatory physiological adjustments, in a manner analogous to the effects of exteroceptive drug administration cues. In this paradigm the CS is clearly not arbitrary or neutral with respect to the US.

1.18.4.1 Special Properties of Naturalistic Learning

The provided examples illustrate that conditioned stimuli that are natural precursors of the US are excellent candidates for conditioning. However, these examples do not prove that learning with naturalistic CSs occurs more rapidly or is more evolutionarily prepared than learning with arbitrary CSs. Evaluation of that hypothesis requires direct comparisons of learning with naturalistic versus arbitrary cues. Such comparisons have been conducted in the context of taste-aversion learning (see reviews by Logue, 1979; Domjan, 1980) and fear conditioning (e.g., Öhman and Mineka, 2001). More recently, Domjan and associates have examined this issue in detail in studies of the sexual conditioning of male Japanese quail, *Coturnix japonica* (see review by Domjan et al., 2004).

Japanese quail are ground birds that live in the Far East and in Hawaii in areas with tall grass (Schwartz and Schwartz, 1949). Although not much is known about their natural history, when a male initially sees a female, he is likely to see only her head and some of her neck feathers. As the two get closer and closer to one another, they get to see more of each other, and that permits more proximal social interactions. Thus, the natural sequence of events that results in an intimate social interaction and copulation begins with limited visual (and perhaps auditory) contact. This sequence of events can be replicated in the laboratory in a special application of a sexual conditioning procedure.

In a sexual conditioning procedure, a signal or CS is presented shortly before a male (or female) is permitted to interact with and copulate with a sexual partner (Pfaus et al., 2001; Woodson, 2002; Krause, 2003). For basic demonstrations, the CS may be a light or an odor. However, the procedure can be also designed to model the sequence of events that potential sexual partners encounter in their natural habitat. In the case of the *Coturnix* quail, this has been done by using a three-dimensional object as the CS that included a taxidermically prepared female head with partial neck feathers. To determine how learning with such a naturalistic CS differs from learning with a more conventional arbitrary CS, an alternative CS object was constructed that was similar in size and general shape to the naturalistic CS but lacked the taxidermic head+neck component.

A basic question that has to be answered at the outset with a naturalistic CS is whether such a CS elicits behavior unconditionally, without pairings with a US. Several studies have examined the responding that develops in male *Coturnix* quail to a head+neck object that is either paired with sexual reinforcement or presented in an unpaired fashion (e.g., Köksal et al., 1994; Cusato and Domjan, 1998; Hilliard et al., 1998). These studies have shown that a head+neck CS elicits a low level of approach responding if it is unpaired with copulation, but this approach behavior is substantially enhanced if the head+neck CS is paired with the sexual reinforcer. Interestingly, this pattern of results is similar to what is typically observed in taste-aversion learning. Unpaired presentation of a novel taste with toxicosis results in a mild aversion or neophobia to the taste solution. Pairing of the taste with illness produces a much more profound aversion. In both of these naturalistic learning situations, conditioning enhances a preexisting response to the CS.

If substantial responding to a naturalistic CS requires pairings with a sexual US, how does such learning differ from learning with an arbitrary CS? The first examination of this question was conducted by Köksal et al. (1994) who compared the extent to which the blocking effect occurs if the blocked CS includes (or does not include) female head+neck cues. All of the male quail that served in the experiment were initially conditioned with an audiovisual CS as a cue for sexual reinforcement. The preconditioned audiovisual cue blocked conditioning of an arbitrary CS object but did not block conditioning if the CS object included head+neck cues. Thus, the naturalistic CS was resistant to the blocking effect.

Subsequent studies have identified a cluster of learning phenomena that serve to differentiate how sexual conditioning proceeds with naturalistic versus arbitrary CS objects. In general, conditioned responding develops more rapidly with the naturalistic CS, and a greater range of conditioned responses come to be elicited (Cusato and Domjan, 1998). In particular, whereas the arbitrary CS object only elicits conditioned approach behavior after modest levels of training (e.g., 10–15 conditioning trials), the naturalistic CS also comes to elicit vigorous copulatory attempts (grabs, mounts, and cloacal contact responses) directed at the CS. Including naturalistic features in a CS object also increases the effectiveness of that CS in producing second-order conditioning (Cusato and Domjan, 2001; also described in Domjan et al., 2004).

Another phenomenon that shows the more robust nature of learning with a naturalistic CS is that such learning is not easily disrupted by increasing the CS-US interval (Akins, 2000). Long-delay learning is one of the signature features of taste-aversion learning. Although learning in the sexual behavior system does not occur with delays on the order of several hours, the use of a naturalistic CS significantly extends the range of effective CS-US intervals in sexual conditioning. Akins found that with a 1-min CS-US interval, conditioned sexual approach behavior develops whether or not the CS includes naturalistic features. However, if the CS-US interval is increased to 20 min, conditioned approach responding develops only if the CS includes female head+neck cues.

Rate of acquisition, blocking, second-order conditioning, and manipulations of the CS-US interval are familiar ways to test the robustness of a learning phenomenon. A more recently developed manipulation involves the I/T ratio, where 'I' refers to the duration of time spent in the experimental context between trials (or the intertrial interval), and 'T' refers to the duration of the CS (or trial time). In general, CS-directed conditioned responding is less likely to develop with small I/T ratios (Gallistel and Gibbon, 2000). However, an I/T ratio that is too low to support conditioned sexual responding to an arbitrary CS will nevertheless support vigorous responding directed towards a naturalistic CS (Gean, 2006).

The original formulation of the concept of preparedness linked acquisition and extinction effects. Instances of evolutionarily prepared learning were assumed to show more rapid and robust acquisition effects as well as slower extinction effects. This

linkage of acquisition and extinction has rarely been examined empirically. In one of the few examples of such linkage, Krause et al. (2003) found that once vigorous sexual conditioned responding develops to a naturalistic CS, the responding is much more resistant to extinction than is conditioned responding to an arbitrary CS. In this experiment, responding to the no-head CS declined to near-zero levels by the 14th day of extinction, but responding to the head+-neck CS remained high through the end of the experiment on day 42. This effect may have been due to the fact that the subjects directed copulatory responses toward the naturalistic CS object. Even though this copulation occurred with an inanimate object, it might have provided some sexual reinforcement, which served to maintain responding during the extended extinction procedure (Köksal et al., 2004).

1.18.4.2 A Continuum of Learning Effects

The evidence reviewed suggests that learning in natural learning paradigms is more robust in a variety of respects as compared with learning with arbitrary cues. At least in the sexual behavior system, naturalistic learning takes place more quickly, recruits a broader range of conditioned responses, motivates stronger second-order conditioning, is resistant to blocking and extinction, and occurs with longer CS-US intervals and lower I/T ratios. This broad range of learning effects has not been examined with naturalistic and arbitrary conditioned stimuli in other response systems. Therefore, the generality of these findings remains to be evaluated. However, since evolutionary selection operates within the ecological niche of a species, it is reasonable to assume that selection for robust learning involves reactivity to naturalistic rather than arbitrary cues. Therefore, the phenomena that were observed in the sexual behavior system probably represent differences that occur more generally.

The naturalistic and arbitrary CS objects that were compared in the sexual conditioning studies represent two points along a continuum. One end of that continuum consists of stimulus objects that are entirely unrelated to a potential sexual partner. At this end of the continuum the CS has no features in common with the US. The other end consists of CS objects that have many features related to a sexual partner or the US. Such a continuum is reminiscent of the continuum of preparedness proposed by Seligman (1970). However, unlike the original preparedness concept, the continuum described here is not circular. Different points along the continuum are characterized in terms of the extent to which the CS is a natural precursor of the US, which can be determined independently of learning. Differences in learning effects can then be predicted based on positions along the continuum.

Many naturalistic learning paradigms fit the model of a CS that has some features in common with the US because unconditioned stimuli are typically complex sensory objects or events with multiple features. For example, food (whether it is inanimate or a potential prey) has visual, olfactory, and sometimes auditory features that are evident to the forager at a distance. These can act as conditioned stimuli that are predictive of other features (taste, texture, and postingestional properties) that are encountered only when the forager contacts and eats the food. The multifaceted nature of a potential food object provides opportunities to learn to predict the location, taste, and other features of the food. How this learning takes place is organized by the microecology of the foraging species. The spatial separation of the foraging animal from the food object determines the temporal order of exposure to different features of the food and determines the nature of the CS-US pairings.

Aversive conditioning during the course of predator defense can be analyzed in a similar fashion. The predator that attacks a prey species also provides a variety of telereceptive and more proximal cues. The sight, smell, or sounds of the predator can be detected at a distance and are predictive of attack and cutaneous pain if the predator manages to catch and bite its prey.

1.18.5 Conclusion

Investigators have always assumed that learning processes evolved because they provide an adaptive advantage. However, the full implications of this claim have been rarely appreciated. One important implication is that how learning occurs will depend on the details of the ecosystem in which it evolved. The generality of conditioning phenomena and processes cannot be established by proclamation or by studying arbitrary stimuli or responses. Rather, the generality of learning has to be established empirically. Furthermore, general learning effects are only apt to be evident to the extent that the demands of diverse ecosystems have common elements. In the case of Pavlovian conditioning, such generality

exists in the causal and temporal structure of the experiences that lead to encounters with biologically significant events or unconditioned stimuli. However, in these natural sequences, the antecedent or signaling events are not arbitrary or unrelated to the US. Instead they have an inherent relation to the US that is determined by the details of the organism's ecosystem. Since learning evolves in the microecology of individual organisms, stimuli and responses that are a part of that ecology will activate the learning process more effectively. Thus, learning with ecologically relevant stimuli and reposes will be more robust than learning with arbitrary cues.

1.19 Learning to Time Intervals

K. Cheng, Macquarie University, Sydney, NSW, Australia

J. D. Crystal, University of Georgia, Athens, Georgia, USA

1.19.1 Introduction

Time is a fundamental dimension of life. Many animals have evolved the ability to time intervals lasting from a fraction of a second to hours. Traditionally, it is thought that a distinction must be made between circadian timing and interval timing (Gibbon et al., 1997a). Circadian timing concerns the ability to adjust to the daily cycle caused by the rotation of the Earth around its axis, which has a period of 24 h. Circadian clocks 'tick over' every 24 h or so when running 'free' (without external input about night and day), and the period is set to 24 h by external cues such as daylight. In vertebrate animals a neurological structure known as the suprachiasmatic nucleus is taken to be the 'master clock.' This chapter concerns interval timing, which is the ability to time shorter intervals, typically in the range of seconds to minutes.

We examine three experimental paradigms used to study interval timing and illustrate them with some characteristic results. Three theories of interval timing are discussed briefly. Then we turn to examining the differences between interval timing and circadian timing more closely, to show that the distinction is not so clear cut. We begin with three cases of the use of interval timing in the natural lives of animals.

1.19.2 Interval Timing in Everyday Life

The rat, normally a highly social animal, varies its eating behavior according to the size of the chunk of food it is eating. The motor patterns are so ingrained that it even does them when alone in an experimental arena, a standard operant chamber (Whishaw and Tomie, 1989; **Figure 1**). If a tiny pellet is delivered into the food magazine, the rat picks it up and eats it right at the magazine, without lowering its forepaws. With larger pellets, the rat lowers itself to the floor before eating. With still larger pellets, the rat takes the pellet and turns away from the magazine before

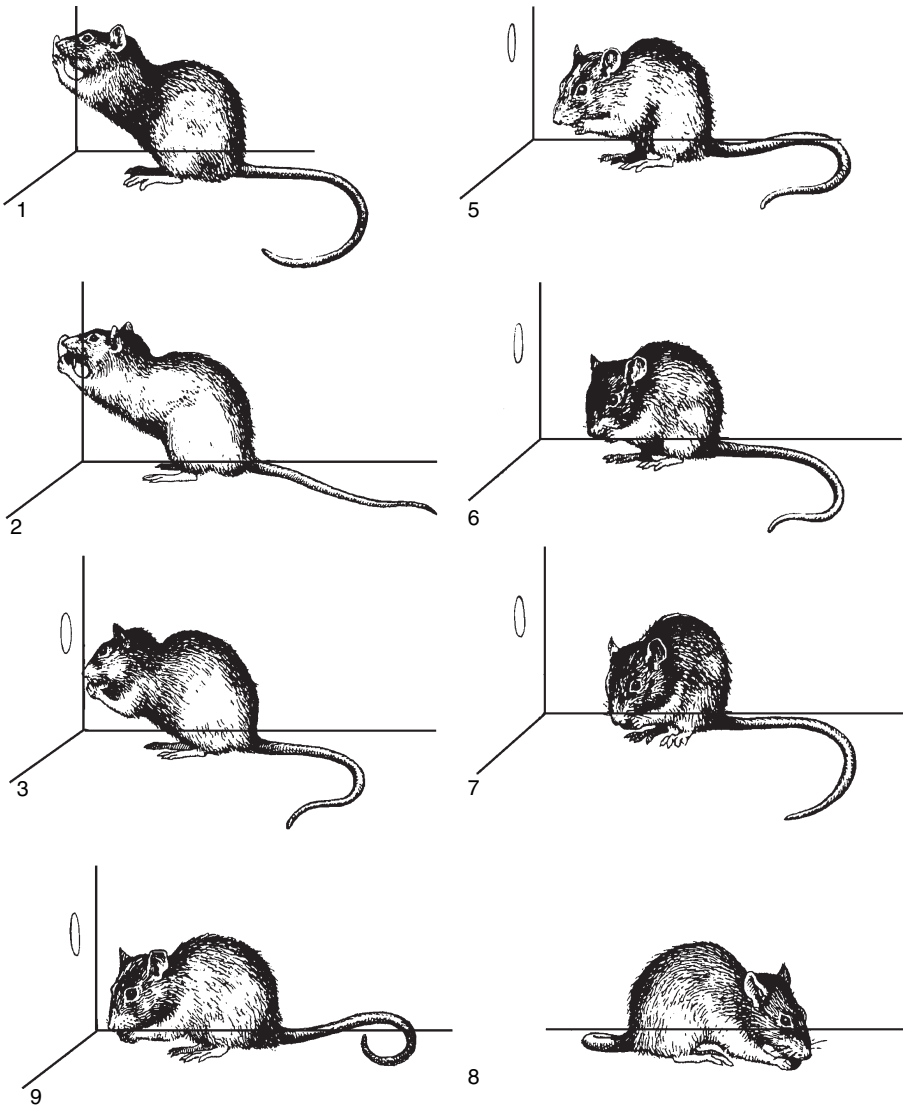

Figure 1 Illustration of what a rat does with a pellet of food of different sizes. Increasing numbers on the panels correspond to increasing food size. At the smallest sizes, the rat eats the food right at the hopper. At bigger sizes, it brings the food to ground level before eating it. At still larger food sizes, it turns away from the hopper before eating. At very large sizes (not shown), the rat hoards the food to an adjacent chamber. Reproduced with permission from Whishaw IQ and Tomie J (1989) Food-pellet size modifies the hoarding behavior of foraging rats. *Psychobiology* 17: 93–101.

eating. At the largest sizes, the rat hoards the pellet to an adjacent chamber. A further study showed that food handling time rather than food size was the determining factor in the rat's eating behavior (Whishaw, 1990). The rat varies what it does with food according to how long it takes to eat the pellet.

A foraging honeybee also needs to time short intervals regularly. Foragers rate the quality of pollen or nectar that they bring back relative to what others bring back (Seeley, 1995). This is achieved because foragers unload their booty to food storers in the hive. The length of time it takes to unload the forage thus indicates how good it is relative to what others bring back. This in turn influences other behaviors, such as whether to recruit other foragers by 'dancing' and how long to do the waggle dance (*See* Chapters 1.25, 1.29). Timing abilities in bees have also been addressed in formal experiments (Greggers and Menzel, 1993; Boisvert and Sherry, 2006).

Another example of timing in everyday life comes from a study of Rufous hummingbirds (Henderson et al., 2006). Hummingbirds adjust their visits to

flowers based on the rate at which the flowers replenish. Henderson and colleagues refilled multiple artificial flowers with sucrose solution 10 min after the bird emptied it; they refilled other flowers 20 min after the bird emptied these flowers. Throughout the day, the birds revisited the 10-min flowers sooner than they revisited the 20-min flowers. To revisit each flower at the right time throughout the day, the birds had to update their memories of when and where food was encountered for each flower and how long it has been since the last visit (Crystal, 2006a; Henderson et al., 2006).

1.19.3 Experimental Paradigms

The examples of timing just described involve learning about the temporal constraints of environmental resources. In the sections that follow, we discuss timing experiments; animals are required to learn to time target intervals in each preparation. In subsequent sections, alternative theories are discussed that make different predictions about the mechanism by which this temporal learning occurs (*See also* Chapter 1.12).

Most of the experimental work on interval timing has been done with three vertebrate species in highly controlled settings: laboratory rats, laboratory pigeons, and adult humans. Three kinds of experimental paradigms have been staples in research, and we describe them here and show some representative results.

1.19.3.1 Bisection Task

In the bisection task, also called the estimation or choice task, the subject is presented with two choices for responding, such as two levers to press for rats, two keys to peck for pigeons, or two keys to press on a keyboard for humans. During training, a single interval of time is presented on each trial. The interval is commonly signalled by the duration of a key that lights up or a tone that sounds. The interval might be one of two durations, a short duration S (e.g., 2 s) or a long duration L (e.g., 8 s). When the interval is over, the subject gets to make a choice. One of the choices is arbitrarily designated the 'short' choice and is correct for the short duration. The other choice, the 'long' choice, is correct for a long duration.

After sufficient training, subjects typically perform very well on the training intervals. Occasional tests are then given using intervals not used in training. These test intervals typically span the range of durations between the short and the long training durations. In the example, durations of 2, 3, 4, 5, 6, 7, or 8 s might be presented on test trials. Typical data from rats and humans are shown in **Figure 2**. In general, a smooth psychophysical curve is obtained, with the probability of choosing 'long' increasing in a sigmoidal fashion with the test duration presented.

Of some concern in bisection studies is the point of subjective equality (PSE) or bisection point, from which the task obtains its name. This is the stimulus duration at which a subject is equally likely to choose 'long' and 'short,' or 50% of each. The bisection point is estimated by various curve-fitting techniques from the psychophysical function that is obtained on tests. For rats and humans, the bisection point is at the geometric mean when the ratio of long to short duration is small (Church and Deluty, 1977; Allan and Gibbon, 1991). The geometric mean of two numbers, **a** and **b,** is defined as:

$$M_{geom}(\mathbf{a},\mathbf{b}) = \sqrt{(\mathbf{a} * \mathbf{b})},\ \text{the square root of } \mathbf{a} \text{ times } \mathbf{b}.$$

This is a midpoint by ratios rather than arithmetic differences, that is:

$$\mathbf{b}/M_{geom} = M_{geom}/\mathbf{a}, \quad \text{for } \mathbf{b} > \mathbf{a}.$$

In contrast, the familiar arithmetic mean (M_{arith}) of **a** and **b**, $(\mathbf{a}+\mathbf{b})/2$, is the midpoint by arithmetic differences:

$$\mathbf{b} - M_{arith} = M_{arith} - \mathbf{a}.$$

A bisection point at the geometric mean, then, suggests a comparison of ratios between the remembered reference durations and the duration presented on the test trial (more on this later).

What size ratio is small enough for a bisection point at the geometric mean differs between humans and rats. Church and Deluty (1977) found rats bisecting at the geometric mean with a L:S ratio of 4:1, as did others (Chiang et al., 2000; Santi et al., 2001; Crystal, 2002). For humans, Allan and Gibbon (1991) used L:S ratios of 2:1 or smaller and also used short durations ($\leq$4 s). With larger L:S ratios, the bisection point is no longer at the geometric mean and is often closer to the arithmetic mean. In rats, an L:S ratio larger than 4:1 led to a bisection point that differed from the geometric mean (Raslear, 1983; Siegel, 1986; Shurtleff et al., 1990; Shurtleff et al., 1992). Unfortunately, the bisection point differed between the studies. In humans bisecting short durations (<1 s), Wearden

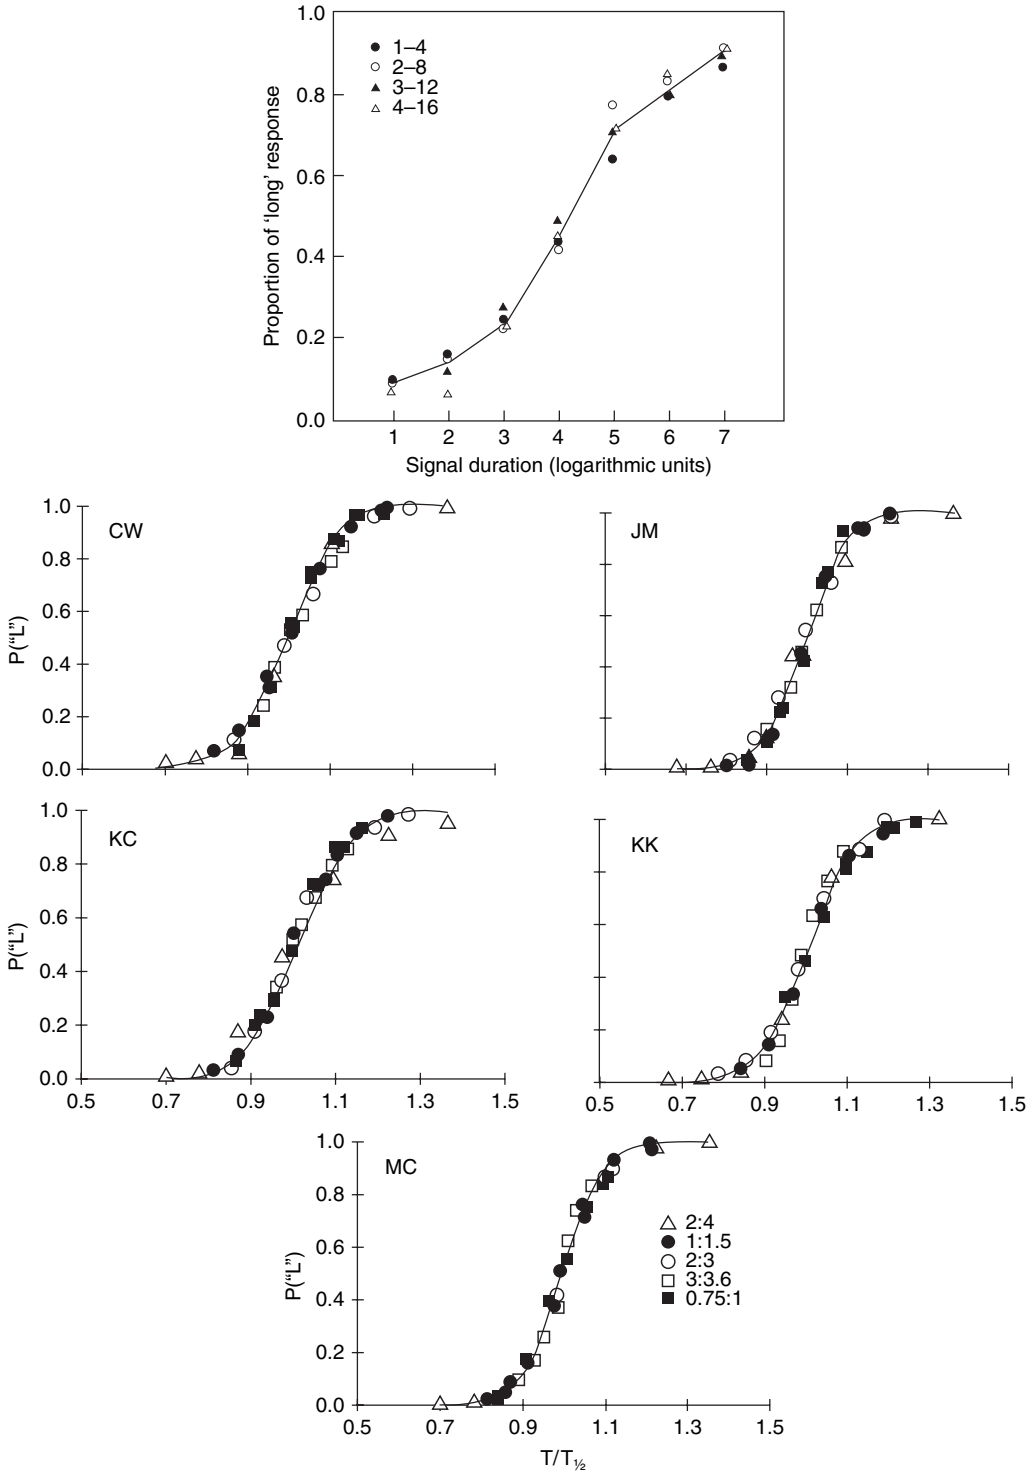

Figure 2 Representative data on the bisection task from rats (top) and individual humans (bottom). Tasks with different reference durations to be discriminated have been pooled together. Data are from unrewarded tests (for rats) and tests without feedback (for humans). Note that data from different conditions superimpose when plotted in this proportional fashion. Top, reproduced with permission from Church RM and Deluty MZ (1977) Bisection of temporal intervals. *J. Exp. Psychol. Anim. Behav. Process.* 3: 216–228; bottom, reproduced with permission from Allan LG and Gibbon J (1991) Human bisection at the geometric mean. *Learn. Motiv.* 22: 39–58.

and Ferrara (1996) found bisection at the geometric mean with an L:S ratio of 2:1, but with larger ratios, the bisection point was closer to the arithmetic mean. With longer durations in the seconds range, bisection was not at the geometric mean with any L:S ratio, including 2:1 (Wearden et al., 1997). The bisection points were closer to the arithmetic mean.

An interpretation for the variable results obtained with larger L:S ratios is that intermediate points are perceptibly different from both the L and the S durations to the subjects. A subject then in effect judges neither, and some strategic rule needs to be invoked as a basis for responding. The strategic rule is likely to vary from subject to subject, thus causing variablility in the data.

1.19.3.2 Peak Procedure

The peak procedure is an adaptation of the fixed interval schedule (**Figure 3**; *See also* Chapter 1.06). It is a production task in that the animal gets to emit responses over a stretch of time signaled by some event. Two types of trials are given to subjects. On training trials, a signal marks the start of an interval to be timed. Typically, this is a light or a tone that stays on. After a set interval has elapsed, a reward is delivered for a response (press a bar, peck a key, push a button), that is, the first response after a fixed interval from signal onset is rewarded. Responses before the fixed interval elapsed have no effect. On test trials, the signal also marks the start of a trial, but no rewards are dispensed. The signal stays on for much longer than the fixed interval on training trials. We illustrate the paradigm and typical results with some examples.

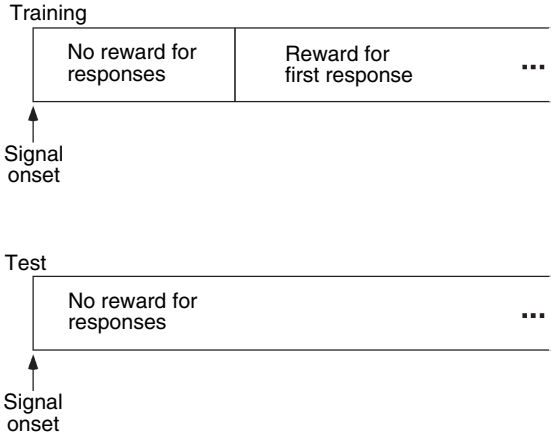

Figure 3 Schematic illustration of the peak procedure. On a training trial (top), a signal indicates the start of a trial. The first response after a fixed duration (FI) has elapsed is rewarded. On a test trial (bottom) the signal stays on for a duration much longer than the FI, and reward is withheld.

Roberts (1981) presented rats the peak procedure using fixed intervals of 20 s and 40 s. A light and a tone signaled the two fixed intervals. For example, when the tone sounded on a trial, reward was given for the first bar press after 20 s; when a light lit up on a trial, reward was given for the first bar press after 40 s. Occasionally, unrewarded tests lasting 80 s were given using the light or the tone. On these trials, the light or tone stayed on for 80 s, but no reward was dispensed. **Figure 4** shows the results on tests from the last five sessions of Roberts' (1981) experiment, averaged across rats and trials. It can be seen that the rats started responding before the fixed interval elapsed, but the probability of responding peaks at around the fixed interval assigned to each signal.

Pigeons show a similar pattern of behavior on the peak procedure (Roberts et al., 1989). In **Figure 5**, the group of pigeons was also trained with two signals, a light and a tone. When the light signaled the start of a trial, a key peck was rewarded after 15 s; when a tone signaled the start of a trial, a key peck was rewarded after 30 s. The data came from unrewarded tests with each signal that lasted 90 s. Other than peaking at around the expected time of reward on training trials, two other features are noticeable. The response distribution curves are not perfectly symmetrical. The slope is steeper on the rise to the peak on the left side than the fall from the peak on the right side. In addition, the response distribution curve for the tone shows a rise toward the end of the test trial.

In a third example, humans were tested on the peak procedure (Rakitin et al., 1998). Training fixed intervals of 8, 12, and 21 s were presented using a

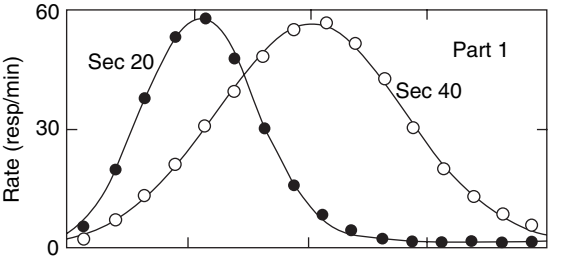

Figure 4 Representative data from rats on the peak procedure. On the *x*-axis is time elapsed because the of start of an unrewarded test trial lasting 80 s. Each tick mark represents 20 s. The peak rate of responding when averaged across trials occurs near the fixed duration. Reproduced with permission from Roberts S (1981) Isolation of an internal clock. *J. Exp. Psychol. Anim. Behav. Process.* 7: 242–268.

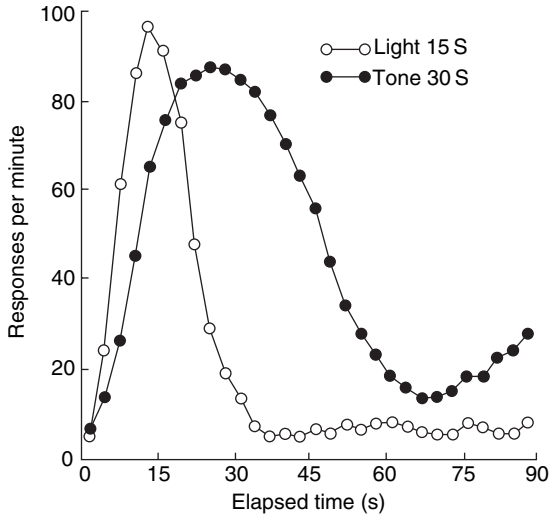

Figure 5 Representative data from pigeons on the peak procedure. These birds were trained with two different fixed intervals. A light was associated with fixed duration (FI) 15 s, whereas a tone was associated with FI 30 s. Data are from unrewarded test trials lasting 90 s. Reproduced with permission from Roberts WA, Cheng K, and Cohen JS (1989) Timing light and tone signals in pigeons. *J. Exp. Psychol. Anim. Behav. Process.* 15: 23–35.

computer. Subjects participated in multiple sessions, with the fixed interval constant in each session. Test trials were slightly different from those given to pigeons and rats. A subject could terminate a trial by pressing the enter key on the keyboard, or the tests ended automatically after the fixed interval for the session had elapsed three times. Results showed orderly near-Gaussian distributions resembling those found for rats (**Figure 6**).

1.19.3.3 Generalization

In generalization, the subject gets to answer yes or no to the 'question' of whether a presented duration is the standard or rewarded duration. For example, Church and Gibbon (1982) presented rats with a house light that stayed on for different durations. A lever was inserted after (but not before) the house light went off. A standard duration was the positive duration, for example, 4 s if the house light lasted 4 s, and a bar press would be rewarded. For other durations, bar presses went unrewarded. Results showed an orderly generalization function peaking at the positive duration and dropping off nearly symmetrically in a Gaussian fashion (**Figure 7**). The response rate did not drop to zero; at all durations, the rats responded on a proportion of the trials.

The generalization paradigm has also been used on humans (Wearden, 1992; Wearden and Towse, 1994; Wearden et al., 1997). One standard duration was presented as the positive duration. Subjects' task was to answer YES or NO according to whether the

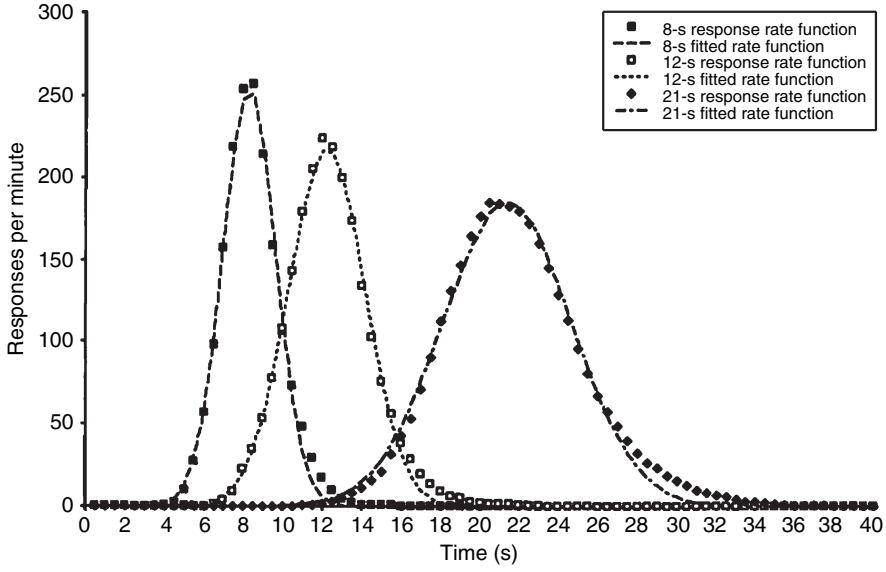

Figure 6 Representative data from humans on the peak procedure. Humans were instructed to hold down a key to 'bracket' a target fixed interval. They were to start before the interval had elapsed and stop after the interval had elapsed. Reproduced with permission from Rakitin BC, Gibbon J, Penney TB, Malapani C, Hinton SC, and Meck WH (1998) Scalar expectancy theory and peak-interval timing in humans. *J. Exp. Psychol. Anim. Behav. Process.* 24: 15–33.

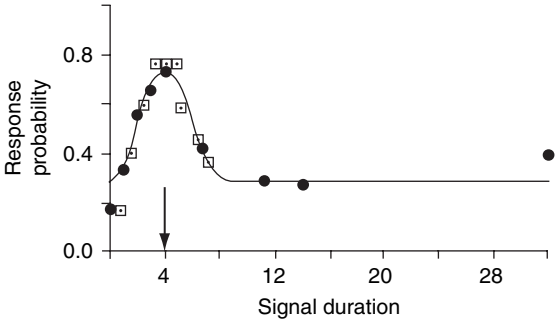

Figure 7 Representative data from rats on the generalization task. A duration of tone was presented to the rat, and then a lever was inserted. Lever presses were rewarded if the tone duration was 4 s, but not if it was any other duration. The data show a symmetric generalization gradient around the reinforced duration of 4 s. Reproduced with permission from Church RM and Gibbon J (1982) Temporal generalization. *J. Exp. Psychol. Anim. Behav. Process.* 8: 165–186.

duration presented on a trial was or was not the standard duration. Wearden (1992) and Wearden and Towse (1994) used very short durations that precluded counting. Longer durations in the seconds range were used by Wearden et al. (1997); subjects were prevented from counting by having to shadow (repeat back) an irregular list of numbers. For both short and long durations, orderly generalization gradients were obtained (**Figure 8**). A difference from those found with rats is that the gradients were asymmetric: More YES responses were given to durations longer than the standard (on the right side) than to durations shorter than the standard (on the left side).

1.19.4 Scalar Property

A property found in all the data examples that we have shown is the scalar property. Most of the data graphs are in absolute units of time. The scalar property emerges when data are plotted in units of time relative to the standard duration being measured (for the peak procedure and generalization) or the subjective middle (for the bisection task). When data are plotted in this fashion, graphs having different absolute standards superimpose, as shown in **Figure 9** for humans on the peak procedure and **Figure 2** (bottom) for humans in the bisection task. For this reason, the scalar property is also called superimposition.

Put more formally, some measure of spread, such as the standard deviation of a response distribution or the distance between the quartiles, is a constant proportion of the duration being measured in the peak procedure or generalization paradigms:

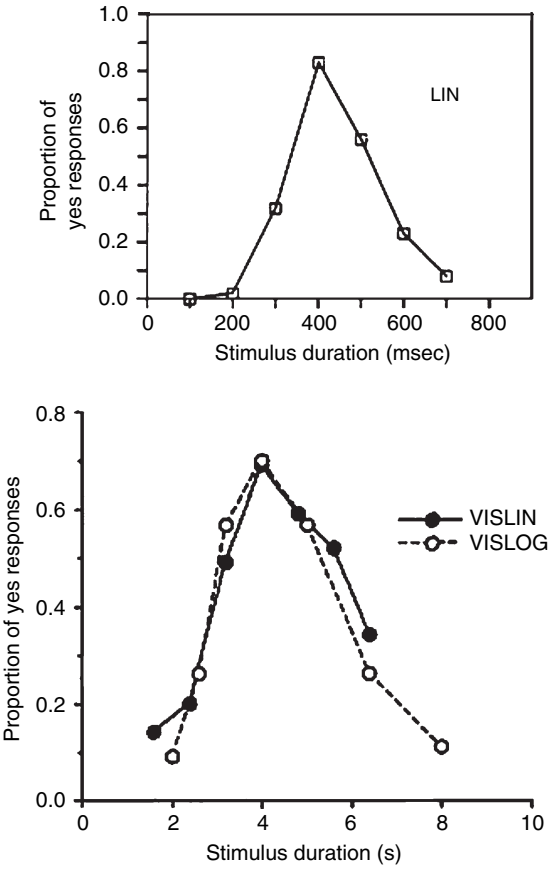

Figure 8 Representative data from humans on the generalization task with very short intervals (top) and intervals in the seconds range (bottom). Humans answered "yes" or "no" to the question of whether a presented duration matched a reference duration (400 ms in the top panel, 4 s in the bottom panel). Unlike rats, the generalization gradients are asymmetric, dropping more slowly to the right (corresponding to durations longer than the standard). Top, reproduced with permission from Wearden JH (1992) Temporal generalization in humans. *J. Exp. Psychol. Anim. Behav. Process.* 18: 134–144; bottom, reproduced with permission from Wearden JH, Denovan L, Fakhri M, and Haworth R (1997) Scalar timing in temporal generalization in humans with longer stimulus durations. *J. Exp. Psychol. Anim. Behav. Process.* 23: 502–511.

$$\text{Spread} = kX, \text{where } X \text{ is the duration being measured.}$$

This is also known as Weber's law. The constant k, which is Spread/X, is known as the coefficient of variation or Weber fraction.

1.19.5 Theories of Interval Timing

We examine briefly three different theories of interval timing; each theory makes different assumptions

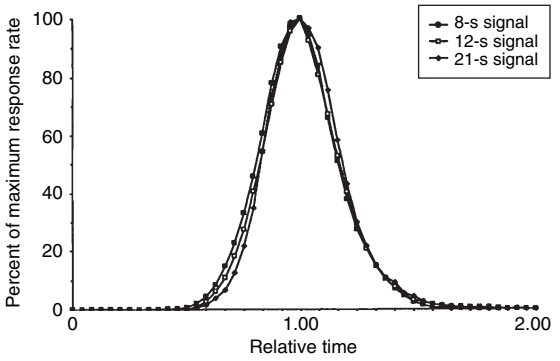

Figure 9 Superimposition in data from humans on the peak procedure. The data in Figure 6 have been replotted in relative terms, with the *x*-axis expressed as a proportion of the fixed duration. Reproduced with permission from Rakitin BC, Gibbon J, Penney TB, Malapani C, Hinton SC, and Meck WH (1998) Scalar expectancy theory and peak-interval timing in humans. *J. Exp. Psychol. Anim. Behav. Process.* 24: 15–33.

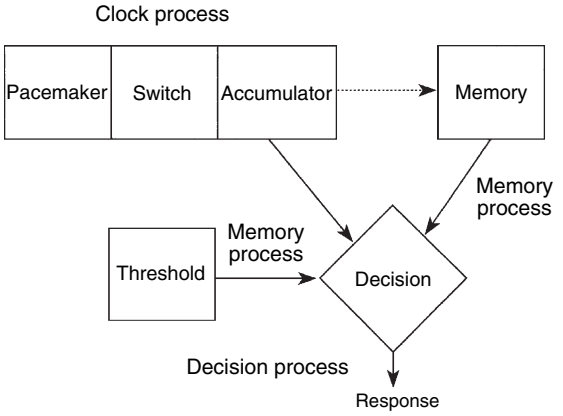

Figure 10 The Scalar Expectancy Theory (SET), consisting of three processes: a clock process, a memory process, and a decision process. The clock consists of a pacemaker that sends out regular pulses. The pulses may be gated by a switch into an accumulator for the purposes of timing a current duration. The elapsed time is compared to a standard duration retrieved from memory. If the ratio of the elapsed time to the reference time exceeds a threshold (which is also retrieved from memory for the trial), then the animal responds at a high rate (in the peak procedure) or answers "yes" in generalization. For the bisection task, two reference durations need to be retrieved, one for the long duration and one for the short duration. Ratio comparison is again made: elapsed time/S is compared with L/elapsed time. The subject chooses the reference (S or L) that generated a smaller ratio. Adapted with permission from Church RM (2003) A concise introduction to scalar timing theory. In: Meck WH (ed.) *Functional and Neural Mechanisms of Interval Timing,* pp. 3–22. Boca Raton, FL: CRC Press.

about the mechanism(s) of learning about the temporal constraints of the environment. A good number of other theories have been developed as well, but the chosen ones give some idea of the range of extant theories. At this stage, the field is far from agreeing to a single theory.

1.19.5.1 Scalar Expectancy Theory

A widely used explanation for interval timing is the Information Processing (IP) model (Gibbon et al., 1984; Church, 2003), also known as Scalar Expectancy Theory (SET; **Figure 10**). According to the IP model, timing is based on three stages of information processing: clock, memory, and decision. The clock stage of information processing consists of a pacemaker that sends pulses to an accumulator. A switch gate pulses from the pacemaker to the accumulator (or, alternatively, diverts these pulses away from the accumulator). The memory stage of information processing consists of working and reference memory storage systems. Working memory contains the current estimate of elapsed time, as indexed by the number of pulses accumulated at a particular point in time. Reference memory contains examples of previously rewarded elapsed durations that were previously transferred from working memory to reference memory. The decision stage of information processing compares a randomly selected example from reference memory to the currently elapsing duration. The decision to respond (or not) is based on the relative similarity of the estimate of current and remembered times.

The scalar property or Weber's law suggests a ratio comparison process. Consider, for example, the peak procedure. The animal is said to switch to a high rate of responding after a ratio of elapsed time (from the clock process) to the reference duration (from the memory process) has been passed. If the *average* ratio threshold is the same at different fixed durations (FIs), this would produce the scalar property. Variations from trial to trial in the thresholds and reference durations used would produce the shape of the response distribution found when many test trials are pooled.

Many timing studies have interpreted results in terms of SET. Consider, for example, the generalization results shown in **Figures 7 and 8**. Results such as those from the rat in **Figure 7** can be modeled by a decision process that compares a ratio of two durations to a threshold ratio. The numerator is the absolute difference between the duration presented

on the trial (clock process feeding working memory) and a reference duration from memory. The denominator is the reference duration. Thus, the comparison can be represented as

$$|t - T|/T < b?$$

In the inequality, T represents a reference duration from memory, whereas t represents the duration on the current trial. Such a process produces a symmetric generalization gradient. Wearden (1992) found that a modification of the comparison rule accounted for the asymmetric generalization gradients found in humans:

$$|t - T|/t < b?$$

The difference is that the denominator is the duration perceived on the current trial rather than a reference duration from memory. This shows that small modifications of SET can sometimes account for different patterns of data.

Another example of the application of SET concerns the role of attention in timing. Attention is thought to be required for the proper functioning of the clock process. We can use the analogy of filling a bucket with a hose, the bucket representing the accumulator. The hose is a pacemaker that drips constantly. The idea is that if attention is diverted, the hose will sometimes miss the bucket. One predicted result is that a longer actual duration of time must elapse under attentional demand before a subject judges that a particular reference duration has elapsed. This idea was tested on human subjects (Fortin and Massé, 2000; Fortin, 2003). Subjects had to stop a tone after 2500 ms had passed (**Figure 11**). As an added complication, the tone had a break in it at some unpredictable point, and the break was not to be timed. That is, subjects had to time 2500 ms excluding the break. The authors reasoned that anticipating the break requires attention. This led to the prediction that the later the arrival of the break, the more subjects should overestimate. It was as if the bucket were likely to be missed by the hose before the arrival of the break. The duration of the break should not make a difference, as the timing process was hypothesized to stop during the break. This was precisely the pattern of results found (**Figure 11**).

1.19.5.2 Timing Without a Clock

One might imagine that to do interval timing, one would need a clock. Models without a clock, however, have been proposed. One such model adapts a neural network to do what a clock does (Hopson, 2003). The network has an input layer, a hidden layer, and an output layer, with weights between the input layer and the hidden layer and between the hidden layer and the output layer. It is different from a standard neural network in that the hidden layer takes time to build up activation. Different units in the hidden layer build up at different rates.

The idea is to have the system build up to a maximal activation level at the predicted time of reward. Activation should come to predict probability of reward. The system learns by a back-propagation-learning algorithm that adjusts the weights. The model can account for a good number of patterns of results in the literature.

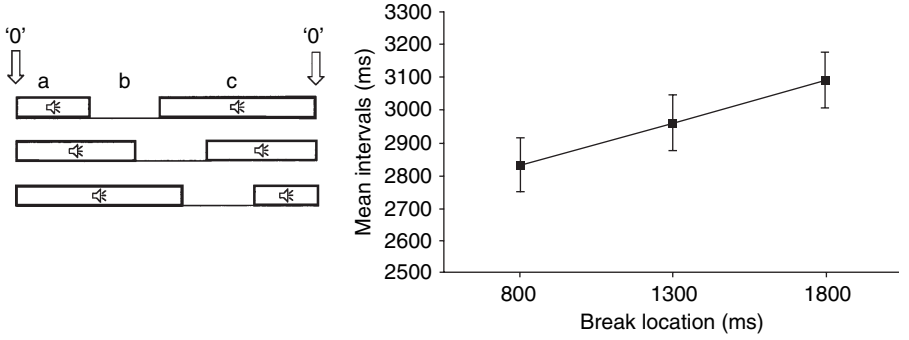

Figure 11 A dual-attention task described in Fortin C (2003) Attentional time-sharing in interval timing. In: Meck WH (ed.) *Functional and neural mechanisms of interval timing,* pp. 235–260. Boca Raton, FL: CRC Press. Reproduced with permission. Left: Humans have the task of holding down a key that produces a tone in order to produce a tone of 2500 ms duration. At some unpredictable time, the tone is interrupted by the experimenter, and the break is not to be timed. The data show that humans overproduce on this task, and the amount of overproduction varies directly with time elapsed before the break appears. The interpretation is that anticipating the break requires attention, which detracts from the task of timing. The result is that more actual time has to elapse before a perceived duration is judged to have elapsed.

1.19.5.3 Packet Theory

A recent information processing theory that makes detailed predictions is Packet Theory (Kirkpatrick, 2002; Kirkpatrick and Church, 2003; Church and Guilhardi, 2005; Guilhardi et al., 2005). It has four component processes (**Figure 12**). As an example, we consider a rat on a FI 30-s schedule of reinforcement for head entries into a food hopper. This means that 30 s after a pellet of food is delivered, the next pellet will be primed. The first head entry after the FI of 30 s results in food delivery.

The perception process is akin to the clock process in SET. It tracks the perceived time to the expected reward, about 30 s in this case. The memory in SET is a collection of reference durations from which the subject picks one for the current trial. In Packet Theory, the memory is the average expected time to reward, averaged over the reward times of the past. In the FI 30 example, this is also about 30 s. The memory process also has a threshold, in parallel with the threshold in SET. The threshold has a normal distribution about some mean proportion of time to expected reward. The decision process is based on the threshold. When the threshold has been passed, the animal switches from a low rate of response packets to a high rate of response packets.

Packets are theoretical entities that generate bouts of responding. This is signified in the response process, which turns packets into bouts of responses with particular characteristics, such as a distribution of interresponse times. The theory is thus explicit in producing an actual stream of response times in a simulated trial. Other theories are typically not quite as explicit about responses. For example, it is not clear how the activation level of the neural net in Hopson's (2003) model translates to actual responses in time.

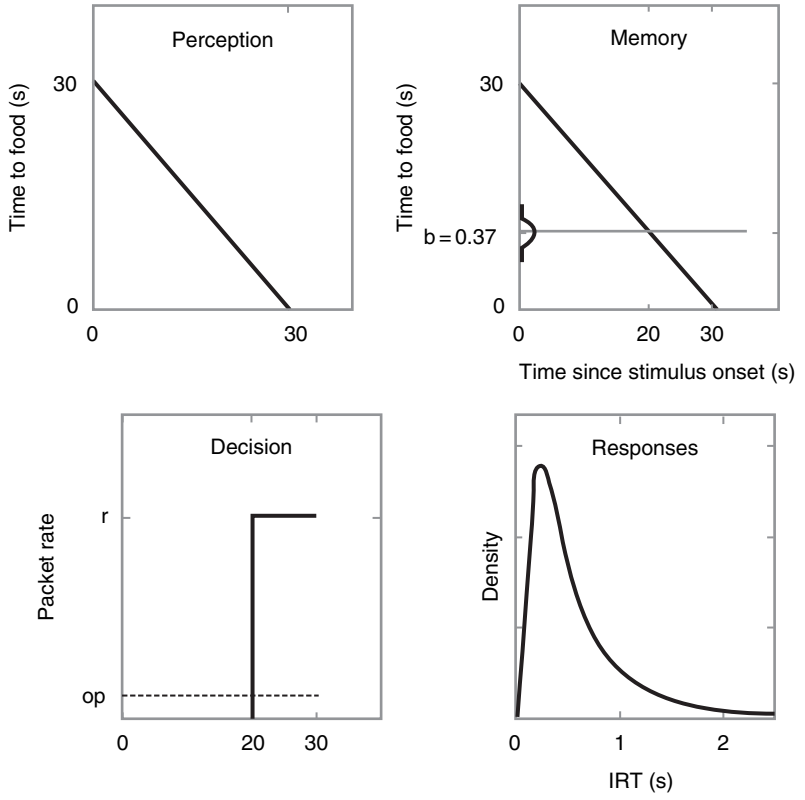

Figure 12 A schematic illustration of Packet Theory in explaining performance on a FI 30 schedule. The theory has four components. A perception unit parallels the clock process in Scalar Expectancy Theory and times the expected time to reward on the current trial. The memory process is a representation of the expected time to reward, derived from an average of past durations to reward. A variable threshold is retrieved for the current trial. The decision process switches to a high rate of production of Packets when the threshold has been crossed. Packets are theoretical underlying units that generate bouts of behavior, according to a function described in the response production unit on the right. Reproduced with permission from Church RM and Guilhardi P (2005) A Turing test of a timing theory. *Behav. Processes* 69: 45–58.

This explicit translation into responses in time means that the model can be compared against empirical data on numerous fronts, including response distributions, response rates, and interresponse times. On these multiple fronts, the model does a reasonable job of simulating the actual data obtained. Because the memory process is said to come up with an average expected time to reward, it does so even when durations to reward varied in the past, as in some random distribution about a mean. This means that the model can predict the behavior of rats in such seemingly 'nontiming' conditioning procedures. One of the strengths of the model is that it can encompass a range of conditioning procedures, and in fact, it is a new theory of conditioning (see other chapters on theories of conditioning in this volume).

A further contribution from the development of Packet Theory is an explicit recommendation for evaluating how well the model accounts for obtained data in the form of a Turing test (Church and Guilhardi, 2005). It is called a Turing test after the mathematician Alan Turing, who devised a similar test to examine whether a human can distinguish the responses of a computer-generated program from those of another human. In the case of Packet Theory, a set procedure such as FI 30 is given to rats and produces a sizeable set of trials at asymptote. The model is given the same procedure, parameters are chosen, and the model generates a set of trials. The data generated are responses in time. To test the 'fit,' one picks one trial from the rat and one trial from the model. A third trial is then picked from either the model or the rat. This trial is formally compared to the two reference trials (one from the model and one from the rat). The comparison process 'decides' whether the sample trial is more similar to the model's trial or to the rat's trial. This process can be repeated many times.

If the model generates data indistinguishable from a rat, the Turing comparison process should be at chance and be correct 50% of the time. In fact, it is correct about 60% of the time, which shows that the model, while having considerable success, may be improved by further development.

1.19.6 Connections Between Interval Timing and Circadian Timing

The examples of timing discussed earlier are referred to as interval timing (sometimes short-interval timing) to denote that the target duration is an elapsing interval. The basic idea is that an interval elapses with respect to the occurrence of some event (e.g., the onset of a light or a sound). A helpful metaphor is the familiar features of a stopwatch (Church, 1978). For example, a stopwatch may be used to time runners in a race. As the runners line up for the race, the stopwatch would be *reset* to zero. When the race begins, the stopwatch is *started*. When the runner crosses the finish line, the stopwatch is *ended*. The reading of the stopwatch provides an estimate of time to complete the event (running the race in this example). Implicit in the stopwatch metaphor is that timing an elapsed interval is quite flexible; the start and stop events are arbitrary.

One mechanism that may be used to instantiate a stopwatch mechanism is a pacemaker-accumulator. A pacemaker emits pulses as a function of time, and an accumulator integrates (i.e., counts) the number of pulses emitted. An hourglass is a familiar example of a pacemaker-accumulator; the amount of sand in the bottom chamber of an hourglass is an index of the elapsed duration since the hourglass was turned over (i.e., reset).

By contrast, circadian timing is based on the completion of a periodic process. As the name circadian implies, the periodic process is approximately a day. Therefore, time of day is indexed by the phase of a circadian periodic process. Circadian timing is widespread (Aschoff, 1981; Takahashi et al., 2001).

Unlike the pacemaker-accumulator and hourglass mechanism described for interval timing, circadian timing is based on an oscillator. The system is referred to as a circadian oscillator because the natural period of the oscillator is approximately 24 h.

1.19.6.1 Formal Properties of Interval and Circadian Timing

Gibbon et al. (1997a) described operating characteristics for interval and circadian timing systems, which is summarized in **Table 1** (the table is reproduced from Gibbon et al., 1997a). The circadian system is based on an endogenous oscillation. An oscillation is endogenous if it does not require continued periodic input to produce ongoing periodic output. For example, activity patterns occur at species-typical times of day when an animal is exposed to daily periodic light cycles (e.g., 12 h of light followed by 12 h of darkness). After the periodic light cycle is terminated (e.g., constant dim illumination), behavior 'free runs,' usually with a period that departs slightly from 24 h.

Table 1 Properties of circadian and interval timing systems

Circadian	*Interval*
Timing properties	
Endogenous oscillation: free run	Requires reset: one shot
Entrainment range: Limited	Training range: Broad
Approximately 8 h maximum	Approx. 3–4 orders of magnitude – seconds to hours
Phase shift adjustment: Slow	Phase shift immediate
Several cycles usually required	Arbitrary onset phase
Variance properties	
High level of precision:	Low level of precision:
$\sigma/\mu = 0.01-0.05$	$\sigma/\mu = 0.10-0.35$
Relationship to entrainment period (?)	Scalar property:
	Superposition in relative time $f_r(rt) = (1/r)f(t)$, $\sigma/\mu = \gamma$.

Reproduced from Gibbon J, Fairhurst S, and Goldberg B (1997a) Cooperation, conflict and compromise between circadian and interval clocks in pigeons. In: Bradshaw CM and Szabadi E (eds.) *Time and Behaviour: Psychological and Neurobehavioural Analyses*, pp. 329–384. New York: Elsevier. © 1997 Elsevier Science B.V.

Free-running behavior after the termination of periodic stimuli provides evidence that the timing system is an endogenous oscillator. In contrast, Gibbon et al. (1997a) described the interval timing system as requiring resetting. The timing system is presumed to time with respect to the occurrence of some stimulus; a single presentation of the stimulus is required to reset the interval timing system (i.e., one shot reset).

The circadian system is subject to a limited range of entrainment. For example, presentation of a periodic input is thought to entrain the endogenous oscillator only if the periodic input is within a limited range of periods near 24 h. By contrast, Gibbon et al. (1997a) described the interval timing system as having a broad training range covering 3-4 orders of magnitude from seconds to hours.

The circadian system adjusts slowly to a phase shift. A phase shift is an abrupt change in the initiation of a periodic process. A familiar example of a phase shift is the unusual wake-up times that people are exposed to after flying to a destination across several time zones. It usually requires several cycles (i.e., days) before one's activities are synchronized to the new time zone. By contrast, Gibbon et al. (1997a) stated that the interval timing system is characterized by immediate phase shift; because interval timing is not based on the phase of a periodic process, the response to a single shift in a cycle is complete adjustment or complete resetting of the timing processes (i.e., one-shot reset in Gibbon et al.'s terminology).

Temporal performance based on a circadian oscillator is highly precise as measured by cycle-to-cycle variation. For example, Gibbon et al. (1997a) summarize the coefficient of variation (CV; standard deviation of time estimates divided by the mean of time estimates) of circadian-mediated performance as approximately 1%–5%. By contrast, interval timing performance is characterized by a relatively low level of precision (coefficient of variation of 10%–35%). Therefore, it appears that a characteristic of a circadian oscillator is relatively high timing precision. In particular, a consequence of having an endogenous oscillator dedicated to timing select values within a limited range appears to be relatively high sensitivity to timing these target durations.

The variance properties of timing have played an important role in understanding interval timing (as noted in the section above about the scalar property). By contrast, the analysis of variance properties has had less impact in the study of circadian timing.

With some notable exceptions (Aschoff, 1984, 1985, 1989, 1993, 1998; Silver and Bittman, 1984; Terman et al., 1984; Aschoff and Daan, 1997; Gibbon et al., 1997a), the interaction of interval and circadian mechanisms has been largely neglected in the literature. In the sections that follow, we describe a series of empirical tests that were designed to evaluate the hypothesis that interval timing is based, at least in part, on oscillatory processes as described in **Table 1** from Gibbon et al. (1997a).

1.19.6.2 Resetting Properties of Short-Interval Timing

Figure 13 shows an example of a phase-shift manipulation applied to short-interval timing. Rats were

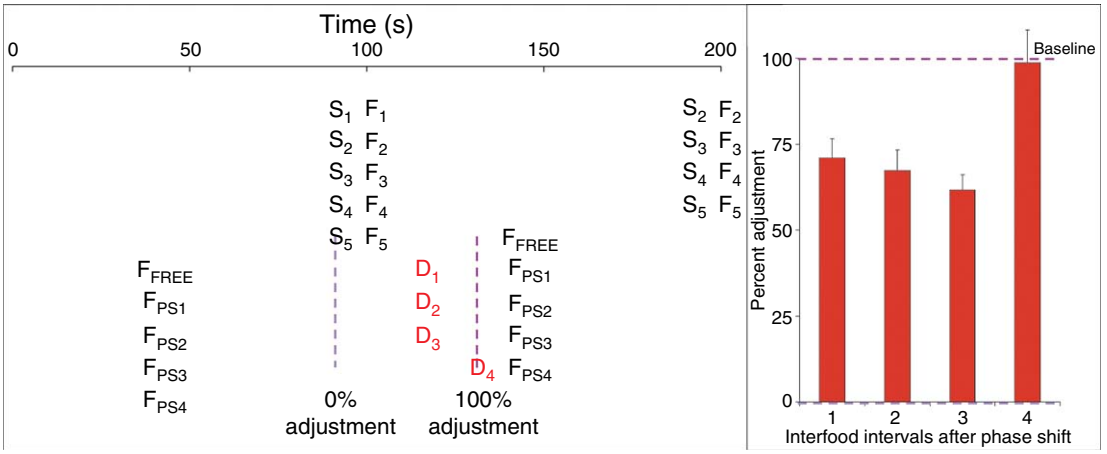

Figure 13 A phase shift produces gradual adjustment in short-interval timing. Left panel: Schematic representation of training, phase-shift manipulation, predictions, and data (double plotted to facilitate inspection of transitions across successive intervals; consecutive 100-s fixed intervals are plotted left to right and top to bottom). Rats ($n = 14$) timed 100-s intervals, and the last 5 intervals before the phase shift are shown (F = food pellet, S = start time of response burst). A 62-s phase advance (i.e., early pellet) on average was produced by the delivery of a response-independent food (F_{FREE}). All other food-to-food intervals were 100 s (F_{PS} = food post phase shift). Dashed lines indicate predictions if rats are insensitive (0% adjustment, purple) or completely sensitive (100% adjustment, pink) to the most recently delivered food pellet. A pacemaker-accumulator mechanism predicts 100% adjustment on the initial interval after the phase shift on the assumption of complete reset (Gibbon et al., 1997a). An oscillator mechanism predicts initial incomplete adjustment. Data (D) indicate incomplete adjustment on the first three trials. Right panel: Start times on the initial three trials were earlier than in preshift baseline ($t(13)$'s > 2, p's < .05). Resetting was achieved on the fourth trial ($t < 1$). Each 45-mg food pellet was contingent on a lever press after 100 s in 12-h sessions. The start of a response burst was identified on individual trials by selecting the response that maximized the goodness of fit of individual responses to a model with a low rate followed by a high rate (analysis as in Crystal et al., 1997). The same conclusions were reached by measuring the latency to the first response after food. Baseline was the average start time on the five trials before the phase shift. Left panel: Zero on the y-axis (purple dashed line) corresponds to complete failure to adjust to the phase shift; 100% (pink dashed line) corresponds to complete resetting. Error bars represent 1 SEM. Adapted from Crystal JD (2006c) Sensitivity to time: Implications for the representation of time. In: Wasserman EA and Zentall TR (eds.) *Comparative cognition: Experimental explorations of animal intelligence,* 270–284. New York: Oxford University Press. Reproduced from Crystal JD (2006d) Time, place, and content. *Comp. Cogn. Behav. Rev.* 1: 53–76. with permission.

trained to time 100 s; a food pellet was dispensed for the first response after the fixed interval of 100 s had elapsed. To implement the phase shift, an early, response-independent pellet was delivered (i.e., free food). Four food cycles were required before adjustment was complete, which is consistent with the hypothesis that short-interval timing of 100 s is based on an oscillator mechanism (Crystal, 2006c, 2006d). The prediction in the third row of **Table 1** is not supported by the data in **Figure 13**.

1.19.6.3 Endogenous Oscillations in Short-Interval Timing

The hypothesis that the timing of an interval is based on a pacemaker-accumulator or oscillator mechanism can be assessed by discontinuing periodic input (i.e., extinction) and assessing subsequent anticipatory behavior. A defining feature of an oscillator is that periodic output from the oscillator continues after the termination of periodic input. By contrast, a defining feature of a pacemaker-accumulator system is that elapsed time is measured with respect to the presentation of a stimulus, according to the classic description of this system (**Table 1**). Therefore, output of a short-interval system is periodic if presented with periodic input, but periodic output can be expected to cease if periodic input is discontinued. Groups of rats were trained to time short intervals (48, 96, and 192 s). The data from a representative individual rat in this experiment are shown in **Figure 14**, and group data are shown in **Figure 15**. As expected, periodic delivery of food produced periodic behavior during training (**Figure 15**, left column). Next, delivery of food was suspended. Behavior was periodic after termination

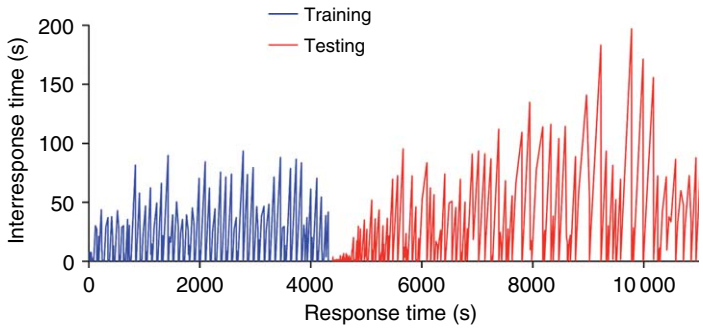

Figure 14 Many small interresponse times in short-interval timing are punctuated by much longer interresponse times, and punctuation by relatively long interresponse times continued after termination of periodic food delivery. Interresponse time (i.e., times of responses $R_{n+1} - R_n$) is plotted as a function of response time for a representative rat. During training, food was delivered on a fixed-interval 96-s schedule. During testing, food was not delivered (i.e., extinction). Extinction began at a randomly selected point in the session. The response measure was the time of occurrence of photobeam interruptions in the food trough. Reproduced from Crystal JD and Baramidze GT (2007) Endogenous oscillations in short-interval timing. *Behav. Processes*. 74: 152–158. © 2007, with permission from Elsevier.

of periodic input (**Figure 15**, right column). Importantly, the period in extinction increased as a function of the period in training, documenting that the periodic behavior in extinction was based on entrainment to the periodic feeding in training. These data suggest that short-interval timing is, at least in part, based on a self-sustaining, endogenous oscillator (Crystal and Baramidze, 2007). The prediction in the first row of **Table 1** is not supported by the data in **Figures 14** and **15**.

1.19.6.4 Timing Long Intervals

It is generally accepted that animals *cannot* anticipate intermeal intervals outside a limited range near 24 h (e.g., Stephan et al., 1979a,b; Boulos et al., 1980; Stephan, 1981; Aschoff et al., 1983; Mistlberger and Marchant, 1995; Madrid et al., 1998; White and Timberlake, 1999). However, this conclusion is based on a relatively limited data set. Indeed, caution is generally warranted when confronted with evidence for the absence of some ability (as in this case with the absence of temporal performance). An alternative explanation for the lack of evidence for timing noncircadian intervals is that timing is relatively superior near 24 h; by contrast, poorer temporal performance farther away from 24 h may make it more difficult to detect temporal performance. A major insight from interval timing in the range of seconds to minutes (Dews, 1970) is that temporal performance may be best compared across ranges if performance is expressed in relative time (elapsed time divided by the target interval, rather than absolute time in seconds; and response rates expressed as a proportion of maximal rates). The power of this data analytic approach was documented in the section titled "Scalar property."

A series of experiments investigating meal anticipation was undertaken to test the hypothesis that a circadian oscillator is characterized by a local maximum in sensitivity to time (Crystal, 2001a); according to this prediction, temporal performance is superior near 24 h, relative to intermeal intervals outside the circadian range. Food was restricted to 3-h meals, which rats earned by breaking a photobeam in the food trough. The rats inspected the food trough before meals started, thereby providing a temporal anticipation function for each intermeal interval condition. **Figure 16** shows anticipation functions for intermeal intervals near the circadian range (22 to 26 h) and outside this range (14 and 34 h). The data are plotted in relative time on the horizontal axis and proportional response rate on the vertical axis (as described by Dews, 1970). Response rates increased later into the intermeal interval for intervals near the circadian range than for intervals outside this range. Sensitivity to time was estimated by the spread of the response distributions. The spread was smaller (i.e., lower variability) for intermeal intervals near the circadian range than for interval outside this range, as shown in **Figure 17**. Note that the data in **Figure 17** document a local maximum in sensitivity to time near 24 h, consistent with the hypothesis that a property of a circadian oscillator is improved sensitivity to time (Crystal, 2001a).

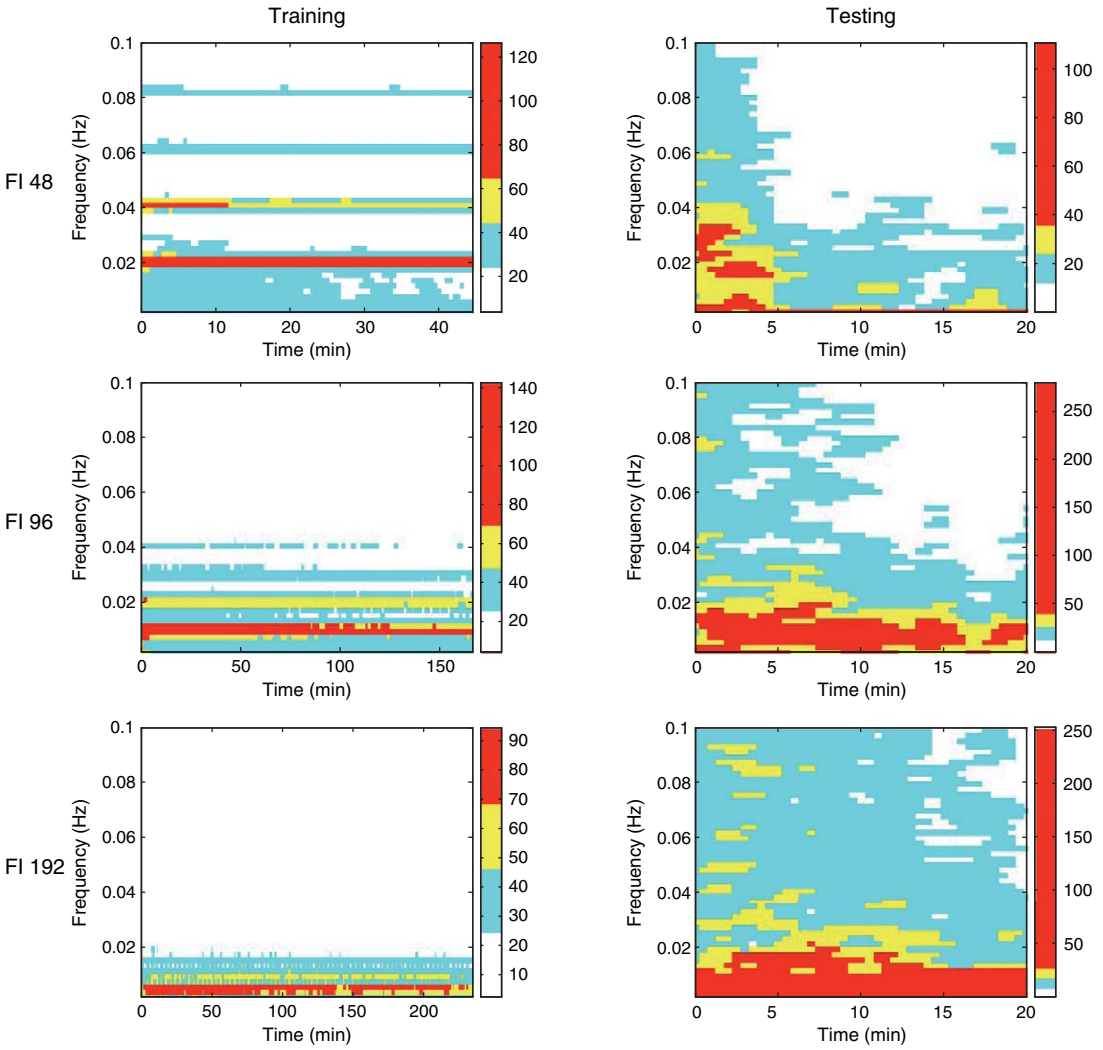

Figure 15 Endogenous oscillations in short-interval timing continue after the termination of periodic input. Short-time Fourier transforms are shown for training (left panels) and testing (right panels) conditions using fixed interval 48-, 96-, and 192-s procedures. The three-dimensional images show frequency (period = 1/frequncy) on the vertical axis as a function of time within the session along the horizontal axis; the color scheme represents the amount of power from the Fourier analysis. Concentrations of high power occur at a frequency of approximately 0.02, 0.01, and .0005, which correspond to periods of approximately 50, 100, and 200 s in top, middle, and bottom panels, respectively. Adapted from Crystal JD and Baramidze GT (2007) Endogenous oscillations in short-interval timing. *Behav. Processes*. 74: 152–158. © 2007, with permission from Elsevier.

Figure 18 shows a reanalysis of earlier published data on this problem. In particular, experiments were selected that used behaviors that are instrumental in producing food (e.g., approaching the food source or pressing a lever). Long intermeal intervals that are substantially less than 24 h are compared with a 24-h condition from each experiment. The critical part of the reanalysis was that the data were expressed in proportional time and rate. The reanalysis reveals that intervals below the circadian range (14, 18, and 19 h) are timed, but these temporal functions are less steep and have lower terminal response rates than do functions for timing 24 h. The reanalysis of published data is consistent with the hypothesis that a property of a circadian oscillator is improved sensitivity to time, as was suggested by Figures 16 and 17.

1.19.6.5 Endogenous Oscillations in Long-Interval Timing

The examples of timing noncircadian long intervals in the section titled "Timing long intervals" document

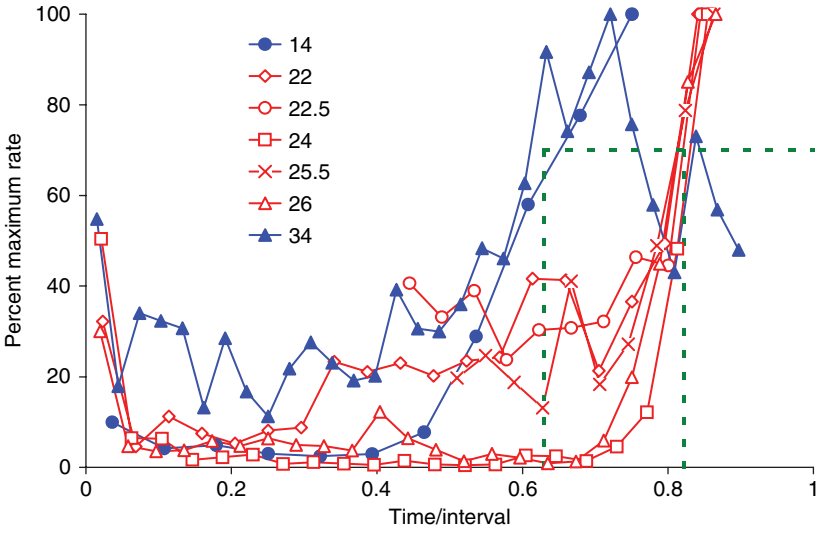

Figure 16 Response rate increased later into the interval for intermeal intervals near the circadian range (unfilled red symbols) relative to intervals outside this range (filled blue symbols); dashed lines indicate width of response rate functions. Anticipatory responses increase immediately prior to the meal for all intermeal intervals except 34 h. Each 45-mg food pellet was contingent on a photobeam break after a variable interval during 3-h meals. Intermeal intervals were tested in separate groups of rats ($n = 3–5$ per group). The end of the meal corresponds to 1 on the *x*-axis. Testing was conducted in constant darkness. Adapted from Crystal JD (2001a) Circadian time perception. *J. Exp. Psychol. Anim. Behav. Process.* 27: 68–78. Reproduced from Crystal JD (2006d) Time, place, and content. *Comp. Cogn. Behav. Rev.* 1: 53–76 with permission.

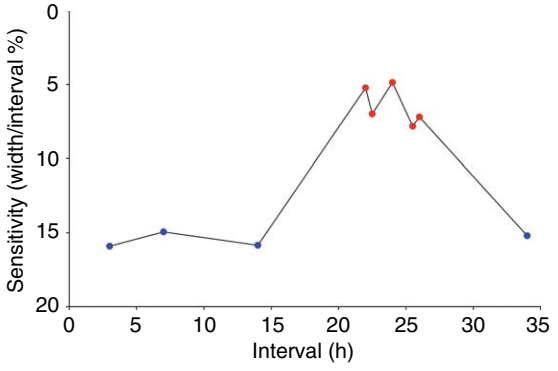

Figure 17 Intervals near the circadian range (red symbols) are characterized by higher sensitivity than intervals outside this range (blue symbols). Variability in anticipating a meal was measured as the width of the response distribution prior to the meal at 70% of the maximum rate, expressed as a percentage of the interval ($N = 29$). The interval is the time between light offset and meal onset in a 12–12 light–dark cycle (leftmost two circles) or the intermeal interval in constant darkness (all other data). The percentage width was smaller in the circadian range than outside this range ($F(1,20) = 22.65$, $p < .001$). The width/interval did not differ within the circadian ($F(4,12) = 1$) or noncircadian ($F(3,8) < 1$) ranges. The same conclusions were reached when the width was measured as 25%, 50%, and 75% of the maximum rate. The data are plotted on a reversed-order *y*-axis so that local maxima in the data correspond to high sensitivity, which facilitates comparison with other measures of sensitivity (e.g., Figure 20). Mean SEM = 2.4. Adapted from Crystal JD (2001a) Circadian time perception. *J. Exp. Psychol. Anim. Behav. Process.* 27: 68–78. Reproduced from Crystal JD (2006d) Time, place, and content. *Comp. Cogn. Behav. Rev.* 1: 53–76 with permission.

that rats can time intervals below the circadian range, but they do not identify the mechanism. In particular, the data stated earlier do not require an oscillator mechanism; an alternative is that the rats used a pacemaker-accumulator mechanism to time the long intervals. By contrast, the examples in the section titled Endogenous oscillations in short-interval timing document endogenous oscillations in timing short intervals (1–3 min) by demonstrating that timing continues after the termination of periodic input. The data described in this section document examples of endogenous oscillations in long-interval timing (16 h) by using the same experimental approach.

Rats earned food by interrupting a photobeam in a food trough during 3-h meals. The intermeal interval was 16 h. After approximately a month of experience with the intermeal interval, the meals were discontinued (Crystal, 2006b). **Figure 19** (top panel) shows that response rate increased as a function of time prior to the meals, documenting that the rats could time 16 h. To dissociate alternative timing mechanisms, it is diagnostic to consider the first two nonfood cycles. If the timing documented in the top panel of **Figure 19** is based on a pacemaker-accumulator mechanism reset by the meal, then response rate should increase as a function of time in the first nonfood cycle (as in training) because elapsed time since the last meal corresponds to the training interval. However, an

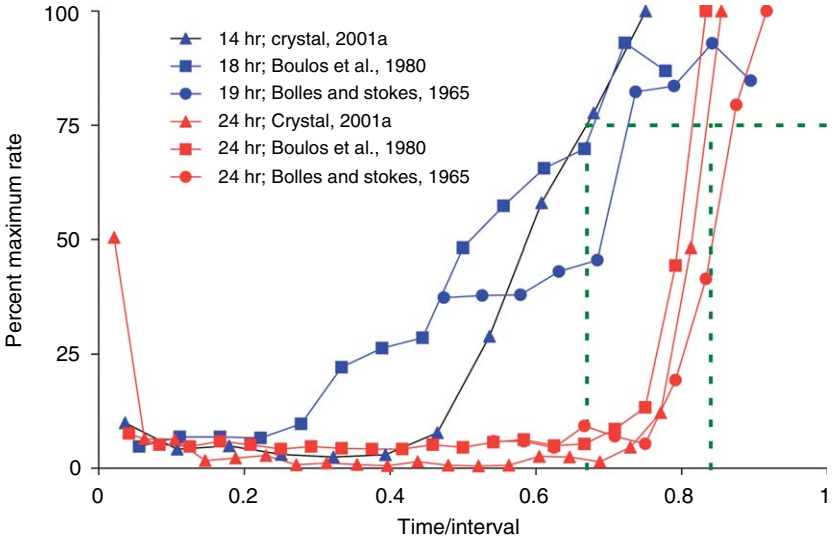

Figure 18 Rats anticipate intermeal intervals of 14, 18, and 19 h (blue symbols) with less precision (i.e., higher variability) than 24 h (red symbols); dashed lines indicate width of response rate functions. Data from Bolles and Stokes (1965) and Boulos Z, Rosenwasser AM, and Terman M (1980) Feeding schedules and the circadian organization of behavior in the rat. *Behav. Brain Res.* 1: 39–65, in which meals were earned by pressing a lever, were obtained by enlarging published figures by 200% and measuring each datum at 0.5-mm resolution. Adapted from Bolles RC and Stokes LW (1965), Rat's anticipation of diurnal and a-diurnal feeding. *J. Comp. Physiol. Psychol.* 60: 290–294 and Terman M (1980) Feeding schedules and the circadian organization of behavior in the rat. *Behav. Brain Res.* 1: 39–65, and Crystal JD (2001a) Circadian time perception. *J. Exp. Psychol. Anim. Behav. Process.* 27: 68–78. Reproduced from Crystal JD (2006b) Long-interval timing is based on a self sustaining endogenous oscillator. *Behav. Processes* 72: 149–160, © 2006, with permission from Elsevier.

estimate of the elapsed time with respect to the last meal continues to increase during the second nonfood cycle according to this proposal. Therefore, a pacemaker-accumulator does not predict an increase in response rate prior to the second skipped meal because elapsed time since the last meal is larger than the intermeal interval during the second nonfood cycle. In contrast, if the timing documented in the top panel of **Figure 19** is based on an endogenous oscillator, then response rate should increase as a function of time in both the first and second nonfood cycles because an endogenous oscillator is self-sustaining (i.e., periodic output from an oscillator is expected to continue after termination of periodic input).

The first two nonfood cycles are also shown in **Figure 19** (middle and bottom panels). Note that response rate increased as a function of time in the first and second nonfood cycles. In particular, response rate was significantly higher in the 3 h during the omitted meal relative to the 13 h prior to this point for both first and second nonfood cycles.

To characterize the period of behavior after termination of the meals, response rates were subjected to a periodogram analysis, which assesses the reliability of a periodic trend and estimates the observed period. A significant periodic trend was detected for each rat. The mean period in extinction was 20.4 ± 0.9 h (mean $\pm$ SEM), which was significantly different from 16 and 24 hr (Crystal, 2006b).

These data are consistent with the hypothesis that the natural period of the oscillator that drove behavior was 20.4 h, which is distinct from the circadian oscillator; according to this hypothesis, the two oscillatory systems are dissociated by their different characteristic periods. However, the data are also consistent with an alternative hypothesis, according to which the circadian oscillator's free-running period is modified by the periodic input to which it was previously exposed. Note that according to both of these hypotheses, long interval timing is based on a self-sustaining, endogenous oscillator; the hypotheses differ in specifying the characteristic period of the oscillator(s). Taken together, the data presented in the sections titled "Timing long intervals" and "Endogenous oscillations in long-interval timing" imply that long-interval timing is based on a self-sustaining, endogenous oscillator, which is not consistent with the prediction in the second row of **Table 1**.

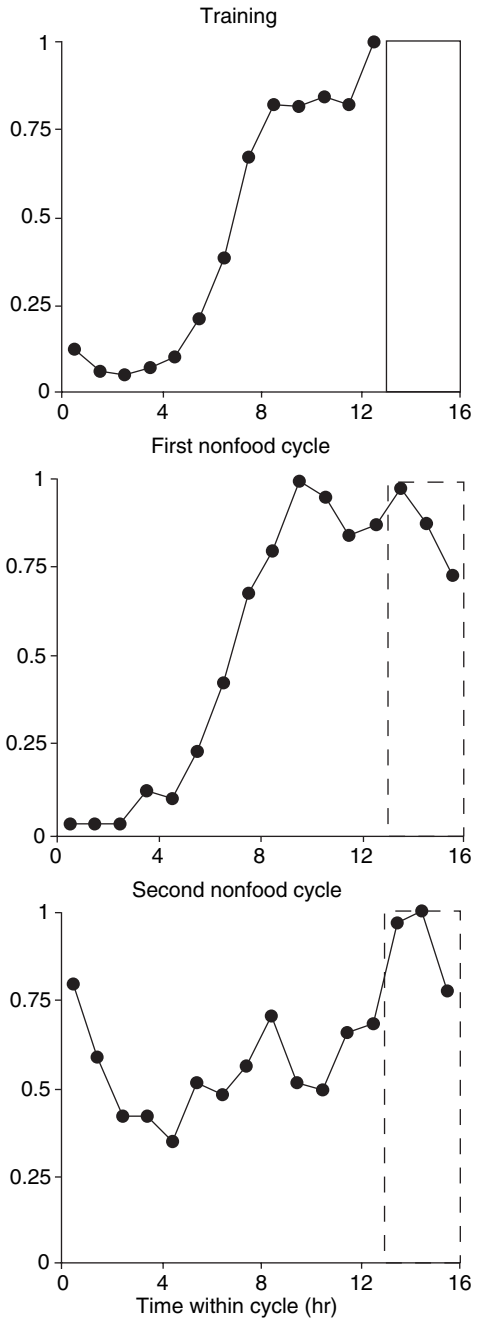

Figure 19 Endogenous oscillations in long-interval timing continue after the termination of periodic input. Response rate increased as a function of time within the 16-h intermeal interval cycle during the first and second nonfood cycle. Response rate (frequency of responses expressed as a proportion of the maximum frequency within the cycle) is plotted as a function of time within the cycle. The cycle included meals (indicated by the solid rectangle) during training (top panel). The meals were omitted (indicated by the dashed rectangles) in the first (middle panel) and second (bottom panel) nonfood cycles. Reproduced from Crystal JD (2006b) Long-interval timing is based on a self sustaining endogenous oscillator. *Behav. Processes* 72: 149–160, © 2006, with permission from Elsevier.

1.19.6.6 Variance Properties in Circadian and Short-Interval Timing

As noted in the section "Formal properties of interval and circadian timing," the study of variance properties has historically played a significant role in the development of theories of short-interval, but not circadian, timing. However, the data summarized in **Figure 17** suggest that a property of the well-established circadian oscillator is the relative improvement in sensitivity to time circadian intervals relative to noncircadian intervals. These data suggest that other putative oscillators may be identified by documenting other local maxima in sensitivity to time. Moreover, the observation that short-interval timing in the range of 1–3 min exhibits endogenous, self-sustaining patterns of behavior after the termination of periodic input reinforces the expectation that short-interval timing may be, at least in part, based on an endogenous oscillatory mechanism.

Figure 20 shows a measure of sensitivity to time plotted as a function of stimulus duration from a series of experiments that evaluated many closely spaced target intervals (Crystal, 1999, 2001b). The data suggest that sensitivity to time short intervals is characterized by multiple local maxima. The procedure involved presenting a short or long stimulus followed by the insertion of two response levers. Left or right lever presses were designated as correct after short or long stimuli. For each short duration, accuracy was maintained at approximately 75% correct by adjusting the duration of the long stimulus after blocks of discrimination trials. Sensitivity to time (as measured by signal detection theory; Macmillan and Creelman, 1991) was approximately constant for short durations from 0.1 to 34 s. However, local peaks in sensitivity to time were observed at approximately 0.3, 1.2, 12, and 24 s.

Figure 21 shows multiple local maxima in sensitivity to time across 7 orders of magnitude. The local maximum in sensitivity to time on the right side of the figure is replotted from **Figure 17**, which shows a local maximum in sensitivity to time of approximately 24 h. The local maxima in sensitivity to time on the left side of the figure are replotted from **Figure 20**. **Figure 21** documents that multiple local maxima in sensitivity to time are observed in the discrimination of time across several orders of magnitude.

To provide an independent, converging line of evidence regarding local maxima in sensitivity to time, **Figure 22** replots coefficients of variability

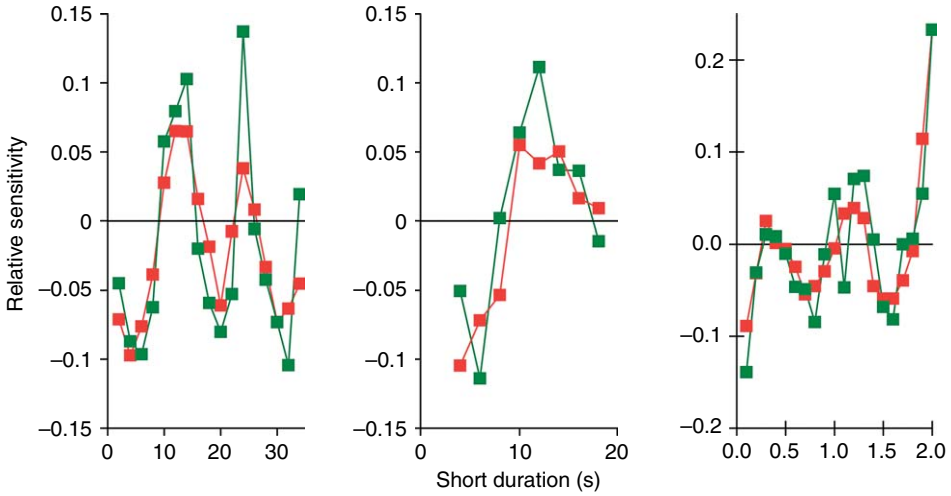

Figure 20 Sensitivity to time is characterized by local maxima at 12 and 24 s (left panel), 12 s (middle panel), and 0.3 and 1.2 s (right panel). Green symbols: average across rats. Red symbols: a running median was performed on each rat's data, and the smoothed data were averaged across rats to identify the most representative local maxima in sensitivity. Left panel: Rats discriminated short and long noise durations with the duration adjusted to maintain accuracy at approximately 75% correct. Short durations were tested in ascending order with a step size of 1 s ($n = 5$) and 2 s ($n = 5$). Sensitivity was similar across step sizes ($r(15) = .701$, $p < 01$), departed from zero based on a binomial test ($p < .001$), and was nonrandom ($r(14)_{lag1} = .710$, $p < .01$). Mean SEM = 0.03. Middle panel: Methods are the same as described in left panel, except short durations were tested in random order ($n = 7$) or with each rat receiving a single-interval condition ($n = 13$); results from these conditions did not differ. Sensitivity departed from zero based on a binomial test ($p < .001$) and was nonrandom ($r(7)_{lag1} = .860$, $p < .01$). Mean SEM = 0.02. Right panel: Methods are the same as described in left panel, except intervals were defined by gaps between 50-ms noise pulses, and short durations were tested in descending order with a step size of 0.1 s ($n = 6$). Sensitivity departed from zero based on a binomial test ($p < .001$) and was nonrandom ($r(18)_{lag1} = 0.736$, $p < .001$). Mean SEM = 0.04. Sensitivity was measured using *d'* from signal detection theory. *d'* = *z*[*p*(short response | short stimulus)] – *z*[*p*(short response | long stimulus)]. Relative sensitivity is *d'* – mean *d'*. Adapted from Crystal JD (1999) Systematic nonlinearities in the perception of temporal intervals. *J. Exp. Psychol. Anim. Behav. Process.* 25: 3–17; Crystal JD (2001b) Nonlinear time perception. *Behav. Processes* 55: 35–49; Crystal JD (2003) Nonlinearities in sensitivity to time: Implications for oscillator-based representations of interval and circadian clocks. Rev.* 1: 53–76 with permission.

(CV; ratio of standard deviation to the mean) as a function of the target intervals using 43 data sets from the literature selected by Gibbon et al. (1997b). The data from Gibbon and colleagues' scatter plot are replotted in the top panel of **Figure 22**, using a reverse-order vertical axis so that high points in the figure correspond to high sensitivity to time. To examine the shape of the sensitivity function, the data from Gibbon et al. were averaged in two-point blocks and subjected to a 3-point running median, which appears in the bottom panel of **Figure 22**. Sensitivity to time using Gibbon and colleagues' selection of data from the literature is characterized by multiple local maxima. The middle of the local maxima in the bottom panel of **Figure 22** occurs at approximately 0.2, 0.3, 1.2, 10, and 20 s. The top panel of **Figure 22** also shows clusters of high points near these intervals. The values of local maxima derived from Gibbon et al.'s selection of data are markedly similar to local maxima that were observed in **Figure 20**: 0.3, 1.2, 12, and 24 s (Crystal, 1999, 2001b, 2003, 2006d). Although the shapes of the sensitivity functions in **Figures 20** and **22** differ, the similarity in the locations of local maxima is significant given that the data in **Figure 22** come from 43 different data sets. Moreover, the data that appear in **Figure 22** were independently selected by Gibbon and colleagues.

1.19.6.7 Integration of Interval and Circadian Timing

The data in **Figures 20, 21,** and **22** suggest that the psychological representation of time is nonlinearly related to physical estimates of time. The existence of a local maximum near a circadian oscillator (**Figure 21**, peak on right side) and local maxima in the short-interval range (**Figure 21**, peaks on left

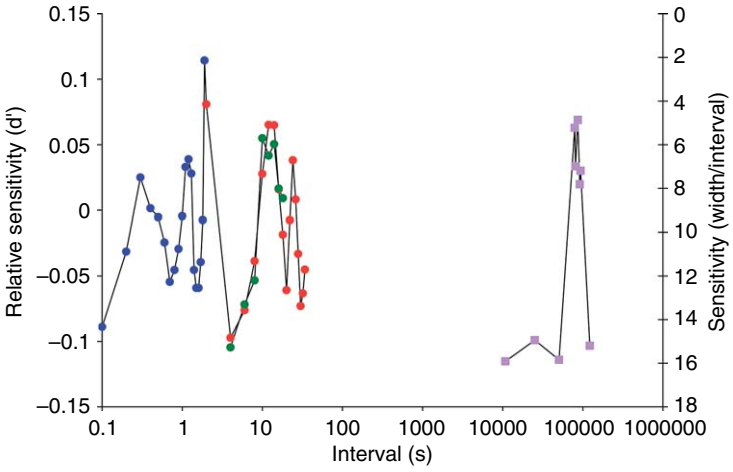

Figure 21 Multiple local maxima in sensitivity to time are observed in the discrimination of time across seven orders of magnitude. The existence of a local maximum near a circadian oscillator (peak on right side; purple squares) and other local maxima in the short-interval range (peaks on left side; blue, red, and green circles) are consistent with the hypothesis that timing is mediated by multiple oscillators. Intervals in the blank region in the center of the figure have not been tested. Left side: Rats discriminated short and long durations, with the long duration adjusted to maintain accuracy at 75% correct. Short durations were tested in sequential order (blue and red circles; $N = 26$) or independent order (green circles; $N = 20$). Circles represent relative sensitivity using d' from signal detection theory and are plotted using the y-axis on the left side of the figure. Right side: Rats received food in 3-h meals with fixed intermeal intervals by breaking a photobeam inside the food trough. The rate of photobeam interruption increased before the meal. Squares represent sensitivity, which was measured as the width of the anticipatory function at 70% of the maximum rate prior to the meal, expressed as a percentage of the interval ($N = 29$). The interval is the time between light offset and meal onset in a 12–12 light–dark cycle (leftmost two squares) or the intermeal interval in constant darkness (all other squares). Squares are plotted with respect to the reversed-order y-axis on the right side of the figure. Y-axes use different scales, and the x-axis uses a log scale. Adapted from Crystal JD (1999) Systematic nonlinearities in the perception of temporal intervals. *J. Exp. Psychol. Anim. Behav. Process.* 25: 3–17; Crystal JD (2001a) Circadian time perception. *J. Exp. Psychol. Anim. Behav. Process.* 27: 68–78; Crystal JD (2001b) Nonlinear time perception. *Behav. Processes* 55: 35–49. Reproduced from Crystal JD (2006d) Time, place, and content. *Comp. Cogn. Behav. Rev.* 1: 53–76, with permission.

side; **Figure 22**) is consistent with timing based on multiple oscillators (Church and Broadbent, 1990; Gallistel, 1990; Crystal, 1999, 2001b, 2003, 2006d). According to multiple-oscillator proposals, each oscillator is a periodic process that cycles within a fixed amount of time; an oscillator is characterized by its period (i.e., cycle duration) and phase (i.e., current point with the cycle). Each unit within a multiple oscillator system has its own period and phase. Therefore, a multiple-oscillator system includes several distinct periods. Sensitivity to time of an interval near an oscillator is expected to be higher than timing an interval farther away from the oscillator. Therefore, the multiple local maxima in sensitivity to time shown in **Figures 17, 20, 21, and 22** suggest the existence of multiple short-period oscillators.

The data reviewed in this section conflict with the predictions of **Table 1**. The first row of **Table 1** focuses on the defining feature that distinguishes oscillator and pacemaker-accumulator mechanisms. Oscillators are endogenous and self-sustaining, meaning that they continue to cycle after the termination of periodic input. By contrast, a pacemaker-accumulator requires resetting by an exogenous stimulus, and the timing system is presumed to be reset by a single event (i.e., one-shot reset). The data in **Figures 14 and 15** suggest that short-interval timing is endogenous and self-sustaining, thereby exhibiting a property of an oscillator rather than a pacemaker-accumulator.

The second row of **Table 1** focuses on the susceptibility of oscillator and pacemaker-accumulator mechanisms to time different ranges of target intervals; the former is described as subject to a limited training range, whereas the latter is subject to a broad training range. The data in **Figures 16 and 18** suggest that many long, but noncircadian, intervals can be timed, and the data in **Figure 19** suggest that long-interval timing is endogenous and self sustaining, consistent with an oscillator mechanism.

The third row of **Table 1** focuses on the responsiveness to abrupt changes in the phase of an input signal. A hallmark feature of an oscillator is gradual adjustment in phase responsiveness – meaning that

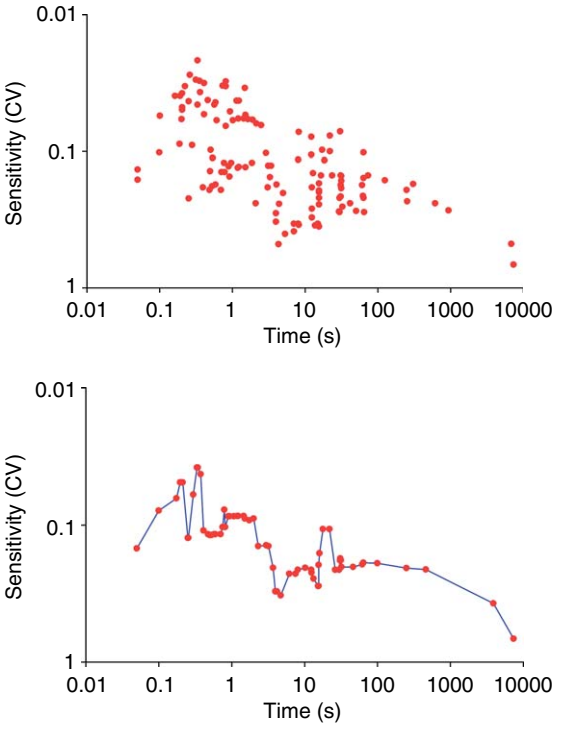

Figure 22 Top panel: Sensitivity is plotted as a function of time across six orders of magnitude. The scatter plot reveals that sensitivity to time declines as a function of increasing intervals. The data are from Figure 3 in Gibbon J, Malapani C, Dale CL, and Gallistel C (1997b) Toward a neurobiology of temporal cognition: Advances and challenges. *Curr. Opin. Neurobiol.* 7: 170–184. The published figure was enlarged by 375%, and each datum was measured at 0.5-mm resolution. The residuals from linear regression (not shown) were not random ($r(128)_{lag1} = .454$, $p < .001$). The data are plotted on a reversed-order *y*-axis to facilitate comparison with other measures of sensitivity. Bottom panel: Sensitivity is plotted as a function of time across six orders of magnitude. The data from Gibbon et al. (1997b) shown in the top panel were averaged in two-point blocks and subjected to a three-point running median. Note that sensitivity to time is characterized by local maxima at approximately 0.2-0.3, 1.2, 10, and 20 s. Note that these values are similar to the local maxima that were observed by Crystal (1999, 2001b): 0.3, 1.2, 12, and 24 s (cf. Figure 21). The residuals from linear regression (not shown) were not random ($r(63)_{lag1} = .869$, $p < .001$). The data are plotted on a reversed-order *y*-axis to facilitate comparison with other measures of sensitivity. Adapted from Gibbon J, Malapani C, Dale CL, and Gallistel C (1997b) Toward a neurobiology of temporal cognition: Advances and challenges. *Curr. Opin. Neurobiol.* 7: 170–184; and Crystal JD (2006c) Sensitivity to time: Implications for the representation of time. In: Wasserman EA and Zentall TR (eds.) *Comparative cognition: Experimental explorations of animal intelligence,* 270–284. New York: Oxford University Press. Reproduced from Crystal JD (2006d) Time, place, and content. *Comp. Cogn. Behav. Rev.* 1: 53–76. with permission.

multiple cycles under the new phase regime are required to produce complete adjustment. By contrast, a hallmark feature of a pacemaker-accumulator is immediate adjustment to a resetting stimulus — meaning that complete adjustment requires presentation of a single shifted cycle. The data in **Figure 13** suggest that short-interval timing is subject to gradual phase adjustment, consistent with an oscillator mechanism.

The fourth, and final, row in **Table 1** focuses on the variance properties of oscillator and pacemaker-accumulator timing systems. Circadian timing appears to be characterized by greater precision (i.e., lower relative variability) compared to short-interval timing. The data in **Figures 17, 20, 21, and 22** suggest that both short-interval and circadian timing are characterized by local peaks in sensitivity to time.

The data suggest substantial continuity between short-interval and circadian timing systems. Indeed, in many situations, the predictions of multiple timing mechanisms are confounded, and specific empirical tests are required to dissociate these mechanisms (e.g., Pizzo and Crystal, 2002, 2004a,b; Babb and Crystal, 2006). The data reviewed in this chapter may prompt the development of a theory of timing that encompasses the discrimination of temporal intervals across several orders of magnitude, from milliseconds to days. The proposal to integrate ideas in short-interval and circadian timing is not unprecedented given the shared genetic makeup of some behaviors over both long and short time horizons (e.g., courtship behavior and circadian period in *Drosophila melanogaster*; Roche et al., 1998).

1.19.7 Conclusions

Time is a fundamental dimension of human and animal experience, affecting behaviors that span from milliseconds to days. Indeed, timing is ubiquitous in such familiar behaviors as speech, music, and motor control in the range of milliseconds, foraging, decision making, and time perception in the seconds-to-minutes range, and sleep–wake cycles and appetite in the range of a day (Buhusi and Meck, 2005). This review has focused on (1) methods of assessing temporal performance and (2) evaluating theoretical proposals about the mechanisms responsible for temporal performance. We draw some conclusions for each of these lines of focus.

The review of experimental methods illustrates the remarkable quantitative precision that may be obtained in studying temporal performance. One of

the unifying principles is the scalar property; seemingly different patterns of performance that unfold in real time may be seen as representing cases from a single process when the data are rescaled in proportional units of time. We reviewed some of the many experiments that have demonstrated the ubiquity of this feature of temporal performance.

Nevertheless, the review of theoretical proposals suggests that the observation of superimposition does not, by itself, identify the mechanism(s) responsible for temporal performance. Although superimposition of data in relative units of time is consistent with SET (a classic pacemaker-accumulator theory of timing), other timing theories are also compatible with this feature of timing data (e.g., Hopson, 2003; Killeen and Fetterman, 1988). Moreover, we reviewed a series of experiments that sought to identify data diagnostic of pacemaker-accumulator or oscillator mechanisms. The conclusion that emerges from these lines of research is that short- and long-interval timing are characterized by oscillator-like properties.

Perhaps the greatest challenge for applying an oscillator mechanism to short-interval timing is the need to have an oscillator mechanism that is flexible enough to time intervals that span several orders of magnitude. Although this has traditionally been assumed to be compatible with a pacemaker-accumulator (but not an oscillator) mechanism, the observation of oscillator-like properties in timing intervals across several orders of magnitude encourages the view that multiple oscillators may be deployed to time a broad range of intervals (Church and Broadbent, 1990; Gallistel, 1990; Crystal, 2006d). Moreover, the data reviewed in this chapter may prompt the development of a unified theory of timing that encompasses the discrimination of time across several orders of magnitude – from milliseconds to days.

1.20.1 Introduction

The oldest organisms on earth live on isolated peaks in the Great Basin. These bristlecone pines look like giant bonsai trees, twisted against the harsh conditions of the high, cold desert. The oldest of these trees are over 4500 years old. They have lived through most of recorded human history, but they do not remember. Indeed, students of learning and memory seldom give plants – whether old or young – a passing thought. It is, however, instructive to recall the differences between plants and animals and to ask whether these differences can tell us something about why one group comes equipped to learn and remember while the other does not. Nearly any introductory biology book will direct your attention to three key differences: animals move, animals have nervous systems, and animals consume living things. These three elements represent a deeply intertwined syndrome of animal features. A plant living in a flux of photons and a sea of CO_2 does not need to move. In contrast, living tissues do not flow into an animal's mouth. For animals, pastures are always greener elsewhere (often quite literally!), so animals need to move to find a fresh supply of living resources. And, of course, animals need nervous systems, and ultimately the ability to learn and remember, to control and refine these movements.

The business of acquiring and consuming living resources ranges from the spectacular – a spider

swinging a bola of sticky silk to ensnare prey – to the mundane – cows eating grass. Whatever form it takes, it is a basic feature of the animal way of life. It follows that an understanding of foraging behavior is fundamental to our understanding of animal behavior and the mechanisms that control it, including learning and memory. To begin, we consider a concrete example that illustrates the role of learning and memory in foraging.

On summer mornings from July to September masses of tiny mayflies (genus *Tricorythyodes*) emerge from cold water streams in North America. The emergence occurs in the early morning. In the hour after dawn, clouds of these tiny flies hover over every riffle in the river. These clouds are mating swarms. As the mating swarms develop, fish in the stream below move into positions downstream of the swarming flies in the workman like manner of commuters arriving at their jobs. An hour and 30 minutes after dawn the mating swarms begin to break up as the mated adults die. Their bodies cover the surface of the stream and create a feeding bonanza for the waiting fish. Although the mayflies fall indiscriminately, the currents and properties of the streambed concentrate the food. The waiting fish are clearly sensitive to these hotspots, because as the mayflies continue to cover the water, one can see patches of the stream where the surface boils with the activity of feeding fish. The ecological drama ends as suddenly as it began. A few hours after dawn the mayflies will have been swept away by the current, and the fish will have dispersed to stations throughout the river.

This predictable daily drama is typical of the situations in which learning abilities guide animal feeding behavior. Like our feeding trout, honeybees and other nectar feeders are, for example, famous for learning the temporal availability and spatial pattern of food sources (*See* Chapters 1.25, 1.29). Feeding blue jays, to take another example, learn that monarch butterflies taste bad due to cardiac glycosides that the butterflies obtain as caterpillars. Broadly speaking, foraging animals clearly learn many basic properties of their prey: how to handle them (e.g., remove spines, avoid stinging parts), where they can be found (under leaves? on tree bark?), and so on. Similarly, foraging animals use memory to guide their decisions about which patches to exploit and when to exploit them. Animals that store food for later retrieval offer an especially compelling example. Clearly, the ability to relocate hidden food items is a basic feature of animal food-caching behavior. Over the last 20 years investigators have exploited this behavior to produce new insights in how memory serves animals in naturally occurring resource gathering (*See* Chapter 1.22). Recently, for example, Clayton and Dickinson (1998) have exploited this aspect of foraging behavior to provide the first evidence that nonhumans can form 'episodic-like' memories (*See* Chapter 1.23).

As these remarks show, learning and memory play key roles in the day-to-day business of resource acquisition. In contrast, many of the classical methods for studying learning and memory seem abstract and somewhat contrived. Yet, there are deep connections between the two. One connection is procedural; food acquisition serves as a useful context with which to study learning and memory. Pavlov's dogs salivate in anticipation of food, Skinner's pigeons peck for access to food, and Olton's rats run down the arms of a radial arm maze to obtain food. It behooves students of learning and memory, therefore, to understand how the components of foraging behavior they study fit within the larger context of animal foraging. The second connection is more conceptual; a complete understanding of learning and memory will require analyses at all levels of biological organization from the molecular to the ecological, and foraging behavior stands out as one of the simplest situations in which to seek an understanding of the ecological significance of learning and memory.

1.20.1.1 Foraging Basics

Foraging refers to the business of food acquisition. Although we restrict the definition to food acquisition, ecologists commonly apply similar principles to other forms of resource acquisition (e.g., 'foraging' for mates). As a broad generalization, foraging is a relatively common and easily observed aspect of animal behavior (*See* Chapters 1.12, 1.21). As explained earlier, foraging is a fundamental component of animal existence both because it is a defining property of animals, and because it provides the fuel for the remainder of an animal's activities. Students of foraging behavior (Stephens and Krebs, 1986; Stephens et al., 2007) typically envision a three-level hierarchy of resources. At the highest level, animals forage within *habitats*. For example, a hummingbird may choose to feed in an alpine meadow or along a stream bank. Choosing a habitat determines the mix of resources that a forager will encounter at a fairly large spatial and temporal scale. Typically, we imagine that it is time consuming or costly to switch habitats. Food is virtually never spread evenly

throughout a habitat, so it is useful to imagine that food occurs in discrete *patches* within habitats. So our hummingbird would encounter clumps of flowers within the alpine meadow. In practice, of course, the 'edges' of food patches are often fuzzy, but foraging models typically ignore this. In contrast with habitats, we imagine that a forager encounters many patches during any given foraging bout, and that it may choose to exploit or ignore any given patch it encounters. However, a forager must also choose how thoroughly a given patch should be exploited. Finally, within patches we commonly imagine that the forager finds *prey* items such as seeds or insects. For our hummingbird, the flower within an inflorescence would serve as prey. While the distinction between patches and prey is usually clear-cut, it can also be subtle. Economically, the key point is that a forager can choose how to exploit a patch, but it can only choose whether to exploit a prey item. Notice finally that we call discrete food items *prey* regardless of whether they are animals or plants.

1.20.2 Basic Foraging Models

Over the last 20 years, behavioral ecologists have developed a basic set of models that make predictions about foraging behavior in a wide range of 'standard' foraging situations (Stephens and Krebs, 1986; Stephens et al., 2007). In the next few paragraphs, we present these models following the hierarchy discussed in the previous section. We begin by discussing prey choice (the lowest level), then we discuss patch exploitation, and finally we discuss habitat choice. All of these models follow the premise of rate maximization. Crudely speaking, we know both from empirical studies of food choice behavior and from first principles that both time and amount matter to foraging animals, and rate represents a simple and natural way to combine time and amount. More formally, the hypothesis of rate maximization holds that natural selection favors behaviors that lead to high rates of food intake, because animals that obtain food at a high rate will have more time and more resources to pursue other important activities (like mating, or territorial defense). One can, of course, imagine situations in which rate maximization would be inappropriate (for example, if the habitat that provides the higher rate of food intake also has the most predators). As one might expect, many papers focus on situations in which this 'standard' assumption does not hold. Nonetheless, the premise of rate maximizing represents a useful way to begin our analysis of how economic forces shape foraging behavior.

1.20.2.1 Prey Choice

Consider a bird searching for moths – prey items – along a tree trunk. We think of these items as particles dispersed through the environment that the animal 'bumps into' as it moves. Of course, there are different types of prey items. Our bird may encounter some small grey moths and some large white moths. The prey types vary in three ways. First, prey types provide different amounts of energy when consumed. To continue our example, small grey moths may provide 1.8 J when consumed, while large white moths provide 6.0 J. Second, prey take different amounts of time to pursue, handle, and consume – collectively we call this handling time. Small grey moths may require 10 s to handle, while the larger white moths take 25 s to handle. Finally, prey types have different abundances. Some types are common so the forager encounters them relatively frequently, while others are rare. This may seem like an odd way to introduce the simple idea of relative abundance, but to simplify our rate calculations we think of the average time between encounters with a particular prey type rather than using direct measures of abundance. The inverse of the time between encounters is the encounter rate, and generally speaking, abundant prey have high encounter rates. To summarize, we characterize prey items by their energy values, their handling times, and their encounter rates.

So, we have our bird hopping along a tree trunk encountering grey and white moths; now we need to think how the bird can express a choice. We will assume that the bird can decide whether to attack or ignore a given type when it is encountered. Mathematically, we represent this as a probability of attack upon encounter, and we have two such probabilities, one for the small gray moths and one for the large white moths. Now our mathematical problem is to find the attack probabilities that give the highest rate of energy intake. To do this, we need to express the intake in terms of the variables outlined here – encounter rates, handling times, energy value, and attack probabilities. This is fairly easy with one final trick. We recognize that our animal spends its time doing two things: searching and handling. By definition, if the λ_1 is the encounter rate of prey type 1, then an animal that searches for T_s units will encounter (not eat but encounter) $\lambda_1 T_s$ type 1 items, and similarly it will encounter $\lambda_2 T_s$ type 2 items.

Since our forager accepts type 1 items it encounters with probability p_1, the number it accepts in T_s units of searching is $p_1\lambda_1 T_s$; similarly the number of type 2s it accepts is $p_2\ \lambda_2 T_s$. Now we know each type 1 prey item requires h_1 time units to handle and provides e_1 calories; while each type 2 prey item takes h_2 time units to handle and provides e_2 calories. So, the rate we want to calculate is just the energy gain $(e_1p_1\lambda_1 T_s + e_2p_2\lambda_2 T_s)$ divided by the total time $(T_s + h_1p_1\lambda_1 T_s + h_2p_2\lambda_2 T_s)$. The rate of intake is

$$\frac{p_1\lambda_1 T_s e_1 + p_2\lambda_2 T_s e_2}{T_s + p_1\lambda_1 T_s h_1 + p_2\lambda_2 T_s h_2} \quad [1]$$

Since T_s is a common factor in every term in both the numerator and denominator, it cancels out to leave us with

$$\frac{p_1\lambda_1 e_1 + p_2 T_s e_2}{1 + p_1\lambda_1 h_1 + p_2\lambda_2 h_2} \quad [2]$$

More generally we have

$$\frac{\sum_i p_i\lambda_i e_i}{1 + \sum_i p_i\lambda_i h_i} \quad [3]$$

This final form is commonly called 'Holling's disc equation' (Holling, 1959) and is the conventional expression for intake rate used in foraging models. The development we followed in the preceding paragraphs shows the central assumption of Holling's disc equation; specifically, it assumes that foraging animals are either searching or handling, and that these are mutually exclusive activities. In broad overview this is a useful assumption that describes the way in which many animals feed; however, there are some important situations in which animals can handle and search simultaneously. Notably, grazing animals can often 'search for the next blade of grass' while they handle (chew) previously encountered grass blades (Spalinger and Hobbs, 1992; Illius et al., 2000).

Now that we have an expression for rate, our problem is to find the probabilities of attack that maximize this rate. This is a straightforward mathematical operation that we can solve via calculus, and which we will not pursue here. We can understand the results without working through the calculus. First, we find that the rate-maximizing value of p_i should be either zero or one; that is, our forager should always attack or always ignore the ith prey type upon encounter. Once we know this, we can ask which types should be ignored and which should be attacked. Suppose, for example, that a hypothetical forager is attacking types A and B; should it also attack type C? If we use Holling's disc equation to compare the rates of intake for a 'diet' of A and B alone to a diet of A, B, and C, then we find the effect of adding C depends on the type C's ratio of energy to handling time (e_c/h_c). We call these energy-to-handling-time ratios 'profitabilities,' and these are key variables to understanding the economics of prey choice. The basic algebraic result is that adding item C to the diet increases the overall rate of intake if C's profitability is greater than the intake rate obtained from a diet of A and B alone. This leads to the idea that foragers should rank prey types by their profitabilities. So we assign the prey type with the highest profitability rank 1, and second highest rank 2, and so on. Then, we can find the diet that maximizes intake rate by working through the prey types in rank order until we reach a situation where the rate obtained from attacking types 1 through N exceeds the profitability of the type $N+1$.

This economically derived, rate-maximizing 'diet' has several intriguing properties. First, it predicts, rather surprisingly, that animals should always take a given type upon encounter or always ignore it. This claim may surprise the casual observer, because people think of mixed-diets or 'well-balanced' diets as good diets. But this model only considers a single dimension of prey value (typically energy content), and so it cannot consider well-balanced diets. However, the idea of a 'single dimension of value' is often appropriate. In experimental studies, we often create prey types (or their logical equivalents) that value only in magnitude (e.g., big vs. small), and in nature many foragers eat a range of food items with similar nutrient contents (e.g., from the perspective of an insectivorous bird most insects have about the same balance of proteins and carbohydrates). Empirically, however, this so-called 'zero-one' rule seldom holds. Second, and most importantly, the model predicts that the better-ranked prey types control whether lower-ranked items should be attacked. When the good prey types are plentiful, foragers should ignore poorer prey types regardless of the abundance of these poorer prey types. Indeed, it is now a widely accepted principle that, in a rich environment (where foragers can easily obtain high-quality prey), animals will feed more selectively.

1.20.2.2 Patch Exploitation

At the next higher level of organization, we imagine that foragers encounter clumps of resources or

patches. Our forager finds food inside well-defined and easily recognized patches but travels between patches by crossing 'empty' space to reach the next patch. In practice, a foraging patch for a small insectivorous bird might be pine cones in which insects hide, or for an aquatic snail it might be the sunlit top of a rock on which algae grow. When we think of prey items, we think of entities that provide a given amount of food in a given amount of time, but animals exploit patches more flexibly. Our insectivorous bird might 'skim the cream' from a patch by quickly extracting the obvious and easily captured prey and then moving to another fresher patch. Alternatively, it might exploit the patch thoroughly by meticulously peering behind every scale of the pine cone before traveling to the next patch. To represent this flexibility, we plot a gain function that represents the relationship between time spent exploiting a patch and amount of food extracted from a patch. **Figure 1** shows a typical gain function.

Patches deplete, of course, so as the figure shows, we expect that gains within a patch will increase at a declining rate, so the gain functions usually bend down as the example in the figure shows. A 'cream skimmer' will leave the patch early, when the gain function is still increasing relatively steeply; while a 'thorough exploiter' will stay much longer, until the curve flattens out. Both strategies have risks, of course. The 'cream skimmer' risks spending too much time unproductively traveling between patches, while the 'thorough exploiter' risks wasting time in the current patch when there are richer fresh patches to be had.

Foraging theory's models of patch exploitation address the balance between cream skimming and thorough exploitation directly. Again, we begin by

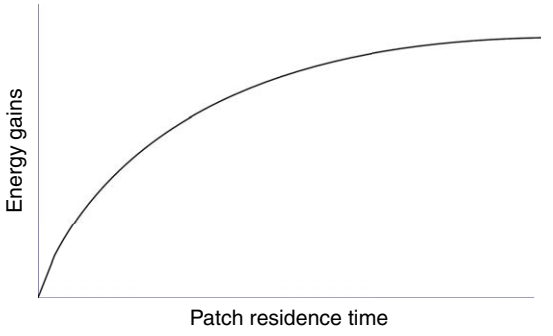

Figure 1 A typical patch gain curve. The x-axis shows the time spent exploiting a patch, and the y-axis shows the energy extracted from the patch. The forager extracts more energy as it spends more time in the patch, but this relationship tends to bend down because the patch depletes.

expressing the rate of food acquisition (again using eqn [3], Holling's disc equation). Let τ be the mean travel time, that is, the time it takes our forager to move from one patch to the next. Let t be the patch residence time. The variable t is the variable of interest here, because a small t corresponds with a cream-skimming strategy, while a large t implies thorough exploitation. Finally, let $g(t)$ be the gain function. Specifically, $g(t)$ gives the energy gains obtained when our forager exploits a patch for t units of time. So

$$\frac{g(t)}{\tau + t} \qquad [4]$$

gives the rate of energy intake for single patch type. Although one can solve this problem via calculus (find the t value that maximizes intake rate), there is an elegant and informative graphical solution.

Figure 2 shows the graphical solution.

We draw the gain function in the right-hand panel, so that patch residence time (t) is on the x-axis and energy gain is on the y-axis. Next we do something a bit unconventional. We let the negative part of the x-axis represent travel time (τ), with travel time increasing as we move away from the origin. Now for a given patch residence time, the intake rate (eqn [4]) is the slope of line drawn from travel time on the (usually) negative part of the x-axis to the point $(t, g(t))$ on the gain curve. If you imagine this point on the gain curve sliding up and down along the curve as we simultaneously maintain the straight line connecting our point to the travel time on the left side of the x-axis, then it is easy to see that the highest slope (and hence the highest rate) occurs when the line is just tangent to the gain curve.

Now that we know how to find the patch residence time that gives the highest rate, we can ask how the properties of the model determine the best patch residence time. There are two things within this simplified version of the model that we can consider: the gain function ($g(t)$) and the travel time (τ). The effects of travel time on patch exploitation have attracted the most attention. Broadly speaking, if the habitat is poor, then travel times will be long, but if the habitat is rich, then travel times will be short. If travel times are short, our tangent-construction solution predicts shorter exploitation times. Intuitively, in rich habitats foragers should adopt a cream-skimming strategy. In contrast, when travel times are long, the tangent-construction method shows that we should expect longer exploitation times. In poor habitats, then, we expect foragers to

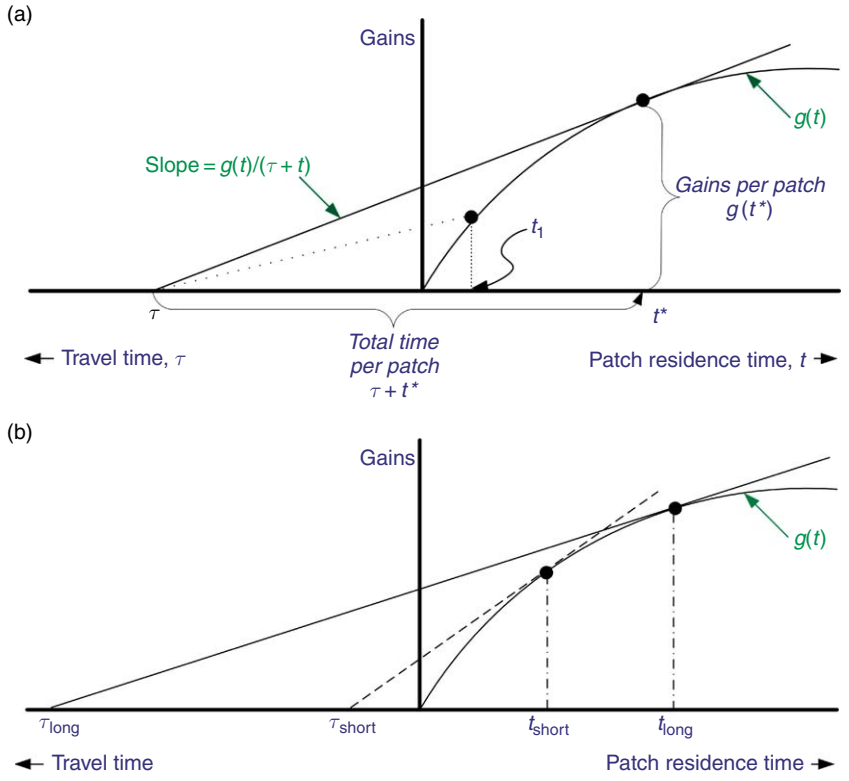

Figure 2 The graphical solution of the rate-maximizing patch exploitation time, sometimes called a Cowie plot or a rooted-tangent plot. Panel (a) shows the graphical method of find the patch residence time (t) that maximizes the forager's intake rate. On the x-axis we plot patch residence time (t) increasing to the right of the origin and travel time (τ) increasing to the left of the origin. The y-axis shows the energy gains as in **Figure 1**. The slope of a line drawn from a given travel time on the left side of the x-axis to a point on the gain curve on the right gives the intake rate associated with the corresponding patch residence time (t). Algebraically the slope of this line is $g(t)/(\tau + t)$, the quantity that our model seeks to maximize. One can readily see that the highest slope corresponds to a line that is just tangent to the gain function. The solid diagonal line illustrates this. Note that a line drawn to any other point on the gain curve will give a lower slope, as the dotted diagonal line shows. Panel (b) shows the main prediction of the model. When the travel time is long (τ_{long}), our tangent construction solution gives a long patch residence time (t_{long}), but when the travel time is short (τ_{short}), we predict a shorter patch residence time (t_{short}).

follow a 'thorough exploiter' strategy. The data provide strong support for the qualitative claim of cream-skimming in rich habitats and thorough exploiting in poor habitats. Indeed, this simple observation may be the single best-supported theoretical prediction from behavioral ecology. An appealing feature of this result is that we can understand it by comparing the value of continuing to exploit the present patch to the value of leaving to find a new patch. Short travel times increase the value of 'leaving,' and so we predict leaving earlier. The simplicity of this value of staying versus value of leaving comparison is important because, as we will see, it is the key to generalizing the model to more complex situations.

Gain functions can vary in a virtually unlimited number of ways, but our simple tangent construction method quickly shows the effects of different shapes. For example, if foragers can search systematically, their gains will follow a simple straight line up to some maximum. The gain function for systematic search will be a straight line from zero to the maximum, and then it will kink and become a flat line at the maximum food obtainable from the patch. Our tangent construction method shows the highest obtainable corresponds to a line intersecting the 'kink' (predicting that foragers should stay until they have extracted the maximum amount, but no longer) in this special case. Obviously, we would predict no travel time effect in this situation. Again, this makes sense when we consider the value of staying versus the value of leaving. There is no point in leaving until you have extracted the maximum amount of food, because the very best thing that could happen if you leave is to encounter a new patch with the same linear rate of gain.

The behaviors associated with patch exploitation have not been widely used in studies of learning and memory, and this is unfortunate, because patch exploitation is an important and well-documented aspect of natural foraging behavior. In addition, the successful family of models described here provides useful insights into the economic forces that have shaped patch exploitation.

1.20.2.3 Ideal-Free Distribution

Now consider a simple and somewhat artificial situation in which each of two sites provide food, say site 1 and site 2. Some distance separates the two sources, so that a forager cannot feed at both sites simultaneously, but must choose whether to feed at site 1 or site 2. Now, suppose that site 1 provides food at a rate of 10 J per hour (call this r_1), while site 2 delivers food at a rate of 5 J per hour (call this r_2). Economically, this is a trivial problem. Any sensible economic agent would stick with the site that delivers resources at the highest rate. This situation is not terribly interesting as it stands, but it becomes much more interesting when we imagine several foragers exploiting the same pair of feeding sites.

If several foragers all move to the single best site, they will have to share the food available there, and this raises the possibility that some of the members of the group could do better by moving to the other, less desirable site. The simplest model that addresses this question is called the ideal-free distribution. Like the two models discussed above, a review of this model provides significant insight into the economic logic of group foraging. To begin, imagine a group of six fish, with two at site 1 and four at site 2. Now if we assume that the fish at site 1 roughly share the food arriving there, then each expects to gain 10 J per hour divided by 2, or by 5 J per hour; using the same reasoning the four fish at site 2 expect to gain 1.25 J per hour per fish (i.e., 5/4). In this situation, we would expect that at least one of the fish at site 2 would be tempted to move to site 1 where it can do better, so we would have 3 fish at site 1 and 3 fish at site 2. But now the per-fish rate at site 1 would be 3.3 J per hour (10/3), while the per-fish rate at site 2 is 1.67 J per hour (5/3). So fish at site 2 are still doing worse, and at least one of them should be tempted to move to site 1, making the distribution four fish at site 1 and two fish at site 2. Now, the per-fish rate at site 1 is $10/4 = 2.5\ \mathrm{J\,h^{-1}}$, and the per-fish rate at site 2 is $5/2 = 2.5\ \mathrm{J\,h^{-1}}$. In this situation, no individuals are tempted to move to the opposite site. So we conclude that this four and two arrangement is stable, and we would expect this pattern to persist. Notice that, in our imaginary scenario, the fish have arranged themselves in a way that matches the inputs to the two sites. This 'input matching' result is the basic prediction of the ideal-free distribution model. This input-matching prediction holds reasonably well in experimental studies of animal feeding groups, even though the idealized assumptions of the model seldom hold. For example, the assumption that individuals share equally at feeding sites almost never holds, because some animals compete more effectively than others. Typically, this does not affect the input-matching result too much, because good competitors tend to occur at all feeding sites.

Logically, the ideal-free distribution's prediction of the input matching is quite similar to Herrnstein's matching law (Herrnstein, 1974), which predicts that individuals should distribute responses across two options in a way that matches the rates of food delivery associated with those responses. The matching law, however, focuses on the behavior of individuals, while the ideal-free model considers how the actions of individuals determine the properties of groups. While one derives the ideal-free model from very simple economic considerations, input matching for individuals (as the matching law predicts) only makes economic sense when rewards wait to be collected, as they commonly do in variable interval schedules.

1.20.2.4 General Principles and Conclusions

The central idea in the described models is the economics of lost opportunity. In prey selection a forager may reject a mediocre item, because to accept it means that the forager may miss an opportunity to obtain a better item. A forager exploiting patches in a rich environment leaves early, because it will lose opportunities to exploit new patches if it stays too long. A forager, feeding in a group, may choose to feed at a less productive site because competitors at the more productive site reduce the opportunities for success there. One should view these three basic models as starting points which, taken together, identify many fundamental variables in foraging behavior and draw our attention to the fundamental role of opportunity costs in foraging behavior.

Behavioral ecologists have extended these models in several significant ways. For example, these models tacitly assume that we can use averages to characterize the properties of resources (patches, prey, foraging sites). Models of risk-sensitive foraging consider the economic consequences of variability, predicting, for example, that foragers may prefer to take risks when

their energy supply is very low, even though they should avoid risks when they are well-off (Bateson and Kacelnik, 1998). Another important theme has been the effects of predation. While the described models only consider energy and time, it is often the case that the best places to forage (sites or patches) are also the most dangerous. Predators, after all, readily learn where prey are concentrated. The threat of predation can have dramatic effects on the behavior of foragers (see the section titled 'Foraging and predator avoidance').

1.20.2.5 Connections to Learning and Memory

Virtually all experimental tests of foraging models rely on learning. For example, in a now classic test of the diet model, Krebs et al. (1977) allowed foraging great tits (a small European bird) to watch prey items passing by on a small conveyor belt. They used the conveyor belt to manipulate encounter rate, and they found that the encounter rate with the highest quality items determined selectivity as the prey model predicted. Obviously great tits did not evolve collecting meal worms from conveyor belts, so their experience must have determined their choice behavior in Krebs et al.'s experiment. In light of experiments like Krebs et al.'s, behavioral ecologists – a group stolidly committed to the idea that muddy boots are required equipment for behavioral studies – came to the realization that they could design better experiments and build more testable models by attending to the large extant literature of animal learning and memory.

Some students of foraging have taken the connection with learning a step further by directly considering the fitness value of learning in foraging situations. Imagine, for example, that the quality of a foraging site changes unpredictably according to some mathematically well-defined process. One can then ask whether a forager should use its experience with this variable resource to determine whether to exploit or ignore this resource (see, for example, Krebs et al., 1978; Lima, 1985; Stephens, 1987, 1989, 1991; Tamm, 1987; Shettleworth et al., 1988). The next section discusses this approach in more detail.

1.20.3 Behavioral Ecology of Learning and Memory

Foragers live in a changing world. In the morning, the best feeding sites may be below riffles, while deep pools provide the best foraging in the evening. Competitors and predators may appear unpredictably. Foragers may encounter new prey types as the seasons progress or as the forager moves through its environment. Foragers need mechanisms that help them adjust to these changes, and surely learning and memory are a central part of this toolkit. In stark contrast to the world of change and the subsequent need for adjustment that real foragers face, the basic models of foraging (discussed in the previous section) assume that foragers can act with complete information about their options. Behavioral ecologists have used the machinery of statistical decision theory (Dall et al, 2005) to relax this complete information assumption. The family of models derived from these efforts considers the economics of adjusting to change. These 'incomplete information' models ask when and if it pays to learn about changing resources. The results, we argue, provide the foundation for an evolutionary approach to learning and memory and illustrate how an understanding of foraging can contribute to an enlarged view of the biology of learning and memory.

We will outline three basic approaches to the problems faced by an incompletely informed forager. To begin, we develop a simple model that calculates the value of information. This introduces the idea of environmental uncertainty and focuses our attention on the connection between information and action. Second, we move toward a model of learning by considering the economics of tracking a varying resource. In tracking models we explicitly consider how change generates uncertainty, and how animals may be sensitive to the properties of environmental change. Finally, we briefly discuss how environmental changes and the reliability of experience should influence memory.

1.20.3.1 The Value of Information

The working assumption of behavioral ecologists interested in learning and memory is that animals learn and remember things because acquiring and retaining particular kinds of information produces fitness benefits. Behavioral ecologists generally expect, therefore, that animals should learn and remember more valuable information more readily. But what makes information valuable and why would some types of information be more valuable than others?

To answer this question, imagine a simple situation in which some relevant state of the world (a prey type, a feeding site, . . .) can be any of several states. To be concrete, consider a squirrel foraging from pinecones.

Some pinecones are good feeding sites, others are mediocre, and still others are poor feeding sites. Our hypothetical squirrel cannot tell which is which. So when is information about pinecone type valuable? To find the value of information, we imagine two situations. First, suppose that the squirrel can recognize pinecone types perfectly. If this is true, then it should able to adopt an exploitation strategy that is appropriate for each pinecone type: aggressively exploiting good pinecones, skimming the cream from mediocre pine cones, and completely ignoring poor pinecones. Given the mix of pinecone types in the environment and our knowledge of how a 'knowledgeable' squirrel would treat them, we can – in theory – calculate the expected benefits of being completely informed about pinecone quality. Now, imagine the other extreme. Suppose that our squirrel cannot recognize pinecone quality, so it must treat all pinecones in the same way. Specifically, the best an ignorant squirrel can do is to adopt some average exploitation strategy that represents a compromise between the three types. Again, we can – in theory – calculate the expected benefit that an ignorant squirrel can achieve. The value of information about pinecone type is the difference between the expected benefits that a completely informed forager can obtain and the benefits expected by an 'ignorant' forager who must choose a single compromise tactic to suit all situations.

The general lesson here derives from the focus on action. The difference between informed and uninformed foragers is that the informed forager can treat different states differently, while the uninformed forager must adopt a single one-size-fits-all strategy. It follows that the value of information flows, in a very fundamental way, from information's potential to guide actions. Consider, for example, a situation in which the best way to exploit our hypothetical pinecones is the same regardless of type. What is the value of information then? Clearly, it must be zero. Because if the best action for all three types is the same, then an ignorant forager can adopt this single best action and do just as well as an informed forager. So, if a source of information cannot reveal something that will change the forager's action, then according to this definition it is not valuable. Valuable sources of information have the potential to change behavior.

1.20.3.2 Tracking

The value of information approach imagines a static but uncertain world – pinecones may be good or bad – and we ask whether a forager should make an effort to find out. In many important natural situations the properties of resources change: pinecones are bad now, but they might improve in the future. This is the problem of environmental tracking. It represents an important next step in models of uncertainty, because it considers the effects of environmental change. By considering change, tracking models make a more direct connection to studies of learning, because we think of learning as a mechanism that helps animals adjust to changing environments.

Tracking models usually assume that some aspect of the environment, say the quality of a feeding site, changes according to some stochastic process. A typical 'tracking' analysis might model the process of environmental change by assuming that the state stays the same from one time period to the next with a constant probability. If this persistence probability is high, the forager experiences relatively long runs of the same state (e.g., the varying site stays in the good state for a long time), but if the persistence probability is low, the state changes frequently. Finally, we imagine that the forager has some alternative but mediocre resource to exploit. So the varying site is the best choice when it is in the good state, but the mediocre alternative is best when the varying site is in the bad state. These assumptions create a basic tracking problem. The forager must somehow use its experience to decide whether to exploit the varying resource or the constant but mediocre resource. Specifically, we can ask how frequently the forager should check the state of the varying resource, given that its last observation showed that the varying resource was in the bad state. The optimal sampling frequency depends on how frequently the environment changes and on the underlying payoffs (i.e., the value of the varying resource when it is good, the value of the varying resource when it is bad, and the value of the constant-mediocre resource). A striking feature of the optimal solution is that it does not make economic sense to sample in many situations. The region which it makes economic sense to sample increases with environmental persistence. When there is no environmental persistence, the varying resource changes randomly from one time to the next, so the forager has no option but to use the resource that yields the highest gains on average (a strategy called averaging). However, when persistence increases, the varying resource switches between long runs of good and bad, and now it makes sense to keep track of the varying resource's state. Recognizing that 'averaging' is the alternative to sampling, one can readily see that

tracking will be most useful when the forager's alternatives are about the same on average. If they are quite different on average, then a nonsampling strategy that sticks with the better of the two options will often be the most sensible choice.

A handful of experimental studies have tested the predictions of these optimal tracking models (Tamm, 1987; Shettleworth et al., 1988; Inman, 1990). A recent review by Stephens (2007) found that animals tend to sample less frequently when environmental persistence is high, as these models predict. In addition, they sample less when we experimentally increase the value of the mediocre-stable resource. Again, this is as we would predict, because when the constant resource is good, there is less value in detecting the onset of a good state. On the other hand, our models predict that increasing the value of the varying resource's good state should increase the sampling rate, but the three experimental studies we have on the topic show no consistent effect of this variable. While our economic model agrees qualitatively with observations, Shettleworth et al. (1988) reported that a mechanistic model based on scalar expectancy gave a better quantitative fit to their data.

1.20.3.3 Optimal Memory

The tracking models discussed in the previous section greatly oversimplify how animals respond to experience. For example, they often assume that a single 'sample' is sufficient to instantly change a forager's behavior. An obvious next step asks how animals integrate information from many experiences, and specifically how foragers should combine past and current experience. This leads us to questions about the economics of memory in changing environments. While there is comparatively little work on the behavioral ecology of memory, those studies which have modeled memory have taken one of two approaches. One family of models (e.g., Cowie, 1977) represents memory as a sliding window, e.g., all experience from the last 4 days is weighted equally. These models typically try to understand how the optimal length of the memory window depends on the properties of environment (e.g., rates of change, reliability of experience, and so on). The second approach uses a past versus present weighting system to represent memory (McNamara and Houston, 1987). This approach is reminiscent of Bush and Mosteller's old stochastic learning rules (Bush and Mosteller, 1955). At each trial the animal's judgment (say x) of the current state of the environment is updated via a linear weighting scheme that puts some weight on the previous judgment and some weight on the animal's most recent experience. In these models, one tries to find the optimal past/present weighting. Of course, both approaches are simplistic mathematical expedients that caricature memory. Both schemes can be extended and elaborated in various ways. For example, one can create a hybrid model by adding a weighting scheme (which weights recent experience more heavily than past experience) to the memory window formulation (see, for example, Hirvonen et al., 1991).

Two economic variables should, in theory, affect how foragers should strike a balance between past and present information. The first key variable is the environmental rate of change. Animals that experience high rates of change should weight recent experience heavily and devalue past experience (i.e., they should have a short memory window). The second key variable is the reliability of experience. Consider a situation with two prey types: good and bad. However, the world is a noisy place, so our hypothetical forager experiences the good state as a distribution of qualities from very good to relatively poor. When the resource quality varies like this, a single experience will not be enough to discriminate between good and bad states. The logic here parallels the statistical concept of standard error: the variance of the measured quantity and the sample size combine to determine the error in our estimate of the mean. When experience is an unreliable guide to the underlying state, then foragers need past information (i.e., a larger sample size) to reasonably characterize the current state. So when experience is unreliable, we expect foragers to weight past experience more heavily (i.e., to have longer memory windows).

Two empirical studies support the idea that change 'shortens' an animal's time horizon. Devenport and Devenport (1994) studied ground squirrels foraging from two baited feeding stations. In one treatment the quality of the stations changed frequently (Left-best, then Right-best, and so on), but in the second treatment the good station was always the same. Next, Devenport and Devenport observed which station the squirrels selected after an experimentally imposed retention interval. Squirrels in the stable environment group always returned to the site that had been best regardless of the retention interval. However, squirrels in the varying environment treatment returned to the old 'best site' after short retention intervals but choose randomly after long intervals. In a similar set of studies Cuthill and colleagues tested the effects of varying travel time on the patch exploitation behavior of

starlings. In one study Cuthill et al. (1994) slowly changed the experimentally imposed travel time (from long to short or from short to long). In this slowly changing environment regime, they found that starlings needed experience with several 'long' travel times to appropriately change their patch exploitation behavior. In another study, however, Cuthill et al. (1990) created a rapidly changing environment by alternating long and short travel times. In this situation, they found that starlings adjusted their patch exploitation behavior after a single experience with a 'long' travel time. We readily acknowledge that these studies do not necessarily show differences in memory. It could be for example, that the Devenports' variable-environment squirrels remember the previous state perfectly, but somehow choose not to act on it (a variant of the well-known learning-performance distinction). However, the observation that environmental change influences how the animals integrate information across various time scales seems important and basic regardless of whether this happens via memory or some other mechanism. Although we do not discuss specific mechanisms here, one potential mechanism may not even be through the weighting of specific memories, but in the processes by which these memories are formed, with regards to time course, stages, and the use of multiple sites and substrates (see Menzel, 1999).

1.20.3.4 What Not to Learn and Remember

As students of learning and memory we tend to assume that these fundamental abilities serve animals effectively in many situations, including, but not limited to, foraging behavior. Yet the models reviewed here reveal many situations where it does not pay to attend to experience: there is no benefit in attending to information that cannot change behavior; when the environment changes frequently, simple fixed strategies can often outperform learning; similarly in an environment with rapid change, the contents of long-term memory will often be hopelessly out of date and misleading. Indeed, if we considered the costs of implementing learning and memory (Dukas, 1999), the conditions that favor learning would be even more restrictive. We do not want to overstate the case, however. Animals clearly derive benefits from learning and memory in many situations, but animals do not learn and remember everything. The ideas presented here provide a useful starting point for analyses that consider the ecological relevance of learning and memory. Do animals adaptively forget in changing environments? Do they filter out experiences that cannot change behavior? A research program that considers the role of learning and memory in foraging and other significant natural contexts may help answer questions like these.

1.20.4 How Learning Constrains Foraging

The previous section discussed how models and data from foraging can inform our thinking about learning and memory. The interactions between foraging and learning, however, run in two directions. This section briefly discusses how results from the study of learning and memory can refine the study of foraging. Consider a migrating bird arriving in a new location. Likely, it will be familiar with the types of prey available at the new site: beetles look very much like beetles everywhere. While many of the new beetle prey will be nutritious and edible, some will probably taste bad or spray noxious chemicals that our hypothetical immigrant has never experienced before. Clearly, the basic models of foraging theory offer us no help in trying to describe or analyze this situation. The prey model, for example, will tell us whether our bird should attack a novel noxious prey from an economic perspective, but clearly this is irrelevant until the forager has an opportunity to adjust to the properties of the prey in its new location. In most situations, these 'adjustments' will occur via learning. It follows that a complete understanding of animal foraging behavior will need to incorporate learning to accommodate situations like our migrating bird's dilemma and probably a great many others.

Unfortunately, the path connecting animal psychology and behavioral ecology has not always been smooth. Early behavioral ecologists advocated a mechanistically agnostic perspective that continues to influence many behavioral ecologists. This perspective recognized that natural selection directly favors behavioral outcomes and acts only indirectly on behavioral mechanisms. According to this view, the prey model (to take a specific example) can be correct and useful regardless of how animals adjust to the properties of prey. Biology is, of course, hierarchical, and one can offer biological explanations at many different levels (e.g., cellular, physiological, population, and so on). Behavioral ecology's mechanistic agnosticism wanders into error, in our opinion, when it seems to diminish the importance of integrating approaches from different levels of

biological explanation. The need for studies that combine foraging and psychology illustrates this point eloquently. This section asks how the properties of learning and memory constrain animal foraging behavior. Of course, learning and memory influence virtually every aspect of foraging. To reduce the problem to manageable size we will focus on the problem of prey choice.

1.20.4.1 Acquisition: The Most Basic Constraint

Our migrating bird cannot adjust to new prey types instantaneously. Learning takes time. During acquisition a learning animal's behavior becomes increasingly appropriate for the new situation. It follows that behavior during acquisition is something less than completely appropriate. Thorndike's fundamental observation that learning proceeds incrementally therefore provides the most basic mechanism through which learning constrains foraging. The next few paragraphs review several ways in which acquisition constrains foraging.

1.20.4.1.1 Search image

The insects that form the basic diet for nesting birds vary in abundance throughout the nesting season. In the 1960s Luuk Tinbergen (Tinbergen, 1960) noticed that there was a considerable lag between the first appearance of prey type and its inclusion in the diet. Tinbergen compared prey choice to prey abundance, and he observed that foragers took fewer prey than expected when few prey were present, but they took more than expected when the prey type became abundant. In a now famous paper, Tinbergen argued that this transition reflected a sort of perceptual learning that we now call search image. This is an intuitive idea for many people: when searching for your lost keys, you barely notice the pencils and paper clips on your desk. The search image hypothesis asserts that foraging animals, like the human key-loser, use a perceptual template of the items they are searching for, and as a consequence their perception of objects that do not fit the search image is reduced. Establishing that this appealing idea applies to foraging animals proved to be an arduous process. One reason for this is that many nonperceptual phenomena could account for Tinbergen's observations. For example, if emerging prey items occur in a different habitat (say under rocks), it may be quite reasonable for birds to continue to glean insects from leaves until prey 'under rocks' are abundant enough to justify a change in foraging habitat.

However, careful experimental studies (e.g., Pietrewicz and Kamil, 1979; Bond and Kamil, 1999) have demonstrated that the search image phenomenon is real. Kamil and colleagues have shown that recognition of cryptic prey improves with experience (*See* Chapter 1.22). However, these effects only appear for cryptic prey; animals do not show the same improvements with experience when tested with noncryptic stimuli of the type commonly used in psychological studies (e.g., red circles vs. green triangles). From the perspective of a cryptic prey species, this 'learning to see' phenomenon means that abundance reduces the protective effect of crypticity. In the course of evolution this can produce polymorphisms (i.e., a prey species with two or more cryptic forms), because an abundant form loses its advantage, while less abundant forms gain an advantage. In an extremely creative set of studies, Bond and Kamil (2002) have demonstrated this effect by training captive blue jays to peck at virtual 'moths' on a computer screen. Bond and Kamil arranged a situation in which the population of virtual moths evolved (in the computer). Using this technique, Bond and Kamil showed that the jay's perceptual learning did, indeed, select for prey polymorphisms.

1.20.4.1.2 Learning to handle prey

Monk's hood (genus *Aconitum*) flowers have an unusual shape. The face of the flower is normal enough, with a patch of stamens in the center; above this is the 'hood' that gives the flowers their common name. The flowers hold their nectar in a pair of receptacles that are 'under the hood' and above the face of the flower. A bee extracting nectar must land on the center of the flower (where its body touches the stamens), crawl up into the hood, and finally extend its tongue upward into the nectar receptacles. Given the complexity of this extractive task, it is not surprising that bumblebees must learn how to exploit monk's hood flowers. Indeed, studies by Laverty (1994) show classical acquisition curves for bumblebees exploiting monk's hood. Experience increases handling accuracy and reduces handling time. While Laverty's work showed that learning plays a critical role in extracting nectar from a complex flower like monk's hood, he also found that experience reduced handling time for simple cup-shaped flowers.

Situations like this must be common. Experience must often improve foragers' abilities to handle prey, but this requires a little rethinking of our standard prey selection model. Handling time is a basic parameter in the standard model, but what happens

if handling changes with experience? Which handling time matters: the handling of a naive forager or the handling that an experienced forager can achieve? Students of foraging think that this learning tends to favor diet specialization, because this process tends to make familiar items profitable (low handling times) and unfamiliar items unprofitable (high handling times). Although foragers could improve their handling times by exploiting unfamiliar prey, the comparative advantage of exploiting familiar types provides a sort of dietary inertia that encourages specialization.

This dietary inertia appears to be important in the flower exploitation choices of honeybees and bumblebees. In a phenomenon called flower-constancy or majoring, individual bees often seem to stick with a single species of flower, even when better flowers become available (Heinrich, 1976) (*See* Chapter 1.29). Given the start-up costs associated with learning to exploit a new flower and relatively short life spans of foraging workers, it is probably better (from the hive's perspective) to have older workers continue their foraging specializations while younger bees adapt to changes in the local flora by forming their own specializations. Another level of specialization is at the species level. How does acquisition apply to a species which specializes on only one type of flower? Laverty and Plowright (1988) compared the learning of a specialist species of bumblebee with that of a generalist species. They found that the specialist bumblebees acquired handling skills specific to its specialized flower more quickly than generalist bumblebees did. Many of the generalist bumblebees give up before locating the nectar, as one might expect for a species having to optimize the ability to learn about a large variety of flower morphologies.

1.20.4.1.3 The generality of the 'acquisition constraint'

These two topics – search image learning and learning to handle prey – represent only two ways in which learning can constrain animal foraging. In both cases the time lags involved in learning mean that foragers must be slightly out of sync with the current economic situation. This scenario must play out in many other contexts. To give two examples, studies of aversion learning suggest that animals are well equipped to learn that certain feeding resources should be avoided, and studies of spatial behavior show that animals learn the locations of food resources. In all these 'learning' situations the basic acquisition constraint applies. The behavior of learning foragers will often be on its way to somewhere, rather than in 'optimal' alignment with the current situation.

1.20.5 Emerging Topics

Using the basic models (discussed in the section titled 'Foraging basics') as a starting point, students of foraging have developed several new topics that make connections with learning and memory. This section reviews two of these topics – predator avoidance and social foraging. Although existing approaches to predator avoidance do not make significant connections to learning and memory, we feel there is enormous potential for studies that combine studies of appetitive learning (e.g., learning about food) with fear conditioning and avoidance learning. These two phenomena must frequently be in conflict in natural situations. Social foraging makes important connections with learning and memory because many animals forage in groups (notably many common 'model' organisms such as rats, pigeons, and humans). There is, of course, a well-developed and fascinating literature of social learning. We argue, in this section, that a deeper understanding of learning in social contexts will result when studies of social learning are informed by an understanding of the economic costs and conflicts inherent in group foraging.

1.20.5.1 Foraging and Predator Avoidance

The basic models outlined in the section titled 'Foraging basics' consider the economics of foraging decisions isolated and abstracted from the world in which foragers live. For muddy-boots biologists the most glaring oversight of this approach is that most animals live with the constant threat of predation. To make matters worse, the options that are the best economically are often the most dangerous. The site that provides the most food typically attracts the most foragers, and since these foragers are food for predators, it also attracts the most predators. In other cases the best feeding strategies expose foragers to the risk of predation. For grazing aquatic invertebrates like snails or caddis fly larvae the safest place is typically under rocks or deep in the substrate, but the algae that these organisms feed on grows in the sunlight on the exposed tops of rocks – ideal hunting conditions for a visual predator.

Animals do, of course, respond to the presence of predators. The crude effects are obvious and easily demonstrated. Guppies forage nearly 24 h per day in

streams without predators, but they restrict their foraging to the daylight hours when predators are present (Fraser et al., 2004). Juvenile sunfish forage in the weeds along lake shores even though they could obtain food at a faster rate in the open water (Werner et al., 1983; Werner and Gilliam, 1984). Tadpoles restrict their movements when predators are in the vicinity (Anholt et al., 2000). Many birds, from ostriches to chickadees, increase their vigilance (looking up) in risky situations, and clearly time 'looking up' is time that must be subtracted from feeding. Many small mammals organize their activities around a central refuge, such as a burrow or nest. Obviously, these animals quickly deplete the resources near their refuge, and so they face a trade-off between poor feeding close to their safe haven and richer pickings at riskier distances. Finally, many animals can dramatically reduce the risk of predation by foraging in groups. Groups allow foragers to spread the risk of predation and share the costs of vigilance, even though they can increase competition for food and other resources.

A striking finding is that the indirect effects of predation (e.g., the changes in behavior caused by predation) can often be more important ecologically than the direct effects of predation (i.e., the direct reduction in population that occurs when predators kill prey). For example, in 1995 the US National Park Service reintroduced wolves into Yellowstone National Park, where they could prey on the abundant herds of elk. Of course, the wolves have killed many elk, but this does not seem to be nearly as important as how wolves have changed the elk's behavior. Since the reintroduction, park biologists have observed a dramatic change in the riparian (streamside) habitats of the park: willow and aspen have proliferated, and streams meander more and beavers are more abundant. Without wolves, elk grazed everywhere, preventing regeneration of willows and aspens that beavers depend on. Now, elk spend more time in groups, more time being vigilant, and they forage less efficiently. They avoid dangerous thickets where predators might lurk (Laundre et al., 2001). In the words of Brown and Kotler (2007): "Fear can be a powerful ecological force."

1.20.5.1.1 Modeling predator avoidance

We can express the qualitative logic of foraging/predation trade-offs in succinct caveman grammar: food good, death bad. But how do we combine the value of food and threat of death by predation into logically coherent common currency? The breakthrough comes when we realize that food and death both connect to fitness via the fundamental life history parameters of survival and reproduction. Imagine, for example, that we can divide an animal's life into a sequence of equal time intervals. For an animal outside of the breeding season, we can write the benefits derived from the current interval as the product SV, where S represents the probability of survival to the next interval, and V represents the expected future reproduction of an individual who survives to the next interval. Foraging and predation combine to influence both the probability of survival and the expected value of future reproduction. To survive to the next period, an animal must obtain a minimum amount of food and avoid being killed by a predator. In addition, the animal's nutritional status and overall well-being determine the expected value of future reproduction V. Models of predation–foraging trade-offs typically proceed by specifying the relationship between foraging behavior (feeding site choice, patch use, etc.) and these two basic life history variables (survival and future reproduction). An especially illuminating case occurs with animals, like fish, that have indeterminate growth. These animals grow continuously, so food intake today leads to a larger body tomorrow, which ultimately leads to more reproduction. For these animals, reasonable assumptions about the effects of foraging on survival and future reproduction lead to the so-called μ over g rule (Gilliam, 1982; Stephens and Krebs, 1986). This formulation predicts that animals foraging under predation risk should forage in a way that minimizes the ratio of mortality rate (μ) divided by growth rate (g). To be explicit, imagine a juvenile fish that can choose to feed in any of three habitats. We can, in theory, express how risky each habitat is in terms of the mortality rate experienced there, and we can express the benefits of foraging there in terms of growth rate. The μ-over-g rule tells us that our hypothetical fish should choose the habitat with the smallest mortality rate to growth rate quotient. Although modelers derived this simple result from fairly restrictive assumptions, it seems to be fairly robust, and it provides a useful and elegant way to think about the trade-off between predation and foraging.

1.20.5.1.2 Learning about predators

Obviously enough, animals cannot learn very effectively from the experience of being eaten by a predator. Yet experience clearly plays an important role in anti-predator behavior. Vervet monkeys, for example, learn that some individuals give unreliable alarm calls (Cheney and Seyfarth, 1988). European

blackbirds learn to fear 'harmless' objects, if they observe others reacting fearfully to them (Curio et al., 1978). In widely cited studies, Cook and Mineka (1990) showed that monkeys could easily learn to fear snakes by observing the fearful reactions of conspecifics, but did not learn to fear plastic flowers from similar experiences. Although most published examples deal with social learning (see the next section), animals must learn about the risk of predation from many other unconditioned stimuli (e.g., moving shadows, the odor of a freshly killed conspecific, and so on). The study of escape responses, startle responses, and fear has a long history in the literature of learning (*See* Chapter 4.11; Bolles, 1970; Cook and Mineka, 1991; Davis, 2006). The lesson that emerges from studies of foraging is that resource acquisition and predator avoidance represent a fundamental and evolutionarily ancient trade-off. We argue, therefore, that a research program that considers the balance between learning about food and learning to avoid danger may reveal important new connections.

1.20.5.2 Social Foraging

In the autumn and winter nearly everyone in the northern hemisphere can observe large aggregations of starlings wheeling in the sky and foraging across lawns and agricultural fields like a hungry army. This is not unusual, of course; many animals feed in groups, including troops of capuchin monkeys, fishing pelicans, and swarms of army ants. Yet behavioral ecology's basic models of foraging focus on isolated individuals foraging as 'economically independent entities' (Waite and Field, 2007). In recognition of this, the topic of social foraging has been a growth area over the last 15–20 years. How does foraging in groups change the dynamics of foraging behavior? Unfortunately, we can only give a complicated answer to this simple question. As we will explain, the presence of others can influence foraging in many ways. Conspecifics can reduce feeding opportunities via competition, but they may also confer benefits such as enhanced predator avoidance and increased rates of food discovery. Perhaps the most interesting complication, from the perspective of learning and memory, is the problem of information transfer within foraging groups. A key advantage of grouping is that animals can benefit from the predator detection abilities of their group mates, and many studies show that group foragers reduce their personal vigilance (compared to individuals foraging alone). On the other hand, sharing information with group mates is not always in an animal's best interest. Group mates who are too well informed might interfere with your food discoveries or block the best escape routes when a predator appears.

1.20.5.2.1 Group size

The key to understanding the economic complexities of social foraging is a game theoretical approach. Game theoretical analyses of adaptation differ from the simpler optimization approaches because they recognize that the advantages of a forager's actions will depend on how others act. We already saw this principle when we considered the ideal-free model of habitat choice: the value of a feeding site depends on the number of competitors present. Among the most basic questions one can ask about social foraging is what determines group size? We typically address this question by plotting the relationship between the intake rate each group member obtains and the group size. In the ideal-free distribution, the simple inverse r/n describes this relationship, and the feeding rate always decreases as the group size increases. In situations like this more group mates are always bad, and we call this a 'dispersion economy.' Given that many animals are solitary foragers, this situation must be quite common in nature. Indeed, students of social foraging think that increasing group size must eventually reduce foraging benefits, even for animals adapted to large aggregations. In many situations, we believe that foraging benefits increase with group size (at least initially), and we call this an 'aggregation' economy. **Figure 3** shows the typical situation for an aggregation economy.

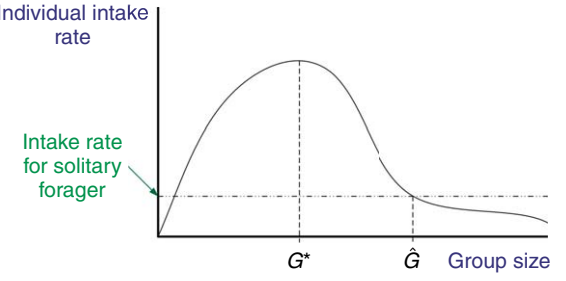

Figure 3 Graphical analysis of foraging group size. The plot shows the relationship between group size and individual intake rate for a so-called aggregation economy (see text). Initially, the per capita intake rate increases with increasing group size to a peak when the group size equals G^*. After that it declines with increasing group size. The dashed horizontal line shows the intake that a solitary forager can achieve. If the group grows beyond $\hat{G}$, then group members can benefit by leaving the group. We generally expect that stable groups should be between G^* and $\hat{G}$ in size.

Initially, individual foraging rates increase with group size, possibly due to the reduced cost of vigilance or the benefits of shared food discovery. During this increasing phase, adding a new member to the group is in the interests of current group members and prospective joiners. Indeed, existing members may even try to recruit new members during this 'increasing benefit' stage. Eventually, however, the foraging benefits will peak, and the mundane negative effects of feeding more mouths will decrease foraging benefits. One might expect groups to converge on the group size that maximizes feeding benefits (G^* in **Figure 3**), but this logic only holds up if existing members can control group entry. If, instead, individuals can join the group freely, then the group size can continue to increase because solitary foragers can still benefit by joining the group. In the language of game theory, one says that the benefit-maximizing group size is unstable. In general we expect to see groups larger than the benefit-maximizing group size (G^*) but smaller than the group size where individuals could do better by foraging on their own ($\hat{G}$ in **Figure 3**). In theory, the degree of control that group members can exert over group entry will determine stable group size: more control will push the predicted value toward the benefit-maximizing group size (G^*), and less will shift things toward larger group sizes near the theoretical maximum $\hat{G}$.

1.20.5.2.2 Producers and scroungers

While animals often benefit from foraging in groups, this does not preclude conflict between group members. The phenomenon of scrounging or kleptoparasitism provides a simple and important example. When one member of a group discovers food, others often parasitize this discovery. One can easily observe this among pigeons feeding in a city park. The mad rush of pigeons toward a successful forager often seems quite comical. From the food discoverer's (or producer's) point of view, scroungers represent a cost of group foraging, but from the scroungers' perspective this 'information sharing' is a distinct advantage. Behavioral ecologists, led primarily by Giraldeau and his colleagues (see Giraldeau and Livoreil, 1998, for review), have investigated this phenomenon in some detail both theoretically and experimentally. To begin, we imagine that group-feeding animals can choose between the producer and scrounger strategies. A producer always finds its own food, and a scrounger feeds by joining producers. So while a producer forages by looking for food, we imagine that a scrounger forages by looking for successful producers. (The reader may object that it is unreasonable to think of producer and scrounger as hard and fast categories, because individuals can easily switch between producer and scrounger tactics, and of course, that is correct, but it turns out that this premise still leads to a useful and empirically successful model.) Now, obviously, a group with only scroungers is a nonstarter, because no one would find anything to eat. The presence of producers makes scrounging a viable strategy, but what mix of producers and scroungers would we expect? Again, this requires a game theoretical approach. The stable mix depends, it turns out, on how much food a producer can obtain – a quantity that we typically call the producer's advantage. If a producer must share everything it finds equally with its group mates, then we predict a minimal number of producers. At the other extreme, if producers can completely monopolize their discoveries, then we expect all group members to act as producers and no scroungers.

In what is perhaps the most elegant study of this problem, Mottley and Giraldeau (2000) created an experimental situation that allowed only certain group members to act as producers and forced others to act as scroungers. By doing this, they established that the benefits derived from scrounging decreased as the number of scroungers increased. After establishing that the basic features of the model applied, they modified the situation to allow animals to switch between producer and scrounger. This study found, as predicted, a higher frequency of producers when producers got a larger share of discovered food and a lower frequency of producers when the experiment forced producers to share most of the discovered food with scroungers.

1.20.5.2.3 Social information use

Foraging animals, like human shoppers, seldom have complete information about their options. So they must often use experience to respond appropriately to changes in prey quality or the properties of a food patch. Often animals will use direct ('personal') experience with food resources to adjust their behavior, but group-foraging animals have another option. The behavior of group mates often provides information about resources. The producer-scrounger situation, we discussed above, provides a simple example; scroungers exploit information about food patches obtained by producers. There are, however, many other examples. Rats may change their foraging

preferences when they smell a new food type on a group mate's breath (Galef and Stein, 1985; Galef and Giraldeau, 2001). Honeybees indicate the distance and direction of food resources by performing their famous waggle dance (*See* Chapter 1.25; von Frisch, 1950). Honeybees may often return to the hive with only partially filled crops, and an interesting explanation for this is that bees foraging in suboptimal patches may be returning early to hive to gain information about better patches from other bees (Varjú and Núñez, 1991, 1993). In parallel with the distinction between personal and social sources of information, behavioral ecologists distinguish between private and public information. Every member of a social group can act on public information, but only the possessor of private information can act on private information, and of course, a key question for the private information possessor is whether to act in way that makes its 'knowledge' public (see, for example, Valone, 1989; Templeton and Giraldeau, 1995).

Social influences on foraging behavior range from the simple (e.g., local enhancement) to the comparatively elaborate (e.g., true imitation, see Galef, 1988). While we leave a complete review of social learning and related phenomena to others (Galef and Giraldeau, 2001) (*See* Chapter 1.16 for a discussion of social learning in primates), we note here that many examples of social learning involve foraging behavior: British titmice opening milk bottles (Sherry and Galef, 1990), quail pecking or stepping on a treadle to obtain food (Zentall, 2004). A full development of the connections between the behavioral ecology of foraging and social learning remains, in our view, an unexploited opportunity. The following paragraphs give two examples, both from work with foraging starlings, that suggest how one might combine social learning and foraging studies.

Templeton and Giraldeau (1996) studied the effects of a partner on patch exploitation. They created experimental patches with discrete holes in which they placed food. Patches varied in that some patches were completely empty (no holes had food), while in others some holes (1 in 10) contained food. This arrangement sets up a classic patch sampling problem that behavioral ecologists have often used to study the behavior of solitary foragers (e.g., Lima, 1983). In this situation the forager must somehow decide how many empty holes to tolerate before leaving to find a new patch. Templeton and Giraldeau's findings suggested that foragers used the explorations of the others to make patch departure decisions. They found that animals foraging in pairs typically probed fewer holes before leaving than animals foraging alone, and that they probed more holes when their companion probed few. Perhaps the most intriguing finding of this study, however, was that the complexity of the sampling task seems to influence the degree to which starlings use social information. Templeton and Giraldeau found that partners influenced patch sampling as described here when they presented patches that were rectangular arrays of 'food holes.' However, partners had no effect on patch departure when patches were simple linear arrays of holes. This suggests that the importance of social learning may depend on the costs and reliability of individual experience.

Krebs and Inman (1992) studied how the presence of a partner changed the basic problem of tracking a varying resource. As explained in more detail above, subjects in tracking studies must choose between two feeding sites. One site is always the same but mediocre, while the other changes from good (better than the mediocre site) to bad (worse than the mediocre site) unpredictably. Here the question is how frequently should one check (or sample) the varying resource? When two animals do this together, however, only one needs to sample. And Krebs and Inman found that, in pairs of starlings, one typically sampled and the other simply followed the behavior of the sampler. This is an extremely intriguing result in several ways. First, if only some members of a group act as 'information gatherers,' this would seem to diminish the information sharing advantage of group foraging. Second, if some individuals in a group simply play follow the leader, then we would expect that followers obtain lower quality information than leaders. Finally, one has to wonder how the asymmetry between followers and leader develops. How, for example, would a prospective follower choose between two tutors performing conflicting actions?

1.20.5.2.4 Intelligence, foraging, and sociality

We end our discussion of 'emerging topics' with a brief mention of possible connections between foraging and general cognitive abilities (i.e., intelligence). We use the word 'intelligence' here fairly uncritically, acknowledging that a rigorous definition eludes us but that most readers will understand our general meaning. Many students of comparative cognition ascribe to the social intelligence hypothesis, which holds that interactions within social groups have favored increased intelligence. The focus of this hypothesis has typically been on the role of

intelligence in disputes about rank and the formation of alliances (Harcourt, 1988; Dunbar, 1998; Reader and Laland, 2002). An alternative hypothesis focuses on the role of foraging and resource extraction (King, 1986). The growing sophistication of social foraging theory suggests that these may be false alternatives. Social behavior does not exist in a vacuum; social interactions are typically about resources. It does not seem far-fetched to speculate that interactions among social foragers have played a role in the evolution of advanced cognitive abilities.

1.20.6 Summary and Conclusions

Behavioral ecologists have developed a large family of foraging models that focus on costs and benefits. These models consider diet selection, patch exploitation, and habitat use. There are many important connections between foraging and learning. Experimental studies of foraging decisions typically depend on animal learning abilities, and many studies of learning focus on situations in which subjects learn about food resources. Students of foraging behavior have considered the adaptive value of learning and memory by constructing models in which hypothetical animals can use or ignore their experience. A surprising result is that it often pays to act without experience. For example, if the environment changes frequently a fixed choice strategy will often serve a forager best. Animals, of course, face many problems other than foraging. They must, for example, avoid being eaten. Unfortunately, the best places to feed are frequently also the most dangerous, so foragers must somehow balance the need to obtain food with the risk of predation. Learning clearly plays a role in predator avoidance. While behavioral ecologists have studied the trade-off between foraging and predator avoidance extensively, we know relatively little about possible interactions between avoidance learning and learning about food. Many animals forage in groups, and this introduces several complications. Group foragers can use the behavior of their group mates to find food or avoid predators, but the availability of the public information can create conflicts of interest within the group.

A complete understanding of learning and memory needs to go beyond an understanding of mechanism and develop an understanding of how these mechanisms serve animals in nature. Foraging is a defining property of animals, and as such it represents an important natural context for learning and memory. At the same time, students of foraging can benefit from an understanding of the basic principles of learning and how these apply in natural situations.

1.21 Navigation and Episodic-Like Memory in Mammals

N. Fortin, Boston University, Boston, MA, USA

1.21.1 Navigation

The word navigation is derived from the Latin 'navis' (ship) and 'agere' (to drive), and in the classic sense, refers to the science of directing a craft by determining its position, course, and distance traveled (*Encyclopedia Britannica*). In ethological terms, navigation refers to self-controlled movement in space toward an unseen goal (Alyan and Jander, 1994; Alyan and McNaughton, 1999). Although habitats vary substantially between species, the navigational demands are fundamentally similar across mammals (Mackintosh, 2002). All mammals must learn and remember locations of importance and compute trajectories that minimize risk given their size, mode of transportation, the characteristics of their environment, and their specific needs. Although such navigational behavior unfolds seamlessly, it reflects the use of multiple strategies based on different types of representation of the environment (O'Keefe and Nadel, 1978; Mackintosh, 2002; *See* Chapters 1.12, 1.20, 1.22, 1.23, 1.25, 1.26). Under some circumstances, a navigational strategy based on a detailed and flexible representation may be ideal (e.g., to find a different way to get to work when one's habitual route is blocked), whereas simpler strategies and representations may be preferable in others (e.g., to tell a tourist how to get to the zoo).

1.21.1.1 Types of Mental Representations That Can Support Navigation

1.21.1.1.1 Egocentric versus allocentric

Egocentric representations encode relations between landmarks in the environment and the organism (e.g., shelter is 30 m to my left, food source is 40 m straight ahead). In contrast, allocentric representations depict exclusively the relations among landmarks in the environment, without consideration of their relation to the organism (e.g., food source is 50 m northeast of shelter). Allocentric representations are more flexible, since a single representation can be used to calculate trajectories between any landmarks, regardless of changes in the position or orientation of the animal.

1.21.1.1.2 Route versus map

A typical example of a route representation is a set of verbal turn-by-turn directions. More formally, according to O'Keefe and Nadel (1978), a route representation consists of information for a trajectory between a start and goal location that is based on the identification of specific landmarks in the environment (e.g., a particular store on one corner) and the performance of the appropriate behavioral response in relation to each landmark (e.g., turn right; O'Keefe and Nadel, 1978). Because routes simply direct attention to particular objects and specify turns within egocentric space, they can be learned rapidly and require very little skill. However, the information provided in a route representation is very inflexible; the information must be used in the proper sequence and allows no freedom of choice. Their accuracy also depends on the stability of the landmarks (e.g., particular store not going out of business) and on the ability to adequately perceive the landmarks (e.g., darkness can complicate their use). Finally, calculating a return trajectory using a route representation is often challenging and prone to errors, an all-too-familiar experience for some.

In contrast, a mental map has the same properties as a real-world road map; namely, it is an allocentric representation of places in terms of distances and directions among items in the environment (O'Keefe and Nadel, 1978). Mental maps are built out of the integration of multiple trajectories within a specific environment, and consequently, require considerable experience with the environment in order to form. Nonetheless, their flexibility is a distinctive advantage, in that they support the calculation of detours, shortcuts, and novel trajectories. Finally, contrary to routes, maps are not disrupted by alteration or disappearance of individual cues, and provide unambiguous directions on the return trajectory (O'Keefe and Nadel, 1978).

1.21.1.2 Strategies for Navigation

Perhaps the most impressive spatial behavior is the seasonal long-distance migration observed in a number of species of birds (e.g., Berthold, 1996; *See* Chapter 1.22) and some mammals (e.g., Berger, 2004). Migrating animals use cues, such as the position of the sun and stars at specific times of the day or gradients in the Earth's magnetic field, to orient themselves and maintain that orientation over hundreds or thousands of kilometers to their destination (Sherry, 1998). Although many nonmigrating mammals, including rodents and primates, have been shown to be sensitive to those same celestial and geomagnetic cues (Baker, 1980; Mather and Baker, 1980; Levine and Bluni, 1994), mammals are not believed to rely on those strategies for their usual navigational needs, and the use of such global-reference cues will not be further discussed here (for a review see Sherry, 1998). Instead, mammals have been shown to rely on three main strategies for navigation: piloting, path integration, and the use of guidances and orientations.

1.21.1.2.1 Piloting

Piloting refers to the use of allothetic (external or distal) cues for navigation (Gallistel, 1990; Whishaw and Wallace, 2003; *See* Chapter 1.12). More specifically, it involves computing relations among cues, usually visual landmarks, to determine one's current position in the environment and plan a trajectory. Although under some circumstances mammals could use a single landmark to calculate their position, experimental manipulations have shown that they instinctively use all available landmarks as a unit (O'Keefe and Nadel, 1978; Suzuki et al., 1980). For instance, spatial performance is not impaired by removing a few of all the available distal landmarks, but it is compromised when one interferes with the relations among landmarks by randomizing their arrangement (Suzuki et al., 1980). Piloting is generally associated with, but is not limited to, navigation based on a mental map of the environment.

1.21.1.2.2 Path integration

Path integration, also known as 'dead reckoning' (from deduced reckoning, or reasoning), is a navigation strategy used by sailors hundreds of years ago to

estimate their ship's position using information about speed of movement, travel time, and directional change whenever visible landmarks were unavailable (Whishaw and Wallace, 2003). From an ethological perspective, Darwin (1873) was the first to propose such a mechanism as a navigational strategy in animals. Path integration is currently defined as the capacity to use idiothetic cues, or cues generated by the animal's movements, to calculate the updated position of the animal by monitoring its trajectory in relation to a start location (Gallistel, 1990; Whishaw and Wallace, 2003). Idiothetic cues include information about self-movement from proprioceptive and vestibular systems (Wallace et al., 2002), sensory flow (e.g., optic flow, odor, or sound gradients; Wylie et al., 1999), and perhaps efferent copies of movement commands (Whishaw and Wallace, 2003). Importantly, the use of such egocentric cues does not imply a lack of flexibility in navigation, as animals using path integration can adjust their trajectory according to unexpected obstacles or changed task demands (Whishaw and Wallace, 2003; McNaughton et al., 2006). Finally, path integration is both automatic and constant, and since it does not require the use of visible landmarks, it can support navigation in case piloting fails due to the unavailability of distal cues (Etienne and Jeffery, 2004).

1.21.1.2.3 Guidances and orientations

As first described by O'Keefe and Nadel (1978), guidances refer to landmarks to be approached or followed, while orientations consist of particular movements in egocentric space to be made in the presence of particular guidances. The defining characteristic of this strategy is that, even though it can be used to solve spatial problems, it is not a spatial strategy per se (O'Keefe and Nadel, 1978; Mackintosh, 2002). A specific example of this strategy would be navigation based on approach or avoidance of specific visible landmarks or other cues such as an odor gradient (e.g., a predator following the odor trace of a prey), or navigation based on route representations consisting of a list of stimulus–response (or guidance-orientation) associations inflexibly leading from one point to another.

It is important to note that these strategies are not necessarily used in a mutually exclusive manner; on the contrary, mammals presumably use all of them simultaneously (Etienne et al., 1998; Eichenbaum and Cohen, 2001). For instance, mammals have been shown to predominantly rely on piloting to distal cues to navigate, but if such cues unexpectedly become unreliable or unavailable, animals will readily switch to path integration and demonstrate precise navigation despite the impoverished stimulus conditions (Whishaw and Wallace, 2003). Furthermore, there are distinct advantages to the concurrent use of multiple strategies. The main limitation of piloting is that distal cues are not always available, whereas path integration has been shown to be progressively degraded by the accumulation of error (Etienne and Jeffery, 2004); optimal navigation may therefore be achieved by relying on 'episodic fixes' (Gallistel, 1990), by which the position calculated via path integration is periodically updated by the position calculated from the distal landmarks through piloting.

1.21.1.3 Neural Basis of Navigation

In recent years, navigation research has focused primarily on elucidating its neural substrate, such that there are now few purely behavioral studies. Consequently, further development in our understanding of the navigational capabilities of mammals is intimately associated with the progress of our knowledge of the contribution of different neural systems. Although crucial to all mammalian species, navigational capacities have been most extensively investigated in rodents, presumably because their small size facilitates the manipulation of their spatial environment in a laboratory setting. Naturally, this focus on rodents raises the concern that our extensive understanding of navigational behavior may not extend to other mammals. However, comparative studies have shown that, despite significant differences in niche or specific adaptations, different mammalian species are remarkably similar in terms of neuroanatomy (Sherry and Healy, 1998) and in the way they solve spatial problems (Save et al., 1998), thereby lending support to the validity of cross-species comparisons (*See* Chapters 1.22, 1.25, 1.26).

After millions of years of evolution, it seems unlikely that the brain regions responsible for navigation are a 'tabula rasa'; instead, spatial behaviors and neural systems themselves are more likely to have been preorganized by evolutionary history (Whishaw and Wallace, 2003). The result of such evolution is a set of distinct navigational strategies, which, because each entails unique types of computation, requires the use of distinct neural systems (Sherry and Schacter, 1987). This section will discuss the role of a number of neural systems in supporting navigational behavior.

1.21.1.3.1 The hippocampus as a cognitive map

The hippocampus of food-storing birds and mammals has been shown to be up to twice as large as the hippocampus of species that do not rely on retrieving food they previously cached (Krebs et al., 1989; Sherry et al., 1989; *See* Chapters 1.22, 1.23). Similarly, anatomical scans have shown that humans with advanced navigational capabilities, such as London taxi drivers, may have bigger hippocampi as well (Maguire et al., 2000). Given the biological costs associated with maintaining a larger hippocampus, these findings indicate that this neural structure must play crucial role in navigation ability.

Elucidating the specific role of the hippocampus in spatial memory has been the main focus of navigation research for almost 30 years. The main inspiration for this line of research is a highly influential book by O'Keefe and Nadel (1978) entitled *The Hippocampus as a Cognitive Map*. In this book, O'Keefe and Nadel provided an extensive review of the anatomical, electrophysiological, and neuropsychological literature pertaining to the hippocampus. Based on the evidence they reviewed, they proposed the theory that the hippocampus specifically mediates the construction and use of a cognitive map, an allocentric topographical map of the physical environment that animals use to navigate among salient locations and other important cues in a flexible manner. In the framework of the present chapter, the cognitive map of the hippocampus is best characterized as supporting the navigational strategy of piloting to landmarks (*See* Chapter 1.33).

1.21.1.3.1.(i) Anatomy of the hippocampal memory system The hippocampus is a structure located deep in the brain, with its name derived from its curved shape in a coronal section, which resembles a seahorse. It is generally defined as consisting of the CA fields (cornu ammonis; CA1-CA3) and the dentate gyrus. The hippocampus receives highly processed sensory information, and as such should be described in the context of a larger system of cortical areas (Amaral and Witter, 1989; **Figure 1(a)**). This connectivity pattern between the hippocampus and cortical areas (**Figure 1(a)**), as well as the local hippocampal architecture circuitry (**Figure 1(b)**), has been shown to be remarkably conserved across mammalian species (Manns and Eichenbaum, 2006).

Individual perceptual and mnemonic representations from virtually all higher-order cortical processing areas are funneled into the parahippocampal region, which consists of the entorhinal, perirhinal, and parahippocampal (postrhinal in rodents) cortices, and in turn, information is then funneled into the hippocampus. This strong convergence of diverse inputs to the hippocampus, combined with the rapid and stable synaptic plasticity characterizing hippocampal circuits (e.g., Bliss and Collingridge, 1993), allows the hippocampus to rapidly form stable associations among previously unrelated elements from disparate cortical areas. A critical feature of the system is that the connections are reciprocated in a topographic manner, such that a representation at every level could reactivate elements of the higher level representation that originally activated it (Amaral and Witter, 1989;

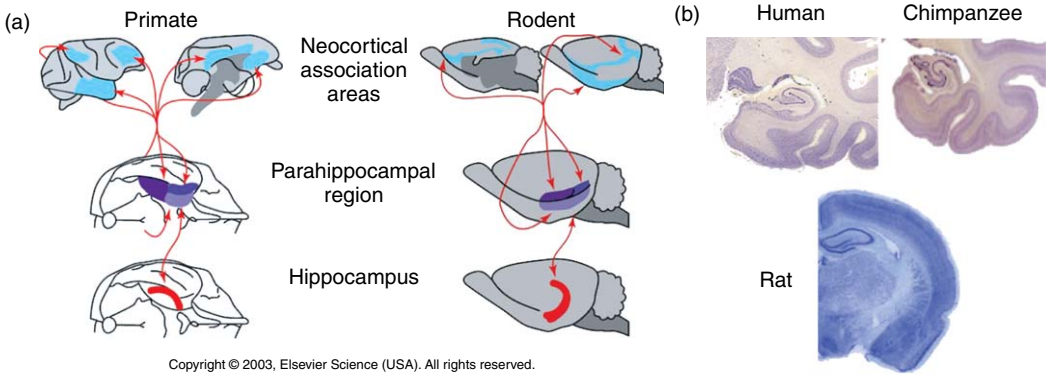

Figure 1 Similarity in the anatomy of the hippocampal system in primates and rodents. (a) Reciprocal connections between the neocortex, the parahippocampal region, and the hippocampus. Lavenex and Amaral, 2000). This organization may be important for consolidating associations formed in the hippocampus back into cortical areas (Buzsaki, 1996). These distinctive features of the anatomy of the hippocampal system suggest that it would be well suited to act as a cognitive map (O'Keefe and Nadel, 1978).

1.21.1.3.1.(ii) Experimental analysis of navigation A number of field studies have shown natural behavior indicative of navigation based on a cognitive map (see O'Keefe and Nadel, 1978). For instance, analysis of the spatial behavior of wolf packs in the wild indicates a flexible maplike representation of the environment. Wolves have been reported to return to their pups from any direction, to take necessary shortcuts or detours, and to be able to divide and regroup as a pack over large distances (presumably beyond the range of howling; Peters, 1973). Menzel (1973) has reported similar abilities in chimpanzees. When chimps were carried around an environment and allowed to observe an experimenter hiding food rewards, they subsequently ran directly between food locations and rarely returned to locations where food had already been obtained. Such efficient navigation, not shown in chimps that did not observe the experimenter hiding the food, demonstrates a clear mental representation of the food locations.

Though valuable insight has been obtained from field studies, the vast majority of studies characterizing the navigational capacities of mammals were performed in controlled experimental settings. The laboratory setting confers an advantage because it allows more control over the cues animals may use to navigate and facilitates measurements of navigation capacity. Importantly, the artificial nature of the laboratory experiment does not seem to be a significant concern, as evidenced by studies showing that spatial behavior does not differ between field and laboratory contexts (e.g., Jacobs and Shiflett, 1999). This section will review the behavioral paradigms that provided evidence suggesting that animals use a cognitive map for navigation. Consideration of all paradigms is beyond the scope of this chapter; consequently, only the most widely used will be discussed. Readers are referred to O'Keefe and Nadel (1978) and Eichenbaum and Cohen (2001) for extensive reviews.

1.21.1.3.1.(ii).(a) Evidence from rodent studies

- *Complex maze learning.* Inspired by the famous maze at Hampton Court Palace in England, Small (1901) introduced the use of complex mazes to study animal intelligence (see **Figure 2**). The method was quite simple. After being placed at the start of the maze, the rat had to learn through trial and error the trajectory that led to the goal, learning being indicated by a gradual decrease in the number of entries in blind (incorrect) alleys across trials.

  Though extensively used to study animal learning, the nature of the task emphasized the learning of series of egocentric left and right turns and as such is not optimally designed to measure navigational capacities. However, careful analysis of the behavior of animals suggested that rats 'navigated' through the maze by relying to some extent on visual landmarks in the room to locate the general direction of the reward. In fact, manipulations such as rotating the maze seemed to disrupt performance (Watson, 1907), and rats were more likely to enter blind alleys

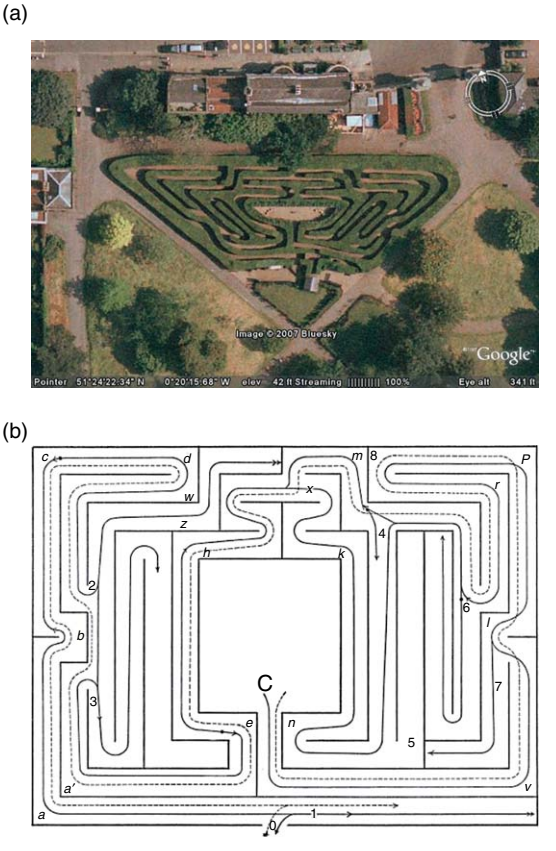

Figure 2 Complex maze learning. (a) Hampton Court Palace maze outside London, which served as inspiration; used with permission from Google Earth mapping service. that pointed toward the goal than those pointing away from the goal (Tolman, 1932). Furthermore, damage to the hippocampus leads to deficits in complex maze learning in a number of studies (see table A20 in O'Keefe and Nadel, 1978), suggesting that the ability of rats to use distal cues to establish their position in relation to the goal location is an important source of information that complements the learning of left- and right-turn associations.

- *Detours and shortcuts: Cognitive maps in rats and humans.* Instead of accepting the commonly held notion from behaviorism that animal learning is based on an assortment of stimulus–response associations which are subsequently triggered by environment stimuli, Tolman demonstrated that rats can learn the spatial layout of a maze as stimulus–stimulus associations and express their knowledge in a flexible manner. In fact, Tolman and Honzik (1930) showed that rats familiar with an environment spontaneously take the shortest detour when their habitual route is blocked (**Figure 3(a)**), and subsequently, Tolman and colleagues (Tolman et al., 1946) used the 'sun-burst' maze to show that rats can select the optimal shortcut when the longer habitual route is suddenly unavailable (**Figure 3(b)**).

  Based on these findings, Tolman (1948) was the first to propose that rats (and humans) use cognitive maps of their environment to get from one place to another. The impact of Tolman's work diminished in the 1950s and 1960s but increased in the late 1970s, as his description of cognitive maps inspired the influential work of O'Keefe and Nadel (1978).
- *Radial-arm maze.* Inspired by the natural behavior of rats, Olton and colleagues (Olton and Samuelson, 1976; Olton et al., 1977) designed the radial-arm maze, a formal testing paradigm to study the ability of rats to collect food efficiently from several locations. The maze is composed of a central platform, out of which runway arms extend radially (typically eight arms). In the original version, a food reward is initially placed at the end of each arm, and optimal foraging performance would consist of running down the end of each arm only once. Since arms are not rebaited, revisiting an arm is considered an error (**Figure 4(a)**).

  Experimental manipulations have shown that distal (extra-maze) cues control behavior (Olton

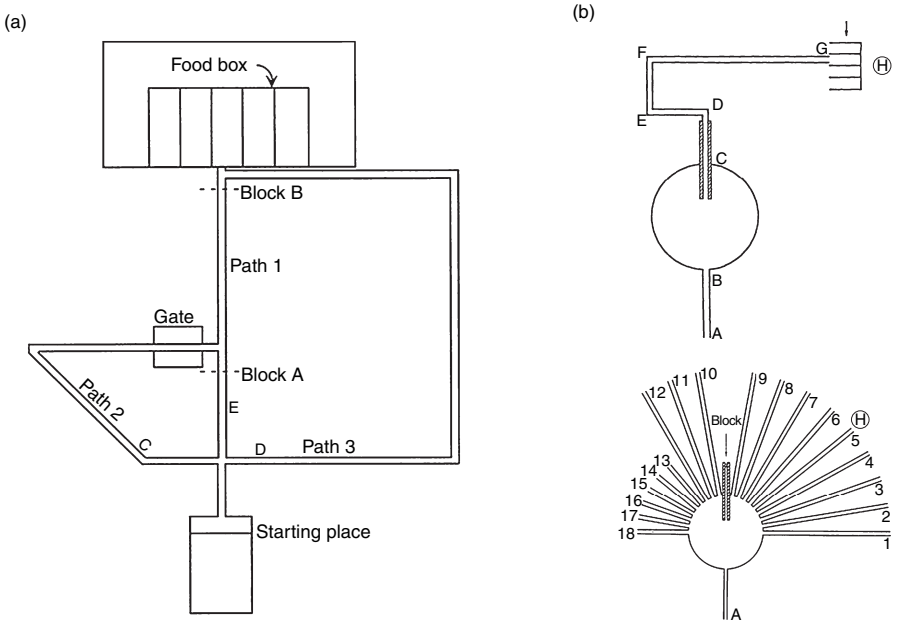

Figure 3 Detours and shortcuts as evidence for a cognitive map. (a) Diagram of the maze used to test the ability of rats to infer a required detour. Figure 4 Radial-arm maze task. (a) The maze consists of eight arms radially extending from a central platform. Before each session, all arms were baited with a food reward, and optimal foraging performance would consist of running down the end of each arm only once. (Olton and Samuelson, 1976). (b) Animals with hippocampal damage were severely impaired in learning the task compared to control groups. Adapted from McDonald RJ and White NM (1993) A triple dissociation of memory systems: Hippocampus, amygdala, and dorsal striatum. *Behav. Neurosci.* 107(1): 3–22, with permission from the American Psychological Association. The use of APA information does not imply endorsement by the APA.

and Samuelson, 1976; Suzuki et al., 1980). Indeed, eliminating local odor cues by washing the maze does not affect performance, and animals are not affected by rotations of the maze on its central axis (i.e., they continue to use the distal cues in the room to orient themselves). Disruptions of the hippocampus severely impair performance on this task, suggesting that the hippocampus plays an important role in the processing of information about spatial location supporting navigation (Olton et al., 1978; Olton and Werz, 1978; **Figure 4(b)**). Although it was shown that the deficits of hippocampal animals in the task may not be indicative of a spatial memory deficit per se (Olton and Feustle, 1981, discussed later), this paradigm has been used extensively and represents an important step in our understanding of the neural basis of navigation.

- *Morris water maze.* The water maze task, developed by Morris (1981), is the quintessential navigational paradigm in behavioral research. It measures the ability of rats to remember the location of an escape platform in a large swimming pool (usually >2 m in diameter). Rats are capable swimmers but, as one would expect, prefer not to swim and instead search for solid ground. To ensure that animals rely on extra-maze cues to find the platform location, the water is made opaque by adding powdered milk, and the escape platform is placed arbitrarily in the pool just below the surface. Unlike spatial paradigms that rely on a limited number of choices (left or right turns, or arms in the radial-arm maze), the water maze tests spatial acuity and requires constant monitoring on the part of the animal (Morris, 1981). Furthermore, rats must use a flexible spatial representation to solve the task, since they are placed in different starting locations at the periphery of the pool on each trial, to avoid the establishment of a rigid swim route, and are also very efficient from novel starting points even if they were trained from a consistent starting point (Morris, 1981; **Figure 5(a)**).

Morris and colleagues (1982) have shown that damage to the hippocampus results in severe impairments in the water maze task (**Figure 5(b)**), providing strong support for the theory that the hippocampus implements a cognitive map of the environment. On the initial trial, control animals could take up to 1 or 2 min to find the platform, but on subsequent trials this latency was reduced considerably to approximately 10–15 s from all starting positions (**Figure 5(c)**). Rats with hippocampal damage also showed some improvement in finding the platform, but their performance reached an asymptote (~35 s), and unlike control animals, they never swam directly to the platform. The trajectories of the rats were also monitored during 'transfer tests,' during which the escape platform was removed (**Figure 5(d)**). Whereas normal rats swam around where the platform should have been (indicating strong memory), hippocampal rats showed no preference for the quadrant where the platform should have been located. Finally, in a control condition in

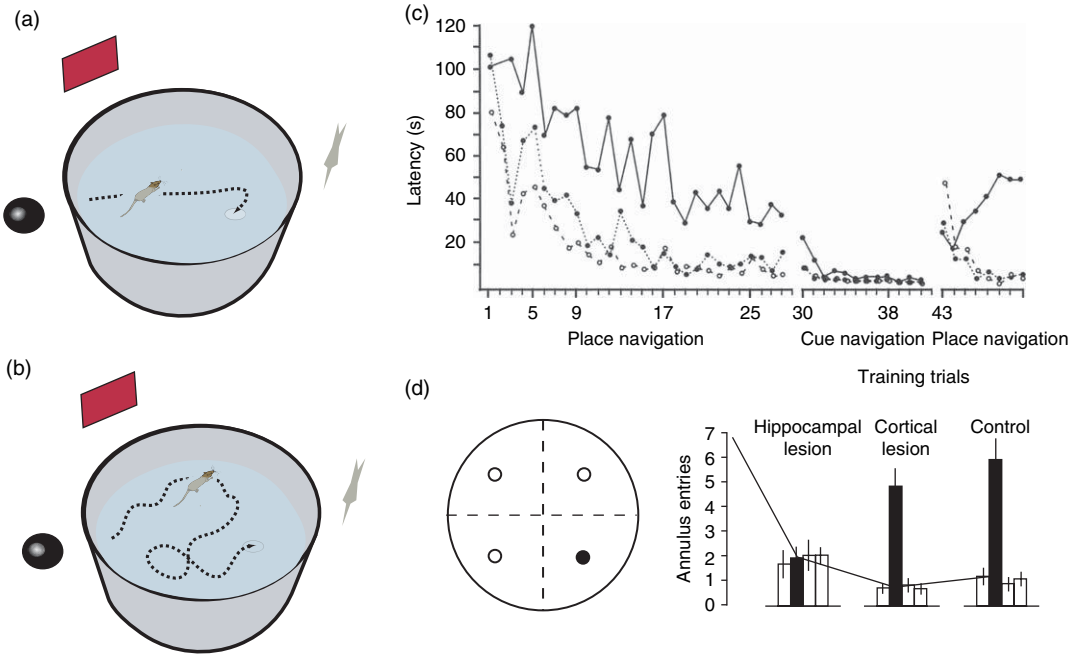

Figure 5 Morris water maze task (Morris, 1981). (a) Example swim path of a control rat. (b) Example swim path of a rat with damage to the hippocampus. (c) Performance of rats with hippocampal lesions (filled circles and lines), cortical lesions (filled circle and dashed lines), and normal controls (open circle) in acquiring the water maze task. Place navigation refers to the condition in which the platform is hidden under the surface; cue navigation refers to a control condition in which the platform is visible to the animals. (d) Performance on transfer test in which the platform was removed. Hippocampal animals were no more likely to pass over the trained location of the platform (filled circle and bar) than the corresponding location in other quadrants (open circles and bars) (c, d) Adapted from Morris RG, Garrud P, Rawlins JN, and O'Keefe J (1982) Place navigation impaired in rats with hippocampal lesions. *Nature* 297(5868): 681–683, with permission from Macmillan Publishers Ltd.

which the escape platform is visible to the rats (cue navigation; **Figure 5(c)**), both groups rapidly learned to swim directly to it, suggesting that hippocampal rats do not suffer from visual or motivational deficits.

The main assets of the water maze task are the speed of training and the robustness of the impairments shown in animals with damage to the hippocampus. For these reasons, the water maze task has become a benchmark test of hippocampal function in rodents (Eichenbaum and Cohen, 2001).

1.21.1.3.1.(ii).(b) Evidence from primate studies

A number of experimental studies in humans and monkeys have also implicated the hippocampus in learning spatial information essential for navigation. Neuropsychological studies have shown that the integrity of the hippocampus is essential for spatial memory, as demonstrated by the deficits of amnesic patients (Smith and Milner, 1981, 1989; Maguire et al., 1996) or monkeys with dysfunctional hippocampi (Murray et al., 1989; Lavenex et al., 2006) in different spatial tests. Functional neuroimaging studies have also identified the hippocampus as part of network of structures important for navigation in large-scale environments. For instance, Maguire and colleagues (1997) scanned London taxi drivers with years of experience while they recalled complex routes around the city. Compared with baseline and other nontopographical memory tasks, such route recall resulted in activation of a network of brain regions, including the right hippocampus. Furthermore, in a different study, Maguire and colleagues (1998) developed a test in which normal human subjects explored an imaginary town using virtual reality technology, and reported that activation of the right hippocampus was strongly associated with remembering where specific places were located and navigating accurately between them.

1.21.1.3.1.(iii) Electrophysiological evidence supporting the cognitive map theory

The concept of a cognitive map has been refined over the years (McNaughton et al., 1996; Muller et al., 1996; O'Keefe and Burgess, 1996) but remains fundamentally similar

to O'Keefe and Nadel's (1978) original description. Conceptually, the cognitive map is a two-dimensional Cartesian reconstruction of the environment, in that it provides metric representations of distances and angles between the relevant stimuli (*See* Chapters 1.33, 1.35).

The discovery of place cells in the hippocampus was a crucial piece of evidence supporting the cognitive map theory of the hippocampus. *Place cells* are hippocampal neurons, typically from regions CA1 and CA3, that fire at a high rate whenever the animal is in a specific location in the environment, called the place field (**Figure 6(a)**). Their existence was first described by O'Keefe and Dostrovsky (1971) in rats, but was later confirmed in numerous more systematic studies (e.g., O'Keefe, 1976; Olton et al., 1978; O'Keefe and Conway, 1980; Hill and Best, 1981; Best and Ranck, 1982) and in other mammalian species (humans: Ekstrom et al., 2003; monkeys: Ludvig et al., 2004; mice: Rotenberg et al., 1996). A number of properties of place cells are suggestive of a cognitive map representation of a specific environment. First, their firing pattern is determined by the global spatial relations among landmarks, not simply associated with a particular cue in the environment. For instance, place cell firing is maintained even if individual distal cues are removed, or if all distal cues are rotated as a unit (the place field rotates with the cues; O'Keefe and Conway, 1978; Miller and Best, 1980; Hill and Best, 1981). Second, many place cells reflect the overall topography of the environment, as they were shown to scale their size to reflect changes in the size of the environment (Muller and Kubie, 1987; O'Keefe and Burgess, 1996). Third, once established, the spatial representation of a specific environment coded by place cell is stable over long periods of time (at least 5 months; Thompson and Best, 1990).

At the conceptual level, a place cell is thought to construct the notion of a place in the environment by encoding the multisensory input pattern that can be perceived when the animal is in a specific part of the environment (O'Keefe, 1979). Each place cell is hypothesized to represent the position of the rat at a particular coordinate position in the map of the environment, and as a population, place cells could underlie a mechanism by which information about the spatial layout of the environment could be used to compute the flexible trajectories required by navigation.

1.21.1.3.2 Processing of spatial information in other brain regions

Despite an intense focus on the role of the hippocampus, it is clear that navigation is a capacity that requires other brain systems as well. In addition to the role of sensory systems to process and represent environmental stimuli, and the involvement of the prefrontal cortex in providing executive control of response selection and planning through interactions with cortico-striatal loops (e.g., De Bruin et al., 1994; Alexander et al., 1986; Dunnett et al., 2005), a number

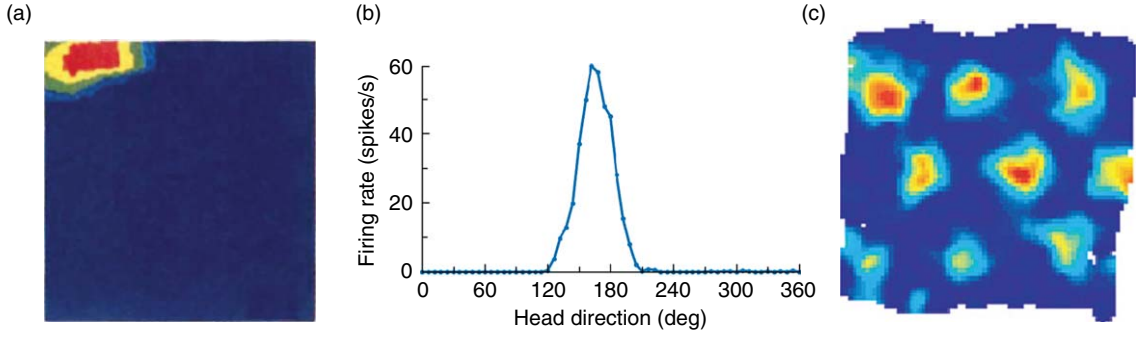

Figure 6 Neurons with spatial firing properties. (a) Place cell: Hippocampal neuron showing an increase in firing rate whenever the animal enters the North-West corner of an open-field environment. of structures are thought to be critical for navigation, either by having a role associated with that of the hippocampus or by supporting navigational strategies independent of the hippocampus.

1.21.1.3.2.(i) Brain systems associated with the role of the hippocampus

1.21.1.3.2.(i).(a) Parahippocampal region

Although the perirhinal, parahippocampal, and entorhinal regions make significant contributions on their own to information processing (Suzuki et al., 1993; Brown and Aggleton, 2001; Burwell et al., 2004), a major role of these regions is to act as a necessary intermediary link between the complex representations in cortical association areas and the hippocampus itself. According to McClelland and Goddard (1996), the parahippocampal region is important for 'compressing' representations of the complex information contained in numerous cortical associational areas, which allows the hippocampus to access and create associations between those complex representations. This network organization would provide a mechanism by which complex visuospatial representations of the environment in the parietal and retrosplenial cortices shown to be important for spatial information processing (Kolb et al., 1994; Ennaceur et al., 1997; Maguire, 2001; Mesulam et al., 2001; Whishaw et al., 2001; Parron and Save, 2004; Vann and Aggleton, 2004; Goodrich-Hunsaker et al., 2005) could reach the hippocampus. This proposal is supported by evidence demonstrating that the entorhinal (Parron et al., 2004; Parron and Save, 2004) and postrhinal/parahippocampal regions (Maguire et al., 1997; Liu and Bilkey, 2002) are important for performance of spatial tasks.

1.21.1.3.2.(i).(b) Areas with spatial coding complementing that of the hippocampus

Though the representations are typically not as precise and sparse as those of the hippocampus, consistent place-related firing has been observed in the lateral septum (Zhou et al., 1999; Leutgeb and Mizumori, 2002), ventromedial entorhinal cortex (Mizumori et al., 1992; Quirk et al., 1992), subiculum (Sharp and Green, 1994; Martin and Ono, 2000), postsubiculum (Sharp, 1996), and parasubiculum (Taube, 1995a; Hargreaves et al., 2005). Such spatial representations in many distinct regions associated with the hippocampus may imply some degree of redundancy in the nervous system, but more likely it reflects the complementary contribution of each of those areas in representing or operating on aspects of the organism's representation of space.

Directional heading is another type of spatial coding important for navigation. It is coded by *head-direction cells,* which are neurons that discharge when the animal points its head in a particular direction and, similar to place cells, are responsive to allothetic and idiothetic cues (**Figure 6(b)**). Head direction cells were initially discovered in the postsubiculum of rats (Taube et al., 1990), but were since then reported in the parasubiculum (Taube, 1995a), anterior thalamus (Taube, 1995b), laterodorsal thalamus (Zugaro et al., 2004), retrosplenial cortex (Chen et al., 1994), and medial entorhinal cortex (Sargolini et al., 2006), as well as in the primate presubiculum (Robertson et al., 1999; see Knierim, 2006, for a review). Information about directional heading is thought to provide an 'internal compass' or an orientation framework for our representation of space, and thus to be important for navigation through piloting (Goodridge et al., 1998) and path integration (Golob and Taube, 1999; Sargolini et al., 2006).

Finally, the most recently discovered type of spatial coding is an environment-independent coordinate system. The key units of this system are *grid cells,* cells located in the dorsocaudal medial entorhinal cortex that exhibit multiple spatial firing fields arranged in a hexagonal grid (Fyhn et al., 2004; Hafting et al., 2005; **Figure 6(c)**). The grid cell representation may offer a robust metric for calculating position, and since the dorsocaudal medial entorhinal cortex projects to the hippocampus, this information must be important for the development of sparse representations of spatial information in the hippocampus.

1.21.1.3.2.(ii) Brain systems implementing alternative navigational strategies

Although navigation research has predominantly focused on the hippocampus, there is considerable evidence that efficient navigational behavior can be supported by strategies other than piloting or the use of a cognitive map.

1.21.1.3.2.(ii).(a) Guidances and orientations

Consider the example of a spatial discrimination task in which an animal is required to learn to turn left on a T-maze in order to obtain a reward. One obvious strategy would be for the animal to use cues surrounding the maze to orient himself and learn that he must choose the arm on the left side of the room in

order to be reinforced, that is, to use a piloting strategy thought to be dependent on the hippocampus. However, the animal could also use at least two other approaches to solve the task, which would fall under the guidances and orientations strategy. First, the animal could develop an attraction, or bias, toward the goal arm, approach it, and obtain a reward.

This navigational strategy of approaching or avoiding particular stimuli depends on the amygdala, a region known to be important for processing the emotional valence of stimuli (McDonald and White, 1993) and other aspects of emotional memory (McGaugh, 2005; Schafe et al., 2005). Alternatively, the animal could also solve the task by learning to perform an egocentric response (i.e., a left turn) at the choice point, a strategy that reflects the use of stimulus–response associations and depends on the integrity of the striatum (McDonald and White, 1993; Packard and McGaugh, 1996). The striatum is best known for its role in planning and modulation of movements, but has been shown to be important for associating specific stimuli or representations to complex behavioral responses, such as forming habits and skills (Graybiel, 1995; White, 1997). The parietal cortex has also been shown to be implicated in the processing of egocentric representations and computation of body turns necessary for navigation (Burgess et al., 1997; Maguire et al., 1998) and displays firing properties that are thought to underlie route representation (Nitz, 2006).

1.21.1.3.2.(ii).(b) Path integration The neural implementation of path integration is not yet well understood. In addition to the neural systems responsible for processing the idiothetic cues (proprioceptive, vestibular, and sensory flow information), behavioral evidence suggests that the parietal (Parron and Save, 2004), entorhinal (Parron and Save, 2004), and retrosplenial cortices (Cooper and Mizumori, 1999) are important for successful path integration (see Etienne and Jeffery, 2004).

The recent discovery of grid cells may help further our understanding of path integration by providing insight into its potential neuronal mechanisms. Grid cells are part of an environment-independent spatial coordinate system that integrates information about location, direction, distance, and speed. In addition to the grid cells previously reported in superficial layers (Fyhn et al., 2004; Hafting et al., 2005), the deep layers of the medial entorhinal cortex contains grid cells that are colocalized with head-direction cells, as well as conjunctive grid X head-direction cells, with all cell types modulated by running speed (Sargolini et al., 2006). Such colocalized representations of location, distance, speed, and direction information have been proposed to be necessary for the neural computations required by path integration (Fuhs and Touretzky, 2006; McNaughton et al., 2006).

The parallel nature of the contribution of distinct strategies to navigation has been cleverly demonstrated experimentally, by creating conditions that expose either their synergistic or their conflicting interactions (McDonald and White, 1993; Packard and McGaugh, 1996). For instance, McDonald and White (1993) designed a simple stimulus–response task in which rats were required to enter arms identified with a light cue (stimulus–response, or habit, learning). As expected, the performance of control animals incrementally improved with training, and animals with damage to the dorsal striatum were severely impaired in learning the task. Interestingly, animals with hippocampal damage outperformed even control animals, implying that the use of a 'hippocampal' strategy, such as trying to remember the location of specific arms entered, is counterproductive in this particular task. This facilitation effect reflects the conflicting contribution of different strategies to solve the same navigation problem.

These findings help clarify the need for distinct neural systems encoding distinct behavioral strategies. For instance, a piloting strategy supported in part by the hippocampus can be employed quickly, but it requires intensive use of the animal's cognitive demands. In contrast, a stimulus–response strategy develops more slowly, but because of its 'habit' nature can support navigation with little mental effort. The latter strategy is particularly advantageous on highly familiar terrain in that navigation can be accomplished on 'automatic pilot,' and can also explain the common human behavior of following a habitual route in error if our concentration wanders.

1.21.1.3.3 Shortcomings of the cognitive map theory: Evidence for an alternative framework

1.21.1.3.3.(i) Navigation by piloting to landmarks does not always require a cognitive map, and navigation reflecting the use of a cognitive map does not always require the hippocampus First, tasks requiring animals to pilot to landmarks do not necessarily require following a unified cognitive map representation of the environment, as different types of associative learning

may often support performance (Mackintosh, 2002). For instance, in the radial-arm maze task, animals could use information from (nonunified) local visual scenes specific to one or a few arms to remember the individual arms already visited on a given trial. Second, elaborate spatial processing indicative of a cognitive map representation can be accomplished in subjects with damage to the hippocampus. For instance, amnesics are impaired at learning new environments but can flexibly recall the spatial layout of a region learned prior to brain damage onset (Teng and Squire, 1999; Rosenbaum et al., 2000), and hippocampectomized animals are able to use the relations between distal landmarks to successfully navigate to an unseen food location (Alyan et al., 2000).

1.21.1.3.3.(ii) Neural representations in the hippocampus are not limited to a faithful Cartesian representation of the layout of the environment The only behavioral protocol in which the firing properties of place cells reflect an allocentric representation, independent of viewpoint and ongoing behavior ('true' place cells; O'Keefe, 1979), is when rats randomly forage for food in an open field environment (e.g., Muller and Kubie, 1987). This experimental protocol is unique in that every task component (e.g., location of reward, direction of trajectory, behavior) is randomized, and consequently most neurons show spatial specificity and no other behavioral correlate. In more elaborate behavioral paradigms, firing patterns of hippocampal neurons can be characterized as encoding task 'regularities' in a variety of paradigms (Eichenbaum et al., 1999). The activity of hippocampal neurons can reflect specific spatial regularities systematically embedded in the task protocol, such as particular speed and direction of movement or angle of turn (McNaughton et al., 1983; Wiener et al., 1989; Markus et al., 1995), but also extends to nonspatial regularities as well. Perhaps the clearest example was provided by Wood and colleagues (1999) in a study in which rats were required to perform the same recognition memory judgment (i.e., is the current odor a match/nonmatch to the previous odor?) in nine distinct locations in a rich spatial environment. They showed that some hippocampal cells fired only in a specific location, others only for one of the nine odors, others to the match/nonmatch status of the presented odor, and others to conjunctions of those task elements. These results indicate that hippocampal neurons encode a broad range of spatial and nonspatial stimuli, behavioral events, and contingencies that characterize the task at hand.

1.21.1.3.3.(iii) The hippocampus is critical for nonspatial memory Accumulating evidence confirms that the role of the hippocampus is not limited to the processing of spatial information. In fact, though the radial-arm maze was designed to take advantage of rats' spatial abilities and was initially discussed as supporting evidence for the role of the hippocampus in processing spatial information (Olton et al., 1978; Olton and Werz, 1978; see earlier section titled 'Radial-arm maze'), Olton's subsequent work suggests that the hippocampus is not crucial for spatial processing per se, but rather plays a specific role in remembering trial-unique information for both the spatial and nonspatial domains (Olton and Papas, 1979; Olton and Feustle, 1981). In addition, the hippocampus has been shown to be important for creating representations of nonspatial information that can be expressed flexibly, in that they support novel generalizations and inferences from the acquired knowledge (e.g., Bunsey and Eichenbaum, 1996; Dusek and Eichenbaum, 1997; Dusek and Eichenbaum, 1998; Alvarez et al., 2002). These studies will be further discussed in later sections.

1.21.1.4 Conclusions

Navigation is a capacity crucial to mammals' survival that depends on the use of multiple strategies and types of representation, and thus emerges from the contribution of distinct neural systems. Striking parallels in neuroanatomy, neurophysiology, and behavior indicate that these navigational principles are fundamentally the same across mammalian species.

The prominent theory of the neural basis of navigation proposed that the hippocampus represents a cognitive map of the environment (O'Keefe and Nadel, 1978). The hippocampus was later shown to have a more limited role in spatial processing than originally envisaged, and to process nonspatial information as well, suggesting that the hippocampus is important for, but not dedicated to, spatial computations (Mackintosh, 2002). Conversely, recent studies have demonstrated that the full extent of the contribution of extra-hippocampal areas in the service of navigation has been underappreciated. Although elements of the cognitive map theory were incorrect, it should be considered a significant accomplishment in

that it acted as a catalyst and generated considerable research evidence on the neural basis of navigation.

Finally, experimental research on navigation has provided a significant contribution to our understanding of general learning and memory principles in mammals. First, it demonstrated that animal learning is not limited to specific stimulus–response associations, but that animals can also internally reorganize information to form cognitive, or stimulus–stimulus, representations (Poucet, 1993). Second, it helped dissociate multiple memory systems by identifying some of their neural substrates and revealing conditions in which they may compete. Finally, because navigation tests such as the watermaze are easy to implement and quick to perform, they are currently being used extensively as a screening tool for learning and memory deficits for a variety of experimental groups (e.g., effects of drug compounds, effects of aging).

1.21.2 Episodic Memory

Unlike the study of navigation, which emphasized research in rodents, episodic memory research has its roots in the study of human cognitive psychology. Unfortunately, the concept of episodic memory is perhaps not as intuitive as the capacity for navigation. Navigation is a behavior that can be accomplished using distinct capacities or strategies, whereas episodic memory should be viewed as a specific memory capacity among many that are essential for adaptive behavior. The precise nature of episodic memory may be better understood by comparisons with other memory systems in a multiple memory system framework, which is the approach taken in this section.

1.21.2.1 Multiple Forms of Memory

1.21.2.1.1 Historical perspective

The existence of multiple forms of memory gained widespread acceptance rather recently, but some prescient thinkers proposed similar ideas a long time ago. Writings from Aristotle (circa 350 BC; translated in Aristotle, 1984), Maine de Biran (1804/1929), Gall (1835), William James (1890), and certainly many others have offered meritorious descriptions of the organization of memory (for reviews, see Schacter and Tulving, 1994; Eichenbaum and Cohen, 2001). Most of these proposals contrast forms of memory that support 'conscious' memory, with other forms which characteristically do not reach consciousness, that are more of a 'habit' nature. In a manner akin to current accounts, some even distinguished capacities similar to our current concepts of 'knowing' and 'recollecting' (Eichenbaum et al., 2005). Although these early accounts relied on introspection and observation rather than experiments, they successfully capture the essence of the idea of multiple forms of memory as it is known today. At the same time, they also offer a sense of the considerable progress made in recent years in refining these ideas, especially in terms of delineating their respective neural substrates.

1.21.2.1.2 Modern taxonomy of memory systems

In recent years, a new memory taxonomy has emerged from the experimental work of several laboratories (e.g., Cohen and Squire, 1980; Squire and Zola-Morgan, 1991; Schacter and Tulving, 1994). Despite evolving primarily from human studies, this classification has been shown to extend to other mammals as well (Eichenbaum and Cohen, 2001), and considerable research evidence indicates that these phenomenologically distinct forms of memory are supported by distinct memory systems (**Figure 7**; Squire, 2004). The two major types of memory, declarative and nondeclarative, are distinguished according to criteria such as the speed of information acquisition, the nature of their represented information, and the means of expression (Squire, 1992).

Declarative memory, also called explicit memory, refers to the memory for facts and events that can be brought into consciousness and expressed explicitly (Cohen and Squire, 1980; Cohen, 1984; Squire and Cohen, 1984; Cohen and Eichenbaum, 1993; Tulving and Markowitsch, 1998). The stored information is of propositional nature (i.e., can be 'declared'), such that one could describe it symbolically and infer relationships among memories. It is a large, complex, and highly structured system with a presumed unlimited capacity, which allows information from all modalities to be stored, often after a single exposure to an event or a fact. A critical feature of the declarative memory representation is its flexibly of access and expression, which allows memories to be retrieved from various logical associations and expressed through a variety of behaviors. Declarative memory is further divided into episodic and semantic memory (Tulving, 1983; Tulving, 1991; Squire et al., 1993), and their distinction has received considerable interest in recent years. In broad terms, episodic memory

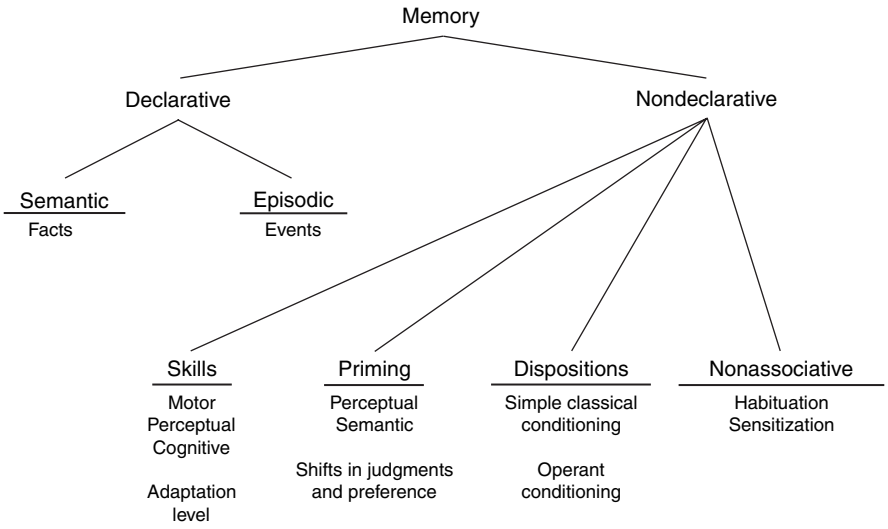

Figure 7 Taxonomy of memory systems. Adapted from Squire LR (1992) Memory and the hippocampus: A synthesis from findings with rats, monkeys, and humans. *Psychol. Rev.* 99: 195–231, with permission from the American Psychological Association. The use of APA information does not imply endorsement by the APA.

refers to the memory for personal experiences (or autobiographical memory for events), while semantic memory is the memory for facts or general knowledge about the world (Squire et al., 1993).

Nondeclarative (implicit) memory, in contrast, consists of a broad set of learning capabilities that involve acquisition of skills and preferences that can be expressed unconsciously by changes in the speed or biasing of performance; they include motor, perceptual, and cognitive skills; habituation and sensitization; sensory adaptations; and priming of perceptual and lexical stimuli (Squire, 1992). Unlike declarative memories, for which the products of retrieval can be consciously 'thought about' and may not lead to overt behavior, retrieval of nondeclarative memories must be expressed through a change in performance (Tulving and Markowitsch, 1998).

1.21.2.1.3 Episodic and semantic memory

Although these two forms of declarative memory have many characteristics in common, they are distinguishable on a number of features (Tulving, 1972, 1993a; Tulving and Markowitsch, 1998). In his earlier work, Tulving (1972) suggested that they differed in their relationship to the context in which information was acquired, in that episodic memories were intrinsically tied to the context, whereas semantic memories were essentially context-free. Recent developments in the definition of episodic memory have focused on differences in the 'experiential' nature of episodic and semantic memory as revealed by careful introspective analysis. According to Tulving and Markowitsch (1998), episodic memory involves 'remembering' specific personal past experiences, whereas semantic memory involves 'knowing' impersonal facts. More precisely, the fundamental difference between episodic and semantic memory lies in the basis of the type of awareness that accompanies recall: episodic memory requires an awareness of personal experience (autonoetic awareness), whereas semantic memory is characterized by the conscious feeling of knowing (noetic awareness; Tulving, 2002). In addition, Tulving (2002) also emphasized that episodic memory is unique in that it is the only form of memory oriented toward the past at the time of retrieval, in the sense that our 'self' must 'mentally time travel' through one's past, in order to 'reexperience' a specific event. In contrast, semantic memory, or knowing, occurs in the present, as one needs not think back to earlier experiences to confirm knowledge of a fact (e.g., knowing that Paris is the capital of France does not require memory for a specific experience).

Annual scientific conferences provide a concrete example of the distinction between the two types of declarative memory. Seeing a particular face may trigger retrieval of an episodic memory, as you think back and distinctly remember having spoken to this person in front of their research poster toward the end of the session on the first day of the meeting. In contrast, seeing another face may simply bring forth a feeling of familiarity as you know you have met this person before but cannot retrieve the

specific experience, a situation with the potential to be quite embarrassing. This ability of normal individuals to discriminate between 'remembering' and 'knowing' has been used to operationalize whether particular recalled memories originated from the episodic or semantic domain, providing evidence that the types of memory can be experimentally dissociated at the phenomenological level ('remember/know' distinction; Tulving, 1993b; Knowlton and Squire, 1995).

1.21.2.2 Role of the Hippocampus in Episodic Memory

As in the study of navigation, the main focus of episodic memory research has been to clarify its neural substrate. Therefore, progress in our understanding of the nature of episodic memory will be discussed along with developments in our knowledge of its neural implementation.

As mentioned earlier, the strong convergence of diverse inputs to the hippocampus, combined with the rapid and stable synaptic plasticity characterizing hippocampal circuits (e.g., Bliss and Collingridge, 1993), allow the hippocampus to rapidly form stable associations among previously unrelated elements from disparate cortical areas. Although such associations could be created in the service of creating a cognitive map, as discussed in the previous section, they could also support episodic memory coding by associating environmental stimuli that constitute elements of individual episodic memories.

1.21.2.2.1 Evidence from human studies

The first insight into the neural implementation of episodic memory came from case studies of neurological patients reported to have a memory deficit for daily life events (Tulving et al., 1988; Vargha-Khadem et al., 1997). In one study, patients who suffered neurological damage selective to the hippocampus demonstrated a pronounced amnesia for the episodes of everyday life, but attained relatively normal levels of speech and language competence, literacy, and factual knowledge (Vargha-Khadem et al., 1997). These findings suggested that episodic and semantic memory differ in their neural implementation, with only the episodic component being fully dependent on the hippocampus.

The evidence provided by these case studies is supported by more formal experiments. First, evidence suggests that the hippocampus is important for tests of recall, which are thought to depend exclusively on episodic memory retrieval (Mandler, 1980), but not for recognition tests, which may be solved in nonepisodic ways (for a review, see Aggleton and Shaw, 1996). Second, using the 'remember/know' method to distinguish episodic and semantic memory, Eldridge and colleagues (2000) demonstrated that the hippocampus was selectively activated when sample items were consciously recollected ('remember'), but not when they were simply recognized ('know'). Unfortunately, the use of these paradigms is unlikely to be the key to determine the role of the hippocampus in episodic memory, as similar studies have failed to show a selective role for the hippocampus in episodic processes (e.g., Squire and Zola, 1998; Manns and Squire, 1999; Manns et al., 2003). These inconsistent findings are in part due to the fact that these paradigms provide inadequate measures of episodic memory capacity. Comparisons between tests of recall and recognition are not sensitive enough to clearly distinguish the contribution of episodic and semantic processes, such that slight changes in methodological details can affect the performance of control and amnesic subjects (Squire and Zola, 1998), and although the 'remember/know' approach may capture the phenomenological distinction between episodic and semantic retrieval, its use of introspective judgments cannot be considered an infallible operational definition, as human subjects are notorious for creating false memories (see Eichenbaum and Fortin, 2003).

Recent approaches focusing on objective and measurable observations to assess episodic memory performance have shown promising results. In line with Tulving's (1972) early proposal that the context in which events are experienced is an integral part of episodic memories, functional imaging studies have shown that the hippocampus is involved in remembering the specific relationships among elements of an episodic memory (Davachi and Wagner, 2002) and the episodic context in which specific items were presented (Davachi et al., 2003). Another approach consists of using *receiver operating characteristics* (ROC) analyses to measure the relative contribution of episodic and semantic processes to recognition memory, which are based on the pattern of correct and incorrect responses across confidence levels or biases (Yonelinas, 2001, 2002; procedures described in further detail in the following). Such studies have also shown that the hippocampus is selectively important for episodic memory (Yonelinas et al., 2002; Daselaar et al., 2006).

Unfortunately, even if considerable progress were made in establishing clear experimental measures of episodic memory capacity, the exclusive use of human studies may not be sufficient to determine the precise contribution of the hippocampus to episodic and semantic processes. First, studies of neurological patients present a number of limitations. The brain damage patients suffered is rarely circumscribed to one specific area, which hinders the establishment of clear structure–function relationships. Conversely, brain damage to one specific area is rarely complete such that remaining fragments with residual function may or may not contribute to memory (Squire and Zola, 1998; Maguire et al., 2001). Second, advances in functional neuroimaging may be able to address some of those issues, but like any experimental technique, it has limitations on its own. The primary concern is that resolving the role of specific structures in different types of memory may be beyond the anatomical and temporal resolution of functional imaging techniques.

In light of these difficulties in providing unambiguous evidence from studies of amnesia or functional brain imaging in humans, it is clear that the development of an animal model of episodic memory to use in convergence with human studies is essential. As demonstrated in the navigation section earlier, animal studies directly compensate for the limitations of human studies by allowing much greater control over the anatomical specificity of the brain lesions and the amount of information learned before and after the damage. Also, the activity of individual neurons in multiple brain areas can be directly observed in animals, and the findings may reveal qualitative as well as quantitative distinctions in the nature of memory representations in these areas.

1.21.2.2.2 Evidence from nonhuman mammals

Do animals have episodic memory? One point of view, proposed by Tulving and others (Tulving, 1972, 2002; Tulving and Markowitsch, 1998), is that episodic memory is unique to humans. Tulving and Markowitsch (1998) claimed that the distinction between remembering and knowing simply does not exist in animals, and that declarative memory in animals corresponds to semantic memory in humans. The opposite position emphasizes parsimony in evolutionary design, which suggests that the antecedents of human forms of episodic memory should be found in animals (Morris, 2001; Whishaw and Wallace, 2003). Evolutionary parsimony implies that a similar algorithm is being used by the hippocampus and its related structures across mammalian species, a proposal supported by the high degree of conservation of the hippocampal system across mammalian species in terms of cell types, connectional architecture, and basic structure (Amaral and Witter, 1989; Lavenex and Amaral, 2000; Manns and Eichenbaum, 2006). Even if the information to be operated upon is different in humans because of language, consciousness, or autonoetic awareness, there are no obvious cellular, connectional, or biochemical differences that would suggest that the computations are of a different nature (Morris, 2001).

According to Tulving (2002), concepts unique to humans such as self, autonoetic awareness, subjectively sensed time, mental time travel, language, and consciousness are all critical to episodic memory. However, though it is clear that these elements of episodic memory cannot be addressed in animals, their absence does not necessarily invalidate attempts to model episodic memory in animals. For instance, language is clearly important for episodic memory in humans, but species that cannot communicate through language are not logically prevented from having private recollective experiences, as experiencing events and recalling them later is certainly independent of their overt communication to conspecifics (see Morris, 2001). In order to develop an animal model of episodic memory, we must operationally define species-independent features of episodic memory that can be tested experimentally by objective behavioral measures reflecting the subject's knowledge of its experiences. Recent theoretical work has identified a number of such features of episodic memory that can be tested in animals (Griffiths et al., 1999; Aggleton and Pierce, 2001; Morris, 2001; Roberts, 2002; Eichenbaum and Fortin, 2003; Whishaw and Wallace, 2003), and four experimental approaches testing the following features will be discussed here: (1) episodic memories are acquired in a single experience, (2) episodic memories contain information about the context in which experiences occurred, (3) episodic memories are structured sequences of events, and (4) episodic memories are characterized by a recollective process with distinct retrieval dynamics.

1.21.2.2.2.(i) Episodic memories are acquired in a single experience The first approach focuses on the fact that episodic memories are formed after a single experience (e.g., Tulving, 1972, 2002; Tulving and Markowitsch, 1998). The main experimental

paradigm used in this approach is the delayed nonmatch-to-sample task, which tests the capacity of animals to remember a single exposure to a novel stimulus (Gaffan, 1974; Mishkin and Delacour, 1975). This recognition task starts with a sample phase in which the animal is presented with a single stimulus, followed by a delay period in which the stimulus is not present, and ends with a test phase in which the animal is required to select the novel stimulus over the sample stimulus (that is, to 'nonmatch' to the sample) in order to be reinforced. A substantial literature in rats and monkeys shows that damage to the medial temporal lobe region (hippocampus and parahippocampal region), or damage selective to the parahippocampal region, produces a severe delay-dependent impairment. In fact, animals perform normally when the delay period lasts a few seconds, but their accuracy declines rapidly with longer delays (Suzuki et al., 1993; Mumby and Pinel, 1994; Zola-Morgan et al., 1994; Murray, 1996). However, selective damage to the hippocampus results in modest (Mumby et al., 1992; Zola et al., 2000; Clark et al., 2001) or no deficit on delayed performance even when the memory load is very high (Murray and Mishkin, 1998; Dudchenko et al., 2000), suggesting that parahippocampal cortical areas can support this form of simple recognition without critical hippocampal involvement.

In contrast, different results have emerged using the visual paired-comparison task, a recognition test similar in memory demands, but with slightly different behavioral procedures. In this test, animals are simply exposed to a novel visual stimulus and then, following a delay, are tested for time spent visually investigating the same stimulus versus a novel stimulus. In this test, selective damage to the hippocampus produces a severe delay-dependent impairment (Clark et al., 2000; Zola et al., 2000). These mixed findings among recognition tests in animals parallel the inconsistent results reported in recall and recognition tests in human neurological patients mentioned above.

At first, such inconsistent findings in recognition tests seemed difficult to reconcile with emerging theories of the role of the hippocampus in episodic memory. However, it has become clear that recognition paradigms can be solved by ways other than episodic memory (e.g., Griffiths et al., 1999). In fact, analogous to the 'remember/know' distinction reported earlier, performance on simple recognition tasks can be supported by at least two processes, one involving a hippocampal-dependent recollective (episodic) process and another involving hippocampal-independent familiarity-based (semantic) processing (Eichenbaum et al., 1994; Griffiths et al., 1999; Fortin et al., 2004; Brown and Aggleton, 2001). Methodological differences between recognition studies may change the degree to which subjects rely on episodic recall or on alternative strategies, a likely explanation for the conflicting results in subjects with damage to the hippocampus.

In conclusion, the formation of a memory after a single experience is not a capacity exclusive to episodic memory, as it can be supported by a number of other memory capacities (e.g., familiarity, imprinting, fear conditioning, taste aversion). Tests of memory for single experiences are not sensitive enough to distinguish the individual contribution of these processes and thus are not optimal for investigating episodic memory.

1.21.2.2.2.(ii) Episodic memories contain information about the context in which experiences occurred In order to be exclusively episodic in nature, experimental paradigms must have behavioral requirements unlikely to be fully subserved by other memory systems. A new approach pioneered by Clayton and Dickinson (1998) is to take advantage of the contextual differences between episodic and semantic memory to contrast them. According to Tulving (1972), episodic memories are tied to the context in which experiences occur, as if labeled for when and where they were acquired, whereas semantic memories are timeless and not bound to the place or other aspects of the context where knowledge was gained. Therefore, tests requiring animals to remember information about the context in which episodes occurred may be successful in measuring episodic memory capacity.

1.21.2.2.2.(ii).(a) What-where-when Clayton and Dickinson (1998) were the first to show that episodic memory may not be a uniquely human phenomenon, by providing behavioral evidence that animals can recall a unique past experience. They investigated memory for when and where events occurred in a clever experiment that utilized the natural caching behavior of scrub jays. Initially, jays cached both worms and peanuts in an array of locations. Jays prefer worms to peanuts, so if recovery is allowed within a few hours after caching, the jays will recover worms first. However, if a multiday interval is imposed between caching and recovery, the jays know that the worms are degraded and proceed to recover peanuts first. Scrub jays were capable of

selecting either type of food depending on the time since caching, leading the authors to conclude the jays remembered *what* had been cached, as well as *where* and *when* each item was cached (what-where-when). Importantly, because the stimuli are equally familiar at the time of test, subjects cannot choose on the basis of differential familiarity, unlike in radial-arm maze and delayed nonmatching tests.

This capacity to retrieve information about the time and place of occurrence of a unique experience has also been shown in rodents (Ergorul and Eichenbaum, 2004), suggesting that it extends to nonhuman mammals as well. However, there are a number of limitations to this model. First, as mentioned by Roberts (2002), the '*when*' component of the study is more a reflection of the jays' sense of how much time has passed since the caching events rather than a measure of a temporally organized memory structure representing when specific experiences occurred in relation to each other, as described by Tulving (1983). Furthermore, the capacity to judge how much time has passed since caching could be guided by signals about the trace strengths of the caching memories instead of episodic recall. Thus, jays may learn to prefer worms 4 hours post-caching when their memory for the caching memory is very strong, but not after a few days when the memory is weaker (Eichenbaum and Fortin, 2003). Second, the requirement for 'what,' 'where,' *and* 'when' is arbitrary and, with regard to the role of the hippocampus, appears inconsistent with the findings of patients and animals with hippocampal damage. In fact, subjects with damage to the hippocampus are impaired when required to remember *where or when* specific events occurred (see below), suggesting that episodic recall is needed to retrieve either type of information associated with the original experience (not necessarily a combination of the two). It therefore appears that the proposal that episodic memories consist of a conjunction of *what*, *where*, and *when* may be too stringent. Overall, however, the demonstration by Clayton and Dickinson (1998) of a possible operational measure of episodic memory has been very influential and generated considerable interest in developing a more complete animal model of episodic memory (*See* Chapter 1.23).

1.21.2.2.2.(ii).(b) Context in which experiences occur There are a number of experimental situations in which animals are required to remember the context in which specific events occurred, and evidence suggests that this capacity depends on the hippocampus. It is important to note that, in this chapter, context is broadly defined as the set of background features, external or internal to the subject, that are present when an event occurs (Ferbinteanu et al., 2006). The context of interest can be a particular visual scene (Gaffan and Parker, 1996) or the environment itself, as in the case of contextual fear conditioning paradigms in which damage to the hippocampus impairs the ability of animals to remember the testing box in which they received a foot shock (Phillips and LeDoux, 1992, 1995). Alternatively, the context may also be more abstract, in the sense that the hippocampus may be critical to remember the relevant component or feature of a particular task. For instance, the hippocampus has been shown to be important for the ability to choose the response that is correct given a specific behavioral context, such as which of two sequences is being completed (Agster et al., 2002), or to remember the task context in which a particular item was presented (e.g., source identification; Davachi et al., 2003). The context can also refer to internal sensations, as demonstrated by a study in which the hippocampus was critical to remember which behavioral response is appropriate, depending on rats' current internal motivational state (i.e., hunger or thirst; Kennedy and Shapiro, 2004).

Another line of evidence came into focus after recent models of episodic memory emphasized the importance of the spatial context of episodic memories (Clayton and Dickinson, 1998). In fact, when reinterpreted within an episodic memory framework, a number of spatial memory deficits in hippocampal animals alluded to previously in the navigation section can be better described as deficits in remembering the spatial location (spatial context) where specific events occurred. For instance, the hippocampus does not seem to be critical for spatial processing per se, but is important for remembering the spatial locations of individual arm entries in the radial-arm maze task (Olton and Papas, 1979), the trial-unique location of the escape platform in the watermaze (Steele and Morris, 1999), and the location where a trial-unique paired-associate was presented (Day et al., 2003). The relationship between navigation and episodic and semantic memory will be further discussed in the final section of this chapter.

In summary, these findings suggest that the experimental approach of testing the memory for the context in which specific events occurred, a function dependent on the hippocampus, is a feature of episodic memory that can be successfully tested in animals.

1.21.2.2.2.(iii) Episodic memories are structured as sequences of events The first two approaches were based on distinctions of episodic memory that have been emphasized explicitly by Tulving and, for the most part, described experimental paradigms already prominent in memory research. This novel approach captures a defining feature of episodic memory, but the formal details of the theory emerged from computational models of hippocampal function (Levy, 1996; Wallenstein et al., 1998; Lisman, 1999). As mentioned earlier, the neural architecture of the hippocampal system is rather unique. Of particular interest is region CA3 of the hippocampus, which has the highest density of recurrent connections in the brain and as such has been proposed to act as a heteroassociative network allowing successive events to be bound together into sequences (Levy, 1996; Wallenstein et al., 1998; Lisman, 1999). In line with Tulving's views (1983) that episodic memories are organized in the temporal dimension and that the central organizing feature of episodic memory is "one event precedes, co-occurs, or follows another," the fundamental principle underlying this approach is that each individual episode is organized as a sequence of events unfolding over time. Thus, this approach tests whether episodic memories contain not only a particular item or items that one is attempting to recall, but also the full sequence of events that precede and follow.

1.21.2.2.2.(iii).(a) Learning new sequences of events To investigate the specific role of the hippocampus in remembering the order of events in unique experiences, recent studies have employed a behavioral protocol that assesses memory for episodes composed of a unique sequence of olfactory stimuli (Fortin et al., 2002; Kesner et al., 2002). In one of these studies, memory for the sequential order of odor events was directly compared with recognition of the odors in the list independent of memory for their order (Fortin et al., 2002; **Figure 8(a)**). On each trial, animals were presented with a series of five odors, selected randomly from a large pool of common household scents. Memory for sequential order was probed using a choice test in which the animal was presented with two odors from the series and was reinforced for selecting the odor that appeared earlier. Similarly, recognition memory for the items in the series was probed using a choice between one of the odors from the series and another odor from the pool that was not in the series, and reinforcement was given for selecting the odor not presented in the series. Normal rats performed well on sequential order judgments across all lags (temporal distance between probed odors; **Figure 8(b)**), and performance on probes was dependent on the lag, indicating that order judgments were easier for more widely separated items. By contrast, rats with hippocampal lesions performed the sequential order task at near-chance levels and were impaired at all lags. However, both control rats and rats with selective hippocampal damage acquired the recognition task rapidly, and no overall difference in performance was observed between the two groups (**Figure 8(c)**).

As mentioned earlier, a potential confound in any study that employs time as a critical dimension in episodic memory is that, due to the inherent decremental nature of memory traces, memories obtained at different times are likely to differ in terms of their trace strength. However, in the study of Fortin and colleagues (2002), both the control and the hippocampal groups demonstrated a temporal gradient in recognition performance (**Figure 8(c)**), suggesting that memories were in fact stronger for the more recently presented items in each sequence (e.g., performance on E vs. X is better than on A vs. X). Therefore, their finding that only hippocampal animals were impaired in sequential order judgments (**Figure 8(b)**) suggests that this capacity cannot be fully supported by the use of relative strengths of memories traces, but rather depends on episodic recall of the odor sequence.

Contrary to the argument that animals lack episodic memory because they are 'stuck in time' (Roberts, 2002; Tulving, 2002), these observations suggest that animals have the capacity to recollect the flow of events in unique experiences. Finally, reports of a similar pattern of findings in subjects with damage to the hippocampus (Spiers et al., 2001; Downes et al., 2002; but see also Hopkins et al., 1995) support the validity of this approach as an animal model of episodic memory.

1.21.2.2.2.(iii).(b) Disambiguating learned sequences of events A major challenge for a robust model of episodic memory is the requirement for a capacity to develop representations that can distinguish two experiences that share common elements (Shapiro and Olton, 1994). Levy (1989, 1996) proposed that memory for the ordering of events mediated by the hippocampus may be especially important when the event sequences have overlapping elements through which memory of earlier elements must be remembered to complete each

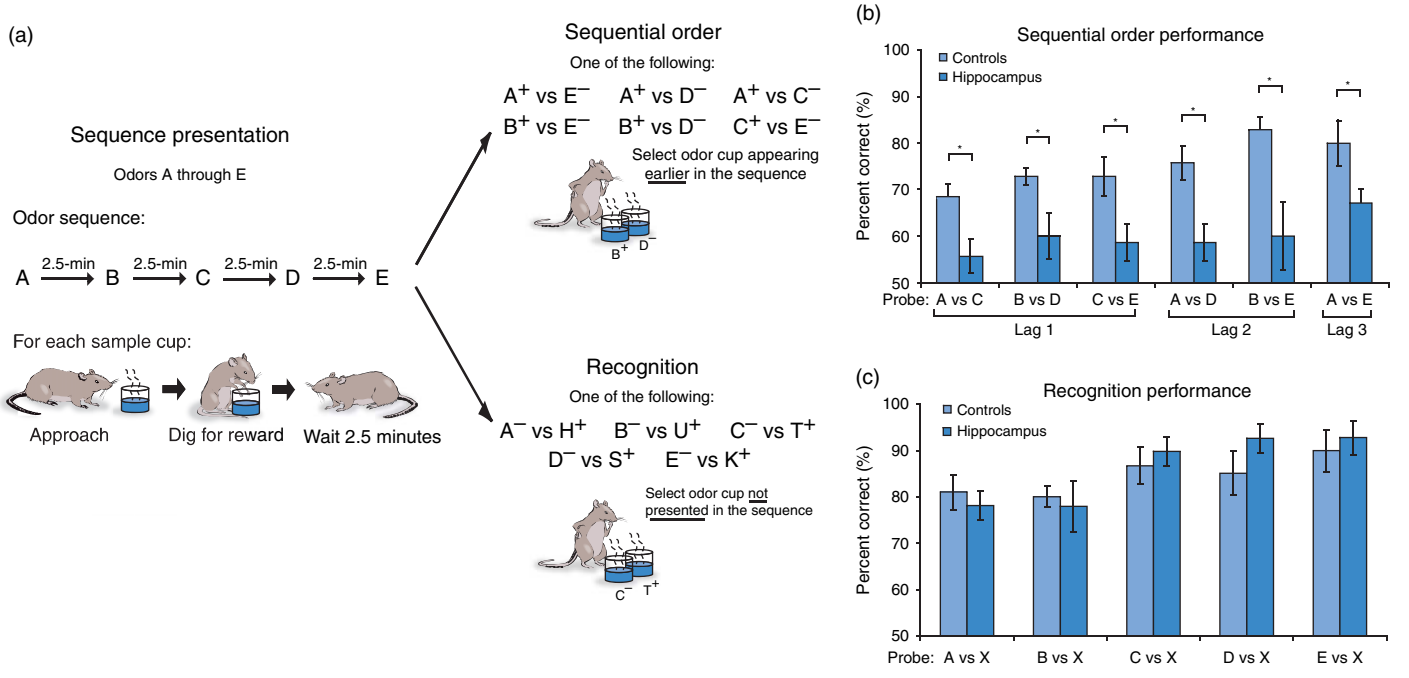

Figure 8 Sequential order and recognition tasks. (a) On each trial the animal was presented with a series of five odors (e.g., odors A through E). The animal was then either probed for its memory of the order of the items in the series (*top*) or its memory of the items presented (*bottom*). +, rewarded odor, −, nonrewarded odor. (b) Hippocampal animals were impaired on all sequential order probes. Performances on different probes are grouped according to the lag (number of intervening elements). (c) Hippocampal animals performed as well as controls on the recognition probes. 'X' designates a randomly selected odor that was not presented in the series and used as the alternative choice. *, $p < .05$. Neurosci.* 5: 458–462, with permission from Macmillan Publishers Ltd.

distinct sequence. In order to test whether such sequence disambiguation is a fundamental feature of memory processing dependent on the hippocampus, Agster et al. (2002) trained rats on a sequence disambiguation task designed after Levy's (1996) formal model that involved two partially overlapping sequences of events (**Figure 9(a)**). The sequences were presented as a series of six pair-wise odor choices where, for each sequence, selection of the appropriate odor at each choice was rewarded (e.g., first choice being A vs. L). Each trial began with two forced choices that initiated production of one of the two sequences (e.g., A then B for Sequence 1). Then the animal was presented with two forced choices that were the same for both sequences (i.e., X then Y). Subsequently, the subject was allowed a free choice and was rewarded for selecting the odor assigned to the ongoing sequence (e.g., if given A→B→X→Y, then select E to complete Sequence 1). Finally the animal completed that sequence with one more forced choice (e.g., F for Sequence 1). The critical feature of this task was the free choice. On that test, animals were required to remember their choices from the first two pairings of the current sequence during the ambiguous components of the trial and then to use the earlier information to guide the correct odor selection.

Rats with damage to the hippocampus were impaired when sequences were presented in rapid succession (**Figure 9(b)**). However, hippocampal rats performed as well as controls in a version of the task in which proactive interference was reduced by increasing the inter-sequence delay (**Figure 9(c)**), but they were subsequently impaired when a 30-min delay was introduced before the free choice (**Figure 9(c)**). These findings suggest that, when memory demands are minimal, as in conditions of low proactive interference or no demand to hold information through ambiguous material, other brain systems, such as corticostriatal pathways, can succeed in coding sequences in which each segment rapidly or unambiguously leads to the next (Nissen and Bullemer, 1987; Reber and Squire, 1998). Conversely, under memory demands characteristic of episodic memory function, such as when proactive interference is high or when a substantial delay is

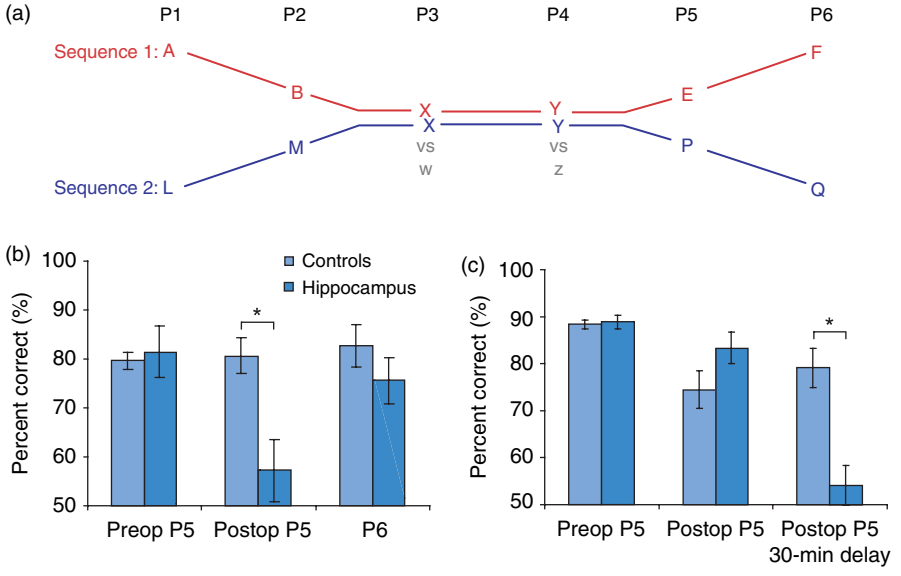

Figure 9 Sequence disambiguation task. (a) The two odor sequences are indicated by letters (Seq1: ABXYEF; Seq2: LMXYPQ). In performing each sequence, the rat selected between vertically aligned odors (e.g., for sequence 1 presentation, the rat should have selected A over L, B over M, X over W, Y over Z, E over P, and F over Q). Note that in both sequences, X was to be selected over W, and Y over Z. (b) When sequences were presented in rapid succession, hippocampal rats were impaired on P5, but not on P6, suggesting that their deficit is limited to a failure to remember the current sequence through the overlapping segment. (c) However, hippocampal rats performed as well as controls in a version of the task in which proactive interference was reduced by increasing the intersequence delay, but were subsequently impaired when a 30-min delay was introduced before the free choice. Modified from Agster KL, Fortin NJ, and Eichenbaum H (2002) The hippocampus and disambiguation of overlapping sequences. *J. Neurosci.* 22: 5760–5768, with permission from the Society for Neuroscience.

imposed between sequential experiences, a representation mediated by the hippocampus is required to disambiguate sequences of events.

In conclusion, the proposal that individual episodic memories are encoded as sequence of events, a hypothesis derived from computational models of hippocampal function, is in agreement with Tulving's view (1983) that the preservation of the temporal structure of events in experience is a central organizing feature of episodic memory. This approach has been successful in showing that the hippocampus of mammals is important for learning new sequences of events (in rodents: Fortin et al., 2002; Kesner et al., 2002; in primates: Spiers et al., 2001; Downes et al., 2002) and for disambiguating overlapping sequences of events (in rodents: Agster et al., 2002; in primates: Kumaran and Maguire, 2006).

1.21.2.2.2.(iv) Episodic memories are characterized by a recollective process with distinct retrieval dynamics The most recently developed approach to investigate episodic memory in animals focuses on mathematically deducing from objective behavioral measures the relative contribution of the two processes underlying recognition memory mentioned earlier: *recollection,* which corresponds to the recall of the original experience characteristic of episodic memory, and *familiarity,* which refers to nonepisodic recognition based on a general sense that an item has been previously experienced. In humans, signal detection techniques have been used to distinguish recollection and familiarity based on the shape of their receiver operating characteristic (ROC) curves, standard curves that represent item recognition across different levels of confidence or bias (Yonelinas, 2001; **Figures 10(a)–10(c)**). In such ROC curves, asymmetry (Y-intercept > 0) is viewed as an index of recollection, whereas the degree of curvature reflects the contribution of familiarity to recognition performance.

In order to determine whether animals also employ multiple processes in recognition memory and to explore the anatomical basis of this distinction, Fortin and colleagues (2004) adapted these techniques to examine odor recognition memory in rats (see **Figure 10(g)** for details). The ROC curve obtained in rats had asymmetrical (Y-intercept > 0) and curvilinear components, indicating the existence of both recollection and familiarity in rats (**Figure 10(d)**). Furthermore, following selective damage to the hippocampus, the ROC curve became entirely symmetrical (Y-intercept = 0) and remained curvilinear, indicating selective loss of recollection capacity but preserved familiarity (**Figure 10(e)**). To further compare the performance of the two groups, the control group was subsequently tested with a longer memory delay (75 min instead of 30 min) to have its overall level of performance (averaged across biases) match that of the hippocampal group. In contrast to the hippocampal group (**Figure 10(e)**), the ROC curve of normal rats at 75 min delay remained asymmetric but showed little curvilinearity (**Figure 10(f)**), indicative of recognition performance mostly based on recollection.

The pattern of findings in this study strongly suggest (1) that the ROC approach, developed in humans, can be used to investigate episodic memory in rodents as well; (2) that rodents also use both episodic recollection and familiarity in recognition memory, providing an explanation for the mixed findings in the recognition tests mentioned; and (3) that, as in humans (Yonelinas et al., 2002), the hippocampus plays a predominant role in episodic recollection compared to familiarity (but see also Wais et al., 2006).

1.21.2.2.3 Hippocampal neuronal mechanisms underlying episodic memory

In addition to the behavioral and neuropsychological findings described, characterizations of the firing patterns of hippocampal neurons in animals performing memory tasks have helped clarify the role of the hippocampus in episodic memory by shedding light on its information processing mechanisms. Observations from rats, monkeys, and humans, and across many different behavioral protocols, show that important attributes of episodic memory are encoded in hippocampal neuronal activity: (1) hippocampal neurons code for the context in which specific events occur, (2) hippocampal neurons encode episodes as sequences of events, and (3) hippocampal neurons disambiguate and link distinct episodic memories (see **Figure 11**).

1.21.2.2.3.(i) Coding of specific events or experiences in their context In this chapter, context is defined as the set of background features, external or internal to the subject, that are present when an event occurs (Ferbinteanu et al., 2006). It includes the spatial location where an event took place, but extends to other aspects of context as well, such as the behavioral significance of particular stimuli in the task, or the emotional or motivational states experienced during specific events. As

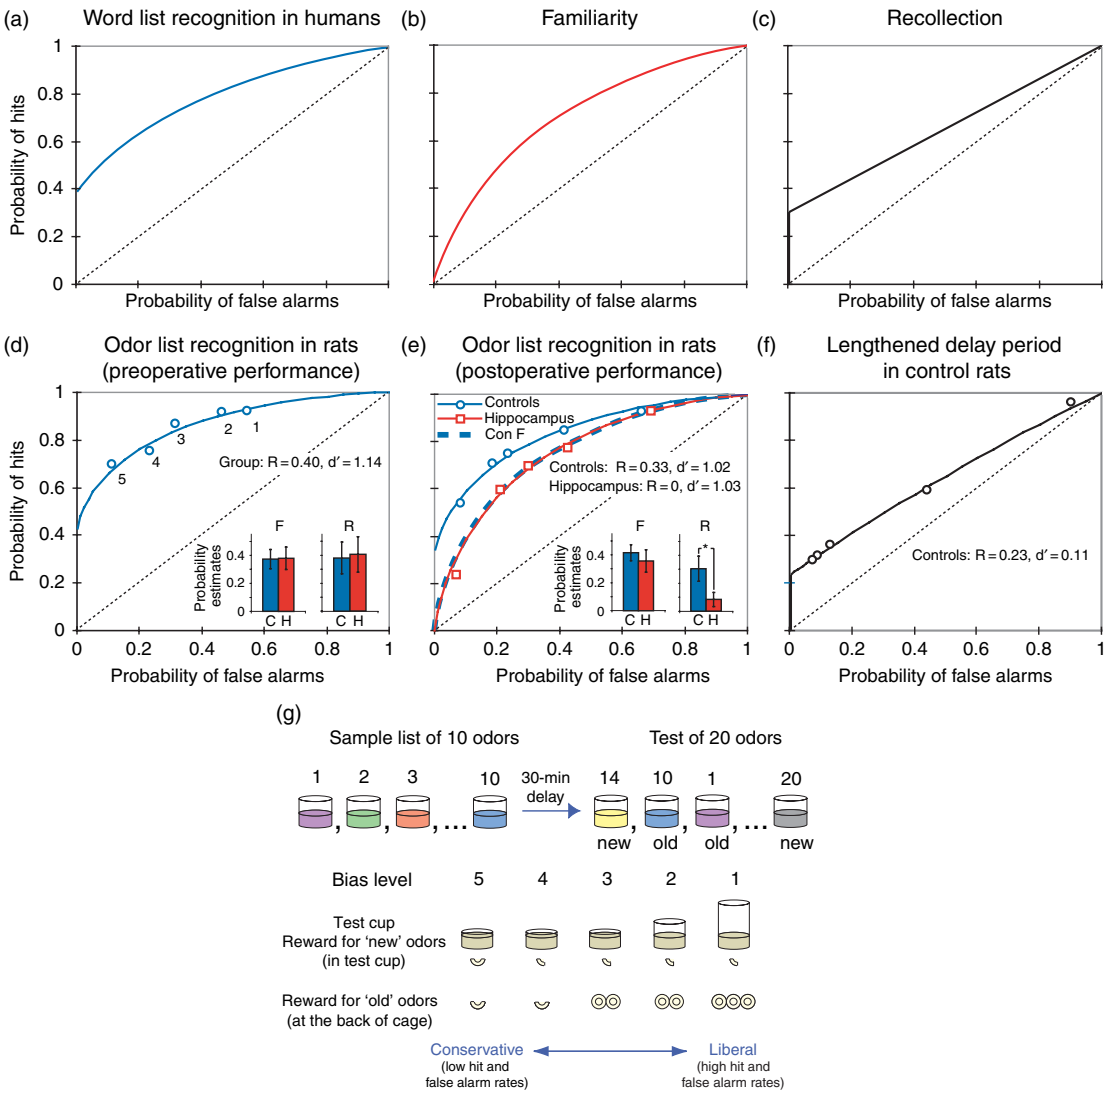

Figure 10 ROCs for recognition performance in humans and rats. (a–c) Performance of humans in verbal recognition. In a typical experiment, human subjects initially study a sample list of words and then are presented with a larger list containing the sample words intermixed with new ones and asked to identify each word as old or new. The resulting ROC analysis plots hits (correct identifications of old items) against false alarms (incorrect identifications of new items as old) across a range of confidence levels or response bias. The data points are then curve fitted by a model with two parameters (Y intercept and d′) using a least-squares method (see Yonelinas et al., 1998, for details). (d–f) Performance of rats in odor recognition (Fortin et al., 2004). (d) Normal rats tested with a 30-min delay. Insets: recollection (R) and familiarity (F) estimates. (e) Postoperative performance with a 30-min delay, including an estimated curve for controls based on familiarity alone (con F). (f) Control rats tested with a 75-min memory delay. Diagonal dotted lines represent chance performance across criterion levels. C, control group; H, hippocampal group. Error bars indicate SEM; *, $p < .05$. (g) Odor recognition task. The behavioral procedures remained fundamentally similar to those used in human studies but were adapted to take advantage of the natural behavior of rats. On each daily test session, rats initially sampled ten common household scents mixed with playground sand in a plastic cup containing a cereal reward. Following a 30-min memory delay, the same odors plus ten additional odors were presented in random order, and animals were required to identify each odor as old or new. To plot ROC curves, hit and false alarm rates were obtained under a range of response criteria, from conservative to liberal. To achieve this, different response criteria were encouraged for each daily session using a combination of variations in the height of the test cup (making it more or less difficult to respond to that cup), and manipulations of the reward magnitudes associated with correct responses to the test and the unscented cup. Top: Sequence of odor presentation. Bottom: Test cup heights and reward payoffs for each bias level. (a–g) Adapted from Fortin NJ, Wright SP, and Eichenbaum H (2004) Recollection-like memory retrieval in rats is dependent on the hippocampus. *Nature* 431(7005): 188–191, with permission from Macmillan Publishers Ltd.

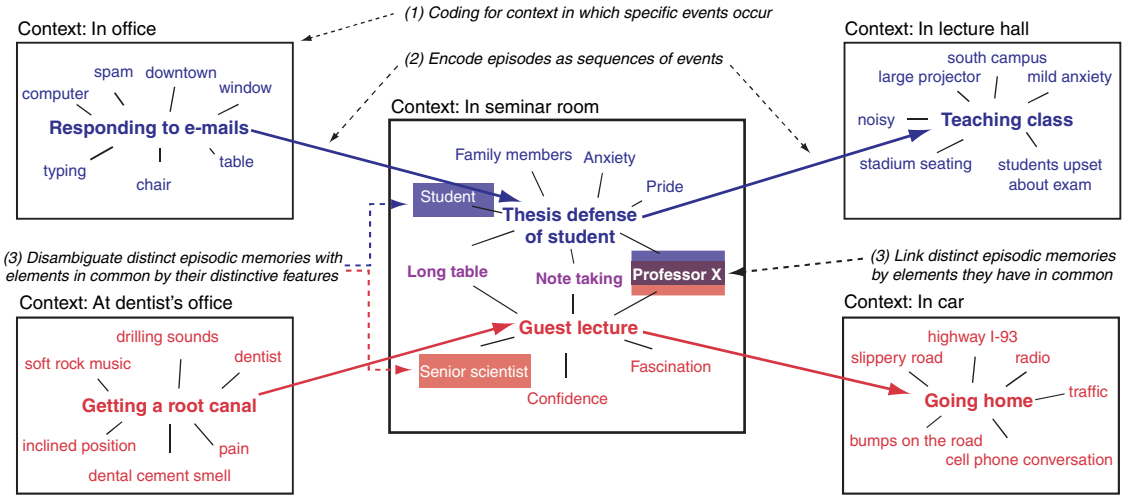

Figure 11 Hippocampal neuronal mechanisms underlying episodic memory. Characteristic features of episodic memories are encoded in hippocampal neuronal activity: (1) hippocampal neurons code for the context in which specific events occur, (2) hippocampal neurons encode episodes as sequences of events, and (3) hippocampal neurons disambiguate and link episodic memories with elements in common.

described in the previous section, a plethora of studies have described the spatial coding properties of hippocampal neurons; however, the focus of the vast majority of these studies was the coding of space itself (e.g., cognitive mapping), not the spatial context of unique experiences, and as such most paradigms had very little memory requirement.

The role of the hippocampus in representing different elements of the context in which specific events take place was first demonstrated by the study of Wood and colleagues (1999) mentioned earlier, in which rats were required to perform the same behavioral judgments (match or nonmatch to the previous odor) at many locations in the same environment. In addition to the cells coding for task regularities, such as specific locations, odors, or match/nonmatch status discussed earlier, they reported other hippocampal cells that fired in association with combinations of events and the context in which they occurred. For instance, some cells fired only if the animal began the approach from a particular location, or fired only for a particular conjunction of the odor, the place where it was sampled, and the match/nonmatch status of the odor. This conjunctive coding representing spatial and nonspatial features of specific events suggests that the hippocampus encodes the context of individual experiences.

A recent study reported very similar results in humans (Ekstrom et al., 2003). The activity of hippocampal neurons was recorded as subjects played a taxi driver game, searching for passengers picked up and dropped off at various locations in a virtual-reality town. Some cells fired when subjects viewed particular scenes, occupied particular locations, or had particular goals in finding passengers or locations for drop off. Many of these cells fired in association with specific conjunctions of a place and the view of a particular scene or a particular goal. Similar coding reflecting context-specific activity in the hippocampus has been reported in a number of other studies as well (e.g., Moita et al., 2003; Wirth et al., 2003). Thus, in rats, monkeys, and humans, a prevalent property of hippocampal firing patterns involves the representation of unique conjunctions of elements reflecting the context in which specific events occur (**Figure 11**).

1.21.2.2.3.(ii) Coding of episodes as sequences of events Computational models have hypothesized that the unique neural architecture of the hippocampus would be well suited for coding individual episodes as sequences of events (Levy, 1996; Lisman, 1999), a prediction supported by aforementioned behavioral studies (Agster et al., 2002; Fortin et al., 2002). Although unequivocal evidence for coding of sequences of individual events is not available

at this time, this hypothesis has received experimental support. In fact, hippocampal neurons show activity patterns reflecting sequential coding of locations (Mehta et al., 1997, 2000) and have been shown to preserve the sequential order in which locations were visited (Lee and Wilson, 2002; 2004; Foster and Wilson, 2006). Moreover, every behavioral event of significance is encoded by individual hippocampal neurons (e.g., presentation of a specific stimulus, response to a cue), such that different subsets of hippocampal neurons are sequentially activated as the animal performs the task at hand (Wiener et al., 1989; Eichenbaum et al., 1999), providing the hippocampal network as a whole with a representation of the full sequences of events composing individual episodes (**Figure 11**).

1.21.2.2.3.(iii) Disambiguating and linking distinct episodic memories Since a large number of episodic memories have elements in common, the neural systems responsible for the encoding and retrieval of episodic memories must use neuronal mechanisms that minimize interference between such similar episodic memories but also preserve the integrity of the relations among dissimilar episodes, which support the flexibility of access and expression as well as comparisons within the episodic memory network (Eichenbaum, 2004). According to the current framework, this can be accomplished by *disambiguating* the representation of similar episodes by emphasizing their differences, and by *linking* common elements between distinct episodic memories to emphasize their similarity (**Figure 11**).

A recent study by Wood and colleagues (2000; see also Frank et al., 2000) lent support to this characterization by recording from hippocampal neurons as rats performed a spatial alternation task in the T-maze. Performance on this task requires that animals distinguish left-turn and right-turn episodes and remember the immediately preceding episode so as to select the other option on the current trial, task demands reflecting the use of episodic memory (Olton, 1984, 1986). The key comparisons focused on the central 'stem' of the maze, which is common to both left- and right-turn trajectories (**Figure 12(a)**). They reported firing patterns that emphasize the distinctiveness between similar episodes, indicative of *disambiguation* coding. In fact, many of the cells that fired when the rat was running down the stem fired differentially on left-turn versus right-turn trials (**Figure 12(b)**), and this differential activity was shown not to be due to differences in head direction, running speed, or location on the two trial types. Thus, even though the behavior and external stimuli were held constant, these cells provided a representation that disambiguated two otherwise identical trajectories on the stem according

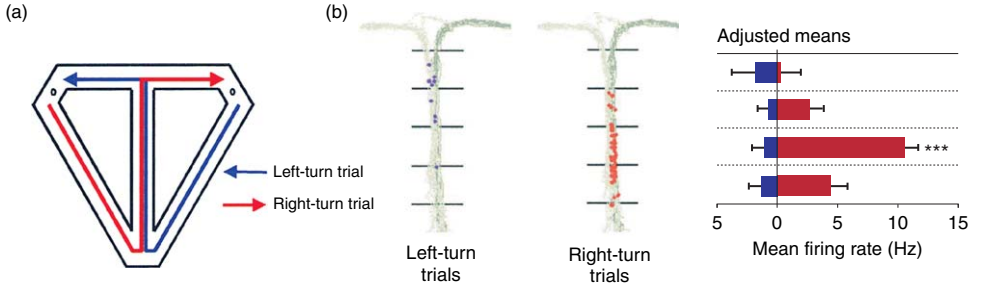

Figure 12 Disambiguation coding in hippocampal neurons. (a) Rats performed a continuous alternation task in which they traversed the central stem of the apparatus on each trial and then alternated between left and right turns at the T junction. Rewards for correct alternations were provided at water ports (small circles) on the end of each choice arm. The rat returned to the base of the stem via connecting arms and then traversed the central stem again on the next trial. For analysis of neural firing patterns, left-turn (blue arrow) and right-turn (red arrow) trials were distinguished. (b) Example of a hippocampal neuron disambiguating between left- and right-turn episodes. This cell fired almost exclusively during right-turn trials. Plots on the left show the location of the rat when individual spikes occurred for left-turn trials (blue dots) and right-turn trials (red dots). In the right panel, the mean firing rate of the cell for each sector, adjusted for variations in firing associated with covariates, is shown separately for left-turn trials (blue) and right-turn trials (red). Adapted from Wood E, Dudchenko P, Robitsek JR, and Eichenbaum H (2000) Hippocampal neurons encode information about different types of memory episodes occurring in the same location. *Neuron* 27: 623–633, with permission from Elsevier.

to the cognitive demands of the task, that is, to remember which turn was performed last. In addition, Wood and colleagues also reported coding patterns reflecting *links* between similar elements of distinct episodes. In fact, they recorded from cells that fired in the same location on the stem for both trial types, potentially providing a link between left-turn and right-turn representations by the common places traversed on both trial types.

In summary, the firing properties of hippocampal ensembles underlie episodic memory by encoding individual episodes as sequences of events as well as the common stimuli, places, and events that are shared across episodes, providing a framework for linking related memories and disambiguating overlapping ones (Eichenbaum et al., 1999; **Figure 11**).

1.21.2.3 Contribution of Other Neural Systems to Episodic Memory

In addition to the hippocampus, a number of other neural systems are important for episodic memory. Evidence from both neuropsychological studies and functional brain imaging indicates that the prefrontal cortex plays a role in the strategic or organizational aspects of episodic retrieval (Milner et al., 1985; Gershberg and Shimamura, 1993; Wheeler et al., 1995; see Buckner and Wheeler, 2001, for a review). The parahippocampal region also plays a crucial role in episodic memory by combining multimodal representations of stimulus details in neocortical areas to form representations of individual items and contextual elements (see Eichenbaum et al., 1994, for a review). These elemental representations in parahippocampal areas would then be combined in the hippocampus to form episodic memories by encoding individual experiences with the context in which they were experienced. Such representations in the parahippocampal region are also thought to underlie nonepisodic recognition memory based on a sense of familiarity, by allowing comparisons between a recently presented item and the current item (Suzuki et al., 1993; Stern et al., 1996; Henson et al., 2003).

1.21.2.4 Conclusions

The idea of multiple memory systems has now gained wide acceptance, and considerable evidence suggests that these memory systems are fundamentally similar across mammalian species. However, the episodic memory system was initially thought to be unique to humans because of its dependence on human-centric faculties such as self, mental time travel, and consciousness. This section reviewed the fundamental features of episodic memory that can be operationally defined and tested in nonhuman animals as well and presented accumulating evidence from behavioral and electrophysiological studies demonstrating that animals are capable of episodic memory, and that, as in humans, this capacity depends on the integrity of the hippocampus. These findings suggest that we are making considerable progress in developing an animal model of episodic memory function, which will help uncover its underlying neuronal mechanisms.

1.21.3 Reconciling the Role of the Hippocampus in Navigation and Episodic Memory

In the service of clarity, this chapter has described the capacities for navigation and episodic memory separately, which parallels the relative independence of the two respective domains until recently. However, accumulating evidence indicates that the two capacities are related. As mentioned in the previous section, the role of the hippocampus in episodic memory can be responsible for deficits observed in a number of spatial paradigms, such as those requiring the animal to remember the trial-unique locations where specific events occurred (Olton and Papas, 1979; Steele and Morris, 1999; Day et al., 2003), though such an account fails to fully capture the extent of all navigational deficits reported in subjects with damage to the hippocampus. In fact, other navigational deficits appear to result from a failure to create a trial-independent mental representation of the environment that the subject can use to navigate flexibly (e.g., a stable cognitive map of a particular environment), suggesting that the hippocampus is critical for some aspects of semantic memory as well.

A careful review of the literature confirmed that subjects with hippocampal damage are indeed impaired at creating a stable memory structure that supports *flexibility* of access and expression, but, more importantly, also revealed that this deficit extends to memories of both spatial and nonspatial nature

(Eichenbaum and Cohen, 2001). For instance, animals with hippocampal damage can use simple strategies to solve spatial tasks, such as learning to approach a specific set of stimuli, but are severely impaired compared to controls when the start location or the destination is changed and a novel trajectory must be conceived (Eichenbaum et al., 1990; Whishaw et al., 1995; Whishaw and Tomie, 1997). Similarly, hippocampal rats perform as well as controls in nonspatial paradigms that require learning of consistent and nonambiguous reward or response associations to individual cues, such as discrimination learning (e.g., learning to select the always-rewarded item 'A' over the never-rewarded item 'B'; e.g., Dusek and Eichenbaum, 1998; Kesner et al., 2002) and recognition memory tasks (e.g., learning that item 'C' was presented earlier in the session, but that item 'X' was not; Dudchenko et al., 2000; Fortin et al., 2002), but are impaired when required to process relations among individual stimuli and use such information in novel situations (e.g., Bunsey and Eichenbaum, 1996; Dusek and Eichenbaum, 1997). For instance, in the transitive inference task, hippocampal rats could learn a series of discriminations involving overlapping elements as well as control animals (i.e., A > B, B > C, C > D, D > E; in which '>' corresponds to 'must be selected over'). However, when confronted with novel pairings (e.g., B vs. D), only control animals could successfully process the relations among all individual items (A > B > C > D > E) and correctly identify the indirect relationship between the items (i.e., B > D; Dusek and Eichenbaum, 1997).

1.21.3.1 Cognitive Maps as Semantic Knowledge Structures Extracted from Individual Episodic Memories

Although aspects of semantic memory can be learned without the hippocampus (e.g., Vargha-Khadem et al., 1997), the hippocampus appears to be important for the process of developing relations among individual episodic and semantic memories, crucial to support the flexibility of declarative memory representations (Eichenbaum et al., 1999; Eichenbaum, 2004). According to the relational theory of hippocampal function, this process occurs by linking common elements between individual memories (e.g., a location, or a person), which ultimately leads to the creation of the large multidimensional relational network of declarative memories (Cohen, 1984; Eichenbaum et al., 1999; Eichenbaum, 2004). According to this model, spatial representations of the environment, or cognitive maps, are simply one type of semantic knowledge represented in the network.

How are mammals creating cognitive maps of their environment to optimize navigational behavior? In humans, there are two ways to create a mental representation of a specific environment (Shelton and McNamara, 2001). The first is to use a 'survey' strategy, which is characterized by an external perspective, such as a bird's eye view, and allows direct access to the global spatial layout. This strategy is predominantly used when subjects are studying an actual map to learn the layout of the environment. The alternative is a 'route-based' strategy, which is characterized by knowledge of spatial layout from the perspective of a ground-level observer navigating the environment. In this case, initial knowledge is represented as individual trajectories or routes (e.g., airport → hotel, hotel → convention center, convention center → restaurant, restaurant → hotel), but with enough experience with routes within a specific environment, subjects can successfully construct a maplike representation out of those individual routes (or episodic memories).

Since most mammals do not have access to aerial views of their environment, nor have the capacity to read a map, it is clear that the survey strategy is not common to all mammals. The route-based strategy, in contrast, takes advantage of the instinctive behavior of mammals to actively explore their environment (O'Keefe and Nadel, 1978) and uses the same circuitry in humans as it does in animals. In fact, in a recent functional neuroimaging study, the survey representation was shown to activate inferior temporal and posterior parietal regions, suggesting that such information is acquired as complex visual scenes, whereas the route-based strategy recruited regions not activated in survey encoding, including the hippocampus and parahippocampal region (Shelton and Gabrieli, 2002). The strong consistency in data on route encoding from studies on hippocampal neuronal firing patterns in rats and hippocampal activation in human functional imaging support the notion that hippocampal representations of space, like those for nonspatial memory, are created from individual sequences of events and places where they occur (see **Figure 13**).

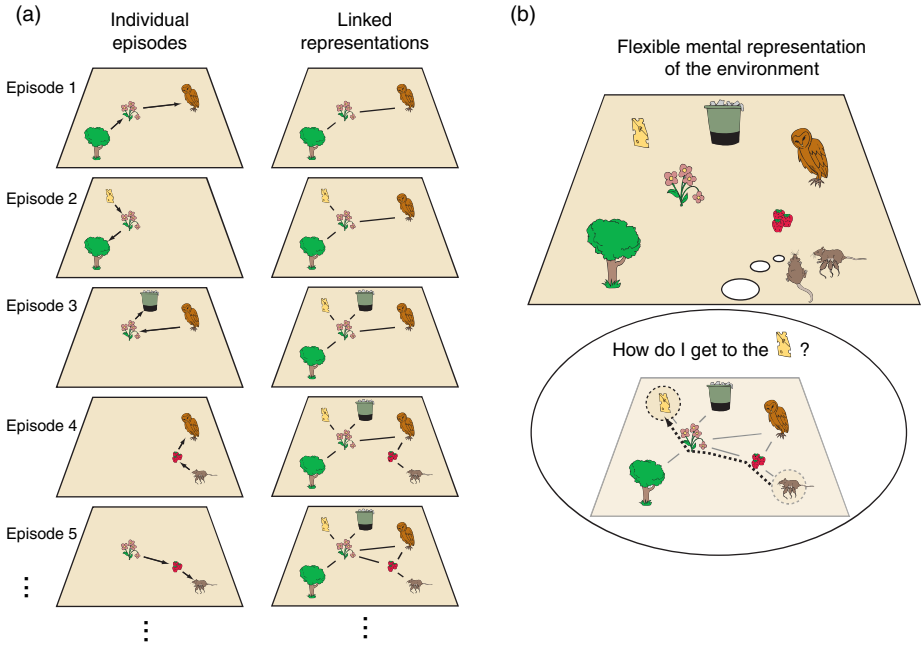

Figure 13 Cognitive map of the environment built out of individual episodes. (a) The column on the left represents individual episodes, each consisting of a particular trajectory in the animal's environment. The column on the right shows the representation that gradually forms as the common features between individual episodic memories (in this case, locations) are linked together. (b) After extensive experience in the environment, the linked representations can support flexible navigation by allowing the animal to determine a novel trajectory between two known points.

1.22 Memory in Food Caching Animals

A. C. Kamil, University of Nebraska-Lincoln, Lincoln, NE, USA

K. L. Gould, Luther College, Decorah, IA, USA

1.22.1 Introduction

One of the more interesting developments in the study of learning and cognition over the past 25 years has been the realization that learning and memory play an important role in the natural world of many animals (e.g., Balda et al., 1998). As this realization led to research into animal cognition in natural settings, it became clear that such research can make important contributions to our understanding of animal and human cognition. In this chapter, we review one of the areas of research that originally stimulated interest in the role of memory in the field, the ability of many food-storing animals to remember where they have cached their food (*See also* Chapter 1.23).

We will begin our review of research in this area with a brief review of the natural history and ecological significance of food-caching. We will then review the evidence demonstrating the use of memory for accurate cache recovery, followed by a discussion of the characteristics of cache site memory and the comparative evidence for differences in memory among

caching and noncaching species. We will conclude with reviews of how caching animals encode spatial information and the neural substrates for spatial memory in caching animals.

1.22.2 The Natural History of Food Storage

Animals face many problems obtaining food. Food may vary in abundance on a daily or seasonal basis, or even unpredictably, in boom–bust cycles. Even when food is abundant, there may be fierce competition for access to the food. And animals have evolved a number of strategies to cope with these problems, such as migration, hibernation, and torpor to deal with variability and food-caching and/or territoriality to deal with competition. Food hoarding is a strategy that can help an animal cope effectively with both variability in food availability and competition. By gathering food and hiding it, an animal can simultaneously store food against lean times and gain control over food against competitors.

Food storing takes many forms, from the nest of eusocial bumble bees to the grain silos of the human farmer (see Vander Wall, 1990, for a comprehensive review). The food storage patterns seen in nature vary considerably in the degree of dispersion among caches. At one extreme is larder-hoarding, in which food is gathered during times of plenty and placed into one or a few large larders. The hive and honeycombs of the honey bee (*Apis mellifera*), the granaries of acorn woodpeckers (*Melanerpes formicivorus*), or the middens of red squirrels (*Tiamiasciuris hudsonicus*) are excellent examples of this type of food storage. Once created, of course, these large caches require defense against competitors. Indeed, it would appear that one of the potential disadvantages of larder-hoarding is that loss of a larder incurs high cost to the original hoarder, since each larder site contains a large proportion of the animal's stored food.

The other extreme, in which food is stored in a large number of widely dispersed locations, is referred to as scatter-hoarding. Examples include fox squirrels (*Sciuris niger*), which store many of their walnuts singly; chickadees and tits, which store single seeds in moss and crevices; and nutcrackers, which store one to 14 pine seeds in each cache site. Larder- and scatter-hoarding define a continuum, not a dichotomy, and some mammals such as fox squirrels and yellow pine chipmunks (*Tamias amoenus*) store both singly and in larders (Vander Wall, 1990). These two storage strategies require quite different defense strategies. The scatter-hoarder creates more caches, each containing less food, over a much larger area than does the larder-hoarder. The caches of a scatter-hoarder cannot be physically defended since they are highly dispersed, but the loss of any single cache site is much less significant for the scatter- than for the larder-hoarder. But scatter-hoarding does raise an interesting question, with intriguing cognitive possibilities. How does the scatter-hoarder relocate the large number of cache sites it has created?

Logically, there are three general classes of answer to this question. We present them in decreasing order of the cognitive demands needed for hoarders to successfully recover their own caches.

1. Memory for cache sites: If the hoarder could remember individual cache sites, it could then use this memory to recover the caches. This would, however, require considerable memory capacity.
2. Site preferences or movement rules: Suppose an animal had certain locations that it preferred to visit or specific paths which it regularly followed, then stored food in those locations or along those paths. If it searched those places, it would be able to find the stored food at a much greater rate than could be achieved by random search. This strategy would require that the animal remember the preferred sites or paths, but it would not be necessary to remember individual cache sites. If, however, the site or path preferences could be learned by an observing competitor, then the potential for loss would be great.
3. Direct cues: The hoarder could relocate its food through detection of cues (such as odor) emanating directly from the cached food itself. While this recovery mechanism would require little cognitive ability except perhaps specialized sensory capacities, it would have a large potential downside. Any animal capable of detecting the cues could recover the cache, with potentially disastrous effects for the animal that originally created the cache.

Interestingly, there appears to be a negative correlation between the cognitive demands of the strategy and the resistance of the strategy to competitors for the caches. This implies that under appropriate conditions – a high risk of loss of scatter-hoarded food – the use of increased cognitive capacities might be favored, even though

cognitive abilities involve heavy metabolic costs (Attwell and Laughlin, 2001).

The results of a field study of cache recovery and pilfering in small mammals (Vander Wall, 2000) is quite interesting from this point of view. Vander Wall allowed some yellow pine chipmunks (*Tamias amoenus*) or deer mice (*Peromyscus maniculatus*) to cache pine seeds in a large outdoor cage and then search for their own caches (knowledgeable foragers), while additional animals searched for caches created by others (naive foragers). The experiment was conducted in the Carson mountain range of western Nevada, where the climate is usually quite dry. Under dry conditions, knowledgeable animals were much more successful finding their own caches than naive animals searching for the caches of others. When conditions were wet, such as following rain, however, the chipmunks and mice found all caches, their own, those of conspecifics, or those of the other species, with equal facility (**Figure 1**). The superiority of the knowledgeable over the naive cachers under dry conditions demonstrates the advantage that detailed spatial memory can give. On the other hand, the ability of the naive foragers to locate the caches created by others demonstrates the potential liabilities of relying on direct cues to relocate cache sites.

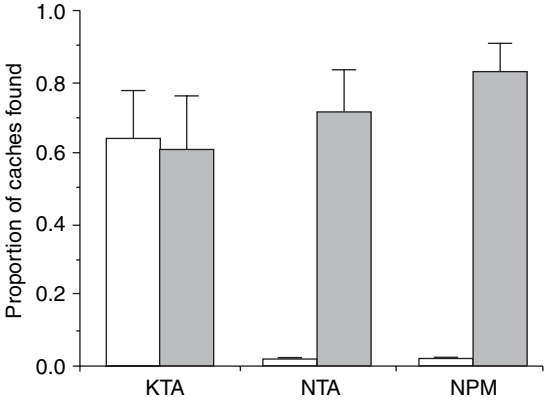

Figure 1 The proportion of caches found by yellow pine chipmunks (TA) and deer mice (PM) who either knew the locations of the caches (K) or were naive about the cache locations (N) under either dry conditions (open bars) or wet conditions (filled-in bars). From Vander Wall SB (2000) The influence of environmental conditions on cache recovery and cache pilferage by yellow pine chipmunks (*Tamias amoenus*) and deer mice (*Peromyscus maniculatus*). *Behav. Ecol.* 11: 544–549; used with permission from Oxford University Press.

1.22.3 Establishing the Role of Memory

Until recently, it was thought unlikely that scatter-hoarders used spatial memory for the recovery of cached food (e.g., Gibb, 1960). Gradually, however, evidence mounted that spatial memory for specific cache sites could be important to accurate cache recovery in a number of species of birds and mammals. Field studies provided suggestive evidence. For example, Tomback (1980) developed a technique for roughly estimating the accuracy of cache recovery by Clark's nutcrackers (*Nucifraga columbiana*) in the field. Tomback's estimated probabilities were quite high, much higher than could be expected by chance. In another field study, Cowie et al. (1981) placed mildly radioactive seeds in a feeder, and they were taken and cached by marsh tits and a scintillation counter used to locate cached seeds in the area around the feeder. A control seed was then placed 100 cm from each cached seed and survivorship of the seeds monitored. The cached seeds disappeared much more rapidly than control seeds, strongly suggesting removal by cachers and consistent with memory for specific cache sites.

MacDonald (1976) conducted similar experiments with a vixen, which almost always found dead mice she had cached but almost never found dead mice cached 1–2 m away by the experimenter.

1.22.3.1 Experimental Evidence for Spatial Memory

Although these types of field studies yielded results consistent with the use of spatial memory for specific cache sites, field studies lack the capacity for experimental control necessary to fully rule out alternative hypotheses. The breakthrough came with a series of laboratory studies that showed that many parids and corvids would cache and recover seeds under laboratory/aviary conditions. In this section, we briefly review the major findings of some of these studies that established the role of spatial memory in the relocation of cached foods.

Balda (1980) tested a single Eurasian nutcracker (*Nucifraga caryocatactes*) in a room with a dirt floor. The bird readily cached and accurately recovered seeds in this room. The search was accurate even when seeds had been removed from caches before recovery, demonstrating that cues emanating directly from caches were not necessary for recovery. Vander

Wall (1982) extended these findings by letting two Clark's nutcrackers individually cache and recover cached seeds in the same aviary. In virtually every case, each bird recovered only its own caches. This also provides strong evidence against direct cues, as well as against site preferences or paths unless these are idiosyncratic.

At the same time as studies were proceeding with nutcrackers, researchers in Canada and England were developing laboratory-based procedures to study cache recovery in chickadees and tits. Sherry et al. (1981) gave marsh tits (*Parus palustris*) sunflower seeds to store in moss-filled trays in an aviary. The birds revisited the areas of the trays used to cache seeds significantly more often than would be expected by chance 3 and 24 h after original storage of the seeds, even though the seeds had been removed. Sherry et al. (1981) also found that the probability of visiting those quadrants in which cache sites were located was higher following caching than it had been during a precaching exploratory session, suggesting that site preferences were not responsible for the performance. Sherry (1984) extended these results in an aviary study with black-capped chickadees (*Parus atricapillus*) by giving the birds specific potential cache sites (as opposed to areas in a tray). The chickadees cached readily in these sites and recovered the caches more accurately than would be expected by chance or by precaching exploratory patterns.

Kamil and Balda (1985) took a more direct approach to the control of site preferences during cache recovery by Clark's nutcrackers. They used a room with 180 holes in the floor, each of which could either be filled with sand for caching/recovery or be capped with a wooden plug. This made it possible to limit the number of sites available for caching sessions, forcing the birds to cache in sites essentially chosen by the experimenters. Even under these conditions, nutcrackers were able to recover caches accurately, demonstrating that site preferences are not necessary to accurate cache recovery by nutcrackers.

Three studies in the early 1990s demonstrated the use of spatial memory to relocate caches in scatter-hoarding rodents. Jacobs and Liman (1991) had gray squirrels cache hazelnuts in an outdoor arena. The squirrels found significantly more of their own caches than the caches of other squirrels that had stored food in the same arena. Vander Wall (1991) allowed yellow pine chipmunks to cache seeds in an arena filled with dry sand. The chipmunks were significantly more likely to find their own caches than caches of other chipmunks. Jacobs (1992) allowed Merriam's kangaroo rats to cache and retrieve sunflower seeds in an arena with plastic cups filled with sand for caching sites (much like Kamil and Balda, 1985). Before retrieval, she removed half of the caches made by each rat. The rats searched significantly more in locations where they buried seeds, whether the seeds had been removed or not. Jacobs also found that a naive rat searching in the arena found significantly fewer caches than the rat that had made the caches.

It is clear that some form of spatial memory for cache sites is used to find cached seeds by members of several taxa (see Vander Wall, 1990, for a broad survey of food-hoarding in animals). Although other mechanisms such as olfaction or site preferences may play a role, many food-storing corvids and parids and rodents can find their food when these mechanisms are controlled for or eliminated. We now turn our attention to what is known about spatial memory in food-storing species.

1.22.3.2 The Characteristics of Cache Memory and Retrieval

It seems likely that the characteristics of cache site memory in any particular species of scatter-hoarders will be a function of a complex interaction between functional and mechanistic variables. For example, as caches are created, they are necessarily created in some sequence. A large psychological literature indicates that in the case of such serial lists, the order in which the items to be remembered are presented can have important effects on how well they are remembered, the serial position effect well known to students of memory (e.g., Wright et al., 1984; Wright, 2006). On the other hand, different orders of recovery may be most adaptive under different circumstances (Andersson and Krebs, 1978). Duration of memory may be another example. In this section, we briefly survey what is known about the duration, contents, and dynamics of cache memory.

1.22.3.2.1 Memory duration

Balda and Kamil (1992) tested four groups of nutcrackers, each at a different amount of time after caching, from 11 to 285 days. All four groups performed well above chance levels. Bednekoff et al. (1997a) used a repeated-measures design in a comparative study with nutcrackers, pinyon jays (*Gymnorhinus cyanocephalus*), Mexican jays (*Aphelocoma ultramarina*), and Western scrub jays (*A. californica*; note that the classification of *Aphelocoma* species was

modified several years ago; we use the current nomenclature throughout this chapter) and found that the birds were still performing above chance after 250 days. In contrast, most studies with parids have suggested much shorter memory durations. For example, Hitchcock and Sherry (1990) found that black-capped chickadees did not find their caches at better than chance levels after postcaching intervals over 28 days, and Brodin and Kunz (1997) obtained similar results in willow tits (*Parus montanus*).

These differences in memory duration correspond with differences in natural history. Many corvids cache in the fall and then depend on their cached food throughout winter into the spring (Vander Wall, 1990). In contrast, within the parids many species cache for shorter periods of time, caching and recovering throughout the winter (e.g., marsh tits, *P. palustris*; Cowie et al., 1981), although there are some parids that cache in fall and use those caches for some months (e.g., crested tits, *P. cristatus*, Haftorn, 1954). Brodin (2005) has suggested that corvids possess a site-specific, accurate long-term memory, whereas parids may use a more general memory along with area-restricted search.

1.22.3.2.2 Memory for cache contents

Several studies indicate that cachers can remember the contents of their caches. Sherry (1984) allowed black-capped chickadees to cache two types of seed and found that they recovered the type they preferred before the nonpreferred type. Clayton and Dickinson (1999) extended this methodology by allowing Western scrub jays to cache two types of food, then prefeeding one of the foods before recovery testing. During recovery, the birds preferentially searched sites in which they had cached (but not retrieved) the food that had not been preferred (*See* Chapter 1.23, research by Clayton and her colleagues on episodic-like memory). This suggests a memory process more dynamic than a simple association of foods and the locations of their caches.

Moller et al. (2001) gave Clark's nutcrackers small and large pine seeds to cache and videotaped recovery sessions. They measured the size of the gape, the distance between the upper and lower bills when beginning to dig out the cache. Gape size was reliably larger for caches containing the larger seeds than for caches containing the smaller seeds.

1.22.3.2.3 Order of recovery

As a number of authors have pointed out (e.g., Vander Wall, 1990), since caches are created sequentially, the psychological literature on memory suggests that there ought to be some relationship between order of cache creation and order of cache recovery, either primacy (first recovering the caches that were created first) or recency (first recovering the most recently made caches). Psychological studies of memory for serial lists regularly find both of these effects in a wide variety of contexts in humans and animals (see recent review by Wright, 2006).

It has also been argued on functional grounds that there should be recency effects in cache recovery (e.g., Shettleworth and Krebs, 1982). The more time that has passed since a cache was created, the less likely that cache is to still be available to the cacher. As time passes, the probability of the cache having been pilfered increases and the chances of the cache location having been forgotten also may increase. Thus, recovery of the most recent caches first could maximize the total number retrieved. There has, however, been no consistent evidence of such effects. For example, when black-capped chickadees stored and recovered sunflower seeds in Sherry (1984, experiment 2), 24 correlation coefficients between cache and recovery orders were calculated. Two were significant in the positive direction, one was significant in the negative direction, and the remainder were not significant.

In a comparative study with Clark's nutcrackers, pinyon jays, and western scrub jays, Balda and Kamil (1989) calculated 42 correlation coefficients between cache order and recovery order. Twenty-five were above zero, one equaled zero, and the remaining 16 were below zero. Six of the positive correlations were significant, as was one of the negative correlations, indicative of a tendency toward recency effects, which was not statistically significant overall.

1.22.3.2.4 Proactive and retroactive interference

Serial position effects are often interpreted as due to the effects of interference, at least in part (see Shettleworth, 1998, for discussion; *See also* Chapters 1.06, 1.10). Two types of interference are generally recognized. If the target information was experienced before the interfering information, the effects of the interfering information are called retroactive interference. If the target was experienced after the interfering information, it is called proactive interference. As might be expected from the failure to find strong serial-position effects during cache recovery, attempts to document retroactive and proactive interference during caching have also yielded only

weak evidence for such effects. Bednekoff et al. (1997b) explicitly tested for interference in nutcrackers' cache memory by allowing caches to be made at different times. They found no evidence of interference between the two sets of caches.

Experiments using techniques other than cache recovery have found clear evidence for interference effects in parids and corvids. For example, when black-capped chickadees were presented with three-item lists in an operant associative task, they showed clear primacy and recency effects (Crystal and Shettleworth, 1994). And when Lewis and Kamil (2006) gave Clark's nutcrackers separate lists of locations to remember, they showed clear retroactive and proactive interference effects between the lists. These results raise the question of why such effects are weak in cache recovery but prevalent with other measures of memory performance.

1.22.3.2.5 Dynamism of memory

As caches are recovered, an additional problem arises: not only are there caches to remember but there are emptied caches to avoid. Do cachers avoid revisiting sites which have been emptied? Sherry (1982) examined this question by allowing marsh tits to cache in moss-filled trays then recover about half these caches 3 h later. Twenty-four hours after the initial caching, he allowed the tits to recover more caches. The birds clearly made more visits and spent more time at sites which had been cached in but not recovered from than sites that had been cached in and recovered from. Sherry (1984, experiment 2) obtained similar results in black-capped chickadees.

Frequent revisits to emptied cache sites have been observed in Clark's nutcrackers (e.g., Balda, 1980; Kamil and Balda, 1985). These studies, however, were not primarily intended to measure revisit probabilities against appropriate controls, so the implications of the frequent revisits were not clear. Balda et al. (1986) found that revisits to emptied caches by nutcrackers were much more frequent than expected by chance, and that revisit probability was not affected either by leaving signs of previous recoveries on the surface of the sand around cache sites or by reducing the number of seeds in a cache.

From a functional perspective, these observations are a puzzle since revisits increase foraging effort and may also increase predation risk. These considerations led Kamil et al. (1993) to take another look at revisits by Clark's nutcrackers, using a technique which allowed independent estimates of search accuracy and of preference. When they tested sites with cached seeds (good sites) vs. sites with cached seeds that had been removed by the birds (old sites) vs. holes that never had seeds in them (bad sites), the results clearly demonstrated that nutcrackers treated old sites differently than good sites. When they visited a cluster that contained an old site, they probed more of the alternative sites than when they visited good sites that contained seeds. In addition, they visited clusters containing good sites earlier than those containing old sites. They also found that old sites were visited earlier than clusters containing bad sites. Once the good sites have been exploited, the birds are more likely to visit old sites where they cached and then removed seeds than to visit bad sites that never contained seeds.

1.22.3.2.6 Are all caches created equal?

In the Balda and Kamil (1992) study of long-term memory for cache sites, the group of birds tested at the longest cache-retrieval interval showed an interesting pattern of errors. Their error rate per recovery was approximately equal to that of the groups with the shorter retention interval until about 75% of their caches had been recovered. After that, they began to make more errors. This pattern suggested that after 280 days, the nutcrackers had begun to forget some of their cache locations and had recovered those that they remembered most accurately first.

Kamil and Balda (1990) controlled the order of cache recovery by covering the floor in one-quarter of the caching room with canvas. Over four recovery sessions, each quarter of the room was covered once. The accuracy of recovery of this group was compared to that of a control group for whom all cache sites were always available. As predicted, the experimental group showed an initial recovery accuracy that was lower than that of the controls. But this accuracy level was constant over the four sessions, whereas the accuracy of the controls declined, so that during the fourth session the experimental group was more accurate than the controls. This clearly supports the hypothesis that some sites are remembered better than others, and then recovered first.

1.22.3.3 Coding of Cache Site Locations

When a scatter-hoarding animal remembers sites at which it has stored food, just what is it about the cache location that is remembered? Just how is the location encoded in memory? This raises basic questions about orientation and navigation. There is

an enormous literature on the cues that animals in a wide variety of taxa use to find locations during, for example, foraging, homing, or migration (*See* Chapters 1.12, 1.20, 1.25). In this section we will focus on studies that relate to how caching animals use landmarks to find locations and divide our review into studies that study cache recovery and studies that use other techniques.

1.22.3.3.1 Landmark use during the recovery of stored food

Many studies have demonstrated that landmarks play a crucial role in accurate cache recovery. For example, animals have been tested for their ability to find their caches when most or all of the landmarks present during caching have been removed from the caching area during recovery testing. If landmarks are important, this should produce substantial decrements in the ability to relocate caches, and it does (e.g., nutcrackers, Balda and Turek, 1984; parids, Herz et al., 1994). Barkley and Jacobs (1998) took a slightly different approach, allowing Merriam's kangaroo rats to cache and recover with either no or with many landmarks present. While the number of landmarks had no effect after a 1-day retention interval, there were large effects after 10 days. The kangaroo rats that had cached and recovered with no landmarks performed at much lower levels than those who had cached and recovered with 16 landmarks present. While such studies establish the role of landmarks in cache recovery, they tell us little about what mechanisms might be used. Few studies, however, have attempted to determine the mechanisms that are used during cache recovery.

The first attempt to do so of which we are aware was by Bossema and Pot (1974). They compared the routes used by individual Eurasian jays (*Garrulus glandarius*) when making and recovering caches. They found that the jays tended to use the same route during recovery as during caching more often than would be expected by chance. Bossema and Pot suggested that the birds used a snapshot of the scene from the cache site when they cached, then matched what they saw to the snapshot during recovery.

Kamil et al. (1999) found the Bossema and Pot interpretation unconvincing. There are many other reasons that could result in use of the same path during caching as during recovery. They conducted an intensive videotape study of movement patterns by nutcrackers during caching and recovery, using a technique that allowed estimates of the accuracy of recovery of each individual cache. Like Bossema and Pot (1974), Kamil et al. (1999) found that the birds tended to frequently use the same path during caching and recovery, but differing paths and body orientations were also often used. Because their procedure allowed cache-by-cache estimates of accuracy, Kamil et al. (1999) were able to determine the effect of consistency of direction on recovery accuracy. There were none: Birds were equally accurate regardless of the path used. This result argues directly against the snapshot hypothesis.

Bossema (1979) looked at the locations of caches and the accuracy of recovery relative to the positions of landmarks. He found that Eurasian jays cached more near vertical objects and were more accurate at retrieving their caches when vertical objects were available as beacons, as opposed to horizontal objects. Similar results have been found in studies in which caching animals have been trained to find food in specific locations (see following). In a second test, he taught the birds to find hidden food in a specific spatial location relative to two vertical landmarks. He performed tests in which one landmark was removed or the landmarks were moved further apart or closer together. From these tests, he concluded that the jays were using the distance between the spatial location and the line between the landmarks to orient.

Vander Wall (1982) took a different approach. After Clark's nutcrackers had cached food in an arena with an array of landmarks, he displaced the landmarks in one half of the room 20 cm from their original location during cache recovery (**Figure 2**). During the subsequent recovery session, the birds shifted their searching approximately 20 cm in the direction of the displacement in that half of the room. When the birds searched for caches made in the center of the room, where some of the nearby landmarks had been displaced and others had not, their search was displaced approximately 10 cm in the direction of the displacement. This suggests that the birds were integrating information from multiple landmarks (shifted and nonshifted) and searching at some kind of averaged location.

One of the ways to use landmarks to find a location is to use the directional relationship between the cache site and one or more landmarks (e.g., Kamil and Cheng, 2001). The use of directional information requires a compass. In a series of studies, Wiltschko and Balda (1989) and Wiltschko et al. (1999) have used clock-shift procedures in outdoor aviaries to demonstrate the use of a sun compass by scrub jays and nutcrackers. For example, Wiltschko and Balda (1989) had scrub jays cache in a 90° sector of a

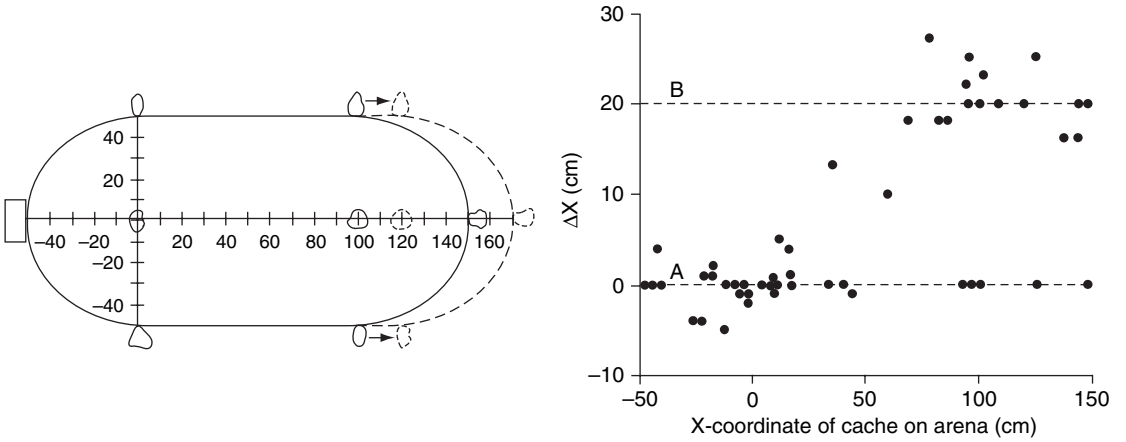

Figure 2 The left panel shows the caching arena during control (solid lines) and during landmark-shift (dashed lines) conditions. The right panel shows the distance between a probe and the nearest cache on the y-axis as a function of the original position of the cache in the x-axis. If the birds followed the shift, a Δx score of 20 cm would be expected. Reprinted from Vander Wall SB (1982) An experimental analysis of cache recovery in Clark's nutcracker. *Anim. Behav.* 30: 84–94, copyright 1982, with permission from Elsevier.

circular outdoor arena and then recover after being clock-shifted 6 h. When clock-shifted, the search was concentrated in an adjacent 90° sector, as would be expected if the sun compass was being used. Although these experiments clearly establish the use of sun compass under some conditions, caches can be recovered in the absence of information from the sun (e.g., indoors). Furthermore, when multiple landmarks are used to encode locations, clock shifts should produce conflicting effects (Kamil and Cheng, 2001).

Another issue that has been investigated both during cache recovery and during other tests of spatial memory in seed-caching animals is the relative importance of local versus global (or distal) cues. Local cues are those located relatively close to the goal location, while global or distal cues are generally larger, but further away. Several studies have found that birds seem to have some preference for caching near objects in the environment, suggesting that local cues may be quite important (e.g., Bossema, 1979). On the other hand, Balda et al. (1986) found that Clark's nutcrackers ignored local cues on the surface when making revisits to cache sites. The results of Herz et al. (1994) suggest the importance of global cues. Black-capped chickadees stored food on artificial trees placed within a symmetrical enclosure that had large global cues on each wall. There were unique color place cues located by each potential cache site. The removal of the place cues did not affect retrieval accuracy, but when the global cues were removed, search accuracy decreased. In a second study, when birds were only given global cues during caching, displacement of those cues during recovery produced a displacement of the search behavior. Watanabe (2005) has also shown the importance of global cues in remembering cache locations in Western scrub jays.

Results from mammals also suggest distal cues are important. Lavenex et al. (1998) found that fox squirrels use distal environmental cues rather than proximal cues to find food in a field experiment. Even when proximal spatial information was available, the squirrels chose to use the environment surrounding the apparatus to gain spatial information, presumably directional information or bearings. Jacobs and Shiflett (1999) devised an outdoor vertical maze to mimic the vertical structure of the squirrel's environment. They found that fox squirrels used distal cues to orient within this maze as well.

1.22.3.3.2 Landmarks and the coding of spatial locations

Cache recovery procedures are very limited for studies on how cachers encode spatial locations. As several of the studies reviewed suggest, the geometrical relationships among landmarks and between landmarks and the location of a cache are important. But it is very difficult to control location-landmark geometry when the caching animal is free to cache throughout the test arena. Therefore, many investigators have used procedures in which animals are trained to find buried food in a location defined by a set of local/global landmarks or other cues.

Bennett (1993a,b) trained Eurasian jays to find hidden food within an array of landmarks on the floor of an arena. The array consisted of landmarks that were either short or tall and either near or far from the hidden food location. He found that the birds relied more heavily on near, tall landmarks to find the food, a finding similar to that of Bossema (1979), described in the section titled 'Landmark use during the recovery of stored food.' This suggests that local cues are most important, especially if tall.

Other experiments, however, suggest that low horizontal features that define an edge can also be important. Cheng and Sherry (1992) trained black-capped chickadees to find food buried in a location defined relative to the locations of a cylindrical landmark and an edge (**Figure 3**). Then, when the landmark was shifted in a direction either parallel or perpendicular to the edge during probe trials, the birds followed parallel shifts more strongly. This was particularly clear during probe trials in which the landmark was shifted in a diagonal direction, which produced more parallel than perpendicular shifts in search. As Cheng and Sherry pointed out, these results suggest that perpendicular distance from an edge can serve as an important means of encoding spatial locations and are consistent with the results of Bossema (1979).

Similar studies with Clark's nutcrackers (Gould-Beierle and Kamil, 1996, 1998), pinyon jays, and scrub jays (Gould-Beierle and Kamil, 1998) have also found that the distance from an edge is important. In all three of these studies, birds found hidden food whose location was defined relative to the locations of an edge and a cylindrical landmark. As in the parids studied by Cheng and Sherry (1992), these corvids followed parallel shifts and shifted more readily in the parallel direction when given diagonal shifts. However, when the landmark was shifted in a direction perpendicular to the edge, nutcrackers, pinyon jays, and scrub jays did not shift their searching in that direction, in contrast to the results of Cheng and Sherry (1992).

Gould-Beierle and Kamil (1998) extended the conditions originally tested by Cheng and Sherry (1992) by testing the effects of varying the position and orientation of an edge and landmark across training trials with nutcrackers, pinyon jays, and scrub jays. Following this training, the birds were more sensitive to shifts in the position of the cylindrical landmark, shifting their search with each landmark shift to a much greater extent than birds trained with a nonshifting edge and landmark. The shifting of the relationship between the local cues (edge and cylinder) and the global cues (features of the room) appeared to result in a devaluation of both the global cues and distance from the edge. The extent to which distance from a line or edge is used thus depends upon the salience and location of other, more distal or global landmarks.

The relative importance of local versus more distal or global cues depends on context and on the distance between the local cues and the target location. Gould-Beierle and Kamil (1999) trained three groups of Clark's nutcrackers to find a hidden food site within an open room filled with wood chips. Two local cues were available near the food site, a cylindrical landmark and a horizontal piece of wood (much like the edge of a tray in previous studies). The groups varied in the distance the cylinder and edge were from the target location. They found that the

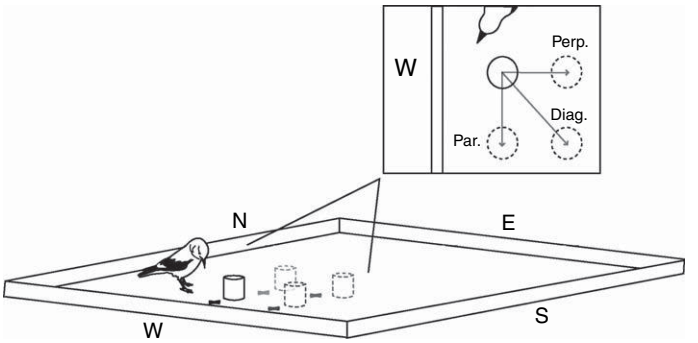

Figure 3 Typical setup (not to scale) for experiments on landmark displacement with an edge and a single landmark present. The birds are initially trained with the cylinder in the location indicated by the solid circle (top left in the inset). They are then tested with occasional nonrewarded trials at each of the three test positions, representing displacements perpendicular (Perp.), parallel (Par.), and diagonal (Diag.) to the long axis of the nearest edge. Drawing by Karina I. Helm.

group with these cues closest to the target used them more heavily to find the location, while the other two groups relied more on information from global cues within the room.

Goodyear and Kamil (2004) extended these results with a study in which different groups of Clark's nutcrackers were trained to find a buried seed at a location defined by an array of four landmarks, each of which was at a different distance from the goal, followed by probe tests with each of the individual landmarks. The groups differed in the mean distance from the landmarks to the goal location. For the group for whom the nearest landmark was quite close to the goal, the presence of the closest landmark had the greatest effect on search accuracy, an effect reminiscent of the overshadowing effect in Pavlovian conditioning (Gallistel, 1990). However, at longer goal–landmark distances, this overshadowing effect disappeared, and each landmark controlled search roughly equally.

Since geometry clearly affects search, there has been some interest in the ability of caching animals to directly learn geometric relationships. Kamil and Jones (1997) tested the ability of Clark's nutcrackers to learn a general geometric rule for spatial locations. They trained nutcrackers to find a seed that was always located halfway between two landmarks whose position in the room and interlandmark distance varied from trial to trial. The birds learned the task readily and searched extremely accurately when tested with new interlandmark distances. Follow-up studies demonstrated that nutcrackers could learn other geometrical rules (Kamil and Jones, 2000), including the use of relative bearings (Jones and Kamil, 2001). Comparative studies found that nutcrackers performed these tasks much more accurately than pigeons (Jones et al., 2002; Spetch et al., 2003).

One of the things that makes the location of cached food so interesting from a coding/navigation and orientation perspective is that successful cache recovery requires a very accurate search. Given the size of a nutcracker's beak and the size of pine seeds, for example, the bird must dig within 1–2 cm of the center of a cache in order to find it. This led Kamil and Cheng (2001) to hypothesize that nutcrackers encode the directional relationship between the goal and multiple landmarks. This was based on a combination of known features of search accuracy and a logical consideration. When nutcrackers are looking for a cache site that is not close to a landmark, the use of directional information results in a more accurate search than the use of distance information. But all compasses have error, and compensation for such error can be achieved by taking bearings to multiple landmarks. Although there are some data that support the model (Kamil et al., 2001), there are, as yet, insufficient data to fully evaluate the hypothesis.

1.22.4 The Evolution of Spatial Memory in Seed-Caching Animals

The capacity, duration, and dynamics of the memory that seed-caching animals use to relocate stored food seem quite impressive compared to the results of many studies of animal memory using standard psychological procedures such as the radial maze or matching-to-sample (*See* Chapters 1.20, 1.21, 1.23, 1.25, 1.26). This led to the development of the hypothesis that dependence on memory for the location of cached food would be associated with heightened memory abilities. This hypothesis, sometimes referred to as the ecological hypothesis, has led to many studies of memory comparing species that differ in their degree of dependence on cached food. We will divide our review of this literature by methodology, first discussing studies that used cache recovery as their measure of memory, then reviewing studies that used measures of spatial memory that do not depend on the caching and recovery of food.

1.22.4.1 Cache-Site Memory

There are relatively few comparative studies involving cache site memory. This is probably because such studies require the availability of a set of closely related species (or populations) which cache, but vary in some dimension of cache-related natural history, and there are few such instances. We are only aware of four such studies, two with corvids and two with parids.

Balda and Kamil (1989) compared the cache recovery accuracy of three corvid species that differ in their degree of dependence on stored food, Clark's nutcrackers, pinyon jays, and Western scrub jays, after a relatively short retention interval of 7 days. They found that the more cache-dependent species, nutcrackers and pinyon jays, recovered their caches more accurately and more rapidly than Western scrub jays. Bednekoff et al. (1997a) tested the same three species as well as Mexican jays after retention intervals of 10–250 days. They found that cache recovery performance of the two *Aphelocoma* species

(Mexican and Western scrub jays) was lower that that of the nutcrackers or pinyon jays, but that all four species performed with only modest accuracy levels (although still significantly better than chance) after the two longest retention intervals (of 150 and 250 days).

Healy and Suhonen (1996) compared marsh tits and willow tits. Willow tits live in harsher environments than marsh tits and are thought to retrieve their caches after longer retention intervals than marsh tits. In this study, however, no differences in the accuracy of cache recovery were found after either a short (1- to 2-h) or a long (17-day) retention interval. Pravosudov and Clayton (2002) compared two populations of black-capped chickadees, one from Alaska and the other from Colorado. They found that the birds from the harsher environment of Alaska cached more food and recovered it more efficiently than the birds from Colorado, demonstrating that different ecological pressures within this single species are correlated with differences in spatial memory ability. Thus three of these four studies found differences in cache recovery accuracy that were correlated with differences in dependence on stored food.

1.22.4.2 Noncache-Site Memory

Most comparative work on spatial memory involving scatter-hoarding species has been based on procedures that do not depend on caching. Such procedures are necessary to compare spatial memory between caching and noncaching species. In addition, data from such tests could address the question of just how specialized the spatial memory abilities of food-caching animals may be. A variety of techniques were applied, and we have organized our review of these comparative studies by the procedures used to test memory.

1.22.4.2.1 Window shopping

The window shopping task is probably the noncaching task most similar to cache memory. Instead of storing food in a location to be remembered, the bird encounters the seed, either behind a transparent window or a seed wedged into a small hole so tightly that it cannot be removed. Shettleworth et al. (1990) showed that memory for such encountered seeds appeared to be similar to that for stored seeds in black-capped chickadees and coal tits. Krebs et al. (1990) used the technique to test coal tits against nonstoring great tits. They found somewhat better performance in the storing coal tits. Coal tits were more likely than great tits to return to sites at which they had seen seeds. They were also better at discriminating between sites seen to contain seeds and those seen to be empty.

1.22.4.2.2 One-trial associative tasks

In one-trial associative tasks, two or more stimuli are all associated with a correct location. Following a single experience at that location, the subject is given test trials in which it chooses between the spatial location or the nonspatial stimuli (which are now presented in a new location; see **Figure 4**). A number of one-trial associative studies have used a variation of window shopping in which the bird finds food at a specific location which is also indicated by cues from an object. The bird is allowed to begin to eat, but is interrupted (removed from the experimental situation) before completely consuming the food. The test is to see where the birds will return to look for the seed, to the correct spatial location or the correct location based on object cues. In comparisons of food-storing and nonstoring species in both parid and corvid families (Clayton and Krebs, 1994), the food-storing birds (marsh tits and jays) went first to the correct spatial location, whereas the nonstorers (blue tits, *Parus caeruleus*, and jackdaws, *Corvus monedula*) went equally as often on their first choice to the correct spatial or object-specific location. When comparing food-storing chickadees to nonstoring dark-eyed juncos (*Junco hyemalis*), Brodbeck (1994) found similar results, with the chickadees responding preferentially to spatial cues and the juncos responding equally to spatial and object cues. These studies provide further evidence that food-storing birds focus heavily on spatial memory when returning to food sites.

In another variation on this theme, Brodbeck and Shettleworth (1995) placed spatial and object-related cues in conflict in the choice phase of test trials in a matching-to-sample experiment. With this technique, they found that while space was the first choice of food-storing chickadees, nonstoring juncos chose space and color equally. They also demonstrated that when shown a compound stimulus of both spatial location and color and tested on each element of the compound alone, chickadees performed better on the spatial element, while juncos performed equally well on both elements. This, along with the other one-trial associative memory experiments, demonstrates the importance of spatial information to food-storing birds.

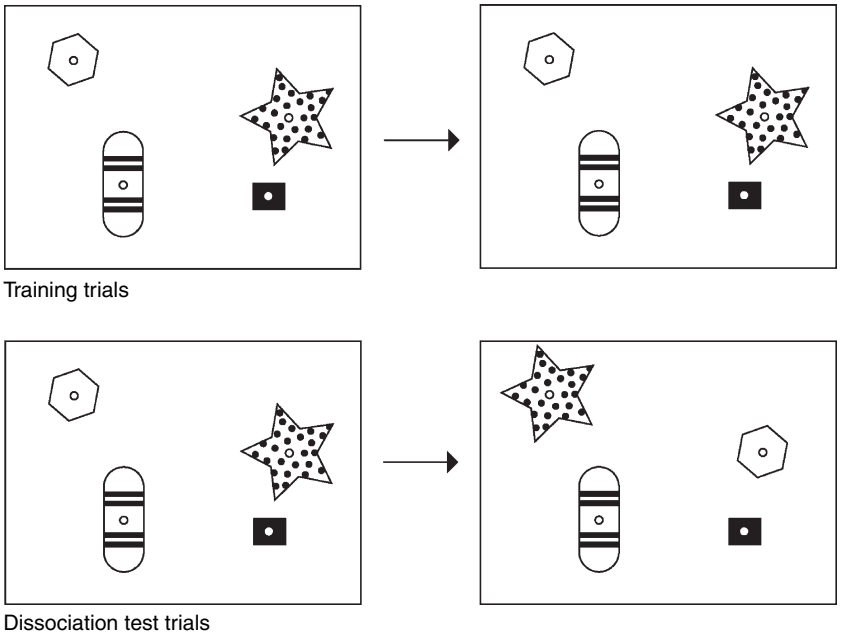

Figure 4 Diagrammatic representation of the logic of one-trial associative tasks. The top pair of figures shows training trials. One of the stimuli is randomly designated correct on each trial (with new, trial-unique stimuli used for each trial). The bird is then rewarded when it pecks the correct stimulus. The display then disappears for a retention interval, and the same display is presented for choice, and the bird is rewarded for pecking at the same stimulus. Once this training is complete, the bird receives occasional dissociation test trials, as shown in the bottom pair of figures. These trials differ from training trials in that the spatial locations of two of the stimuli are switched. If the bird pecks at the same visual stimulus (the dot-filled star, in this case), this indicates control by the stimulus. But if the bird pecks at the old location (the hexagon), it suggests spatial control. Spatial location and visual stimulus have been dissociated. Drawings by Karina I. Helm.

Lavenex et al. (1998) used an approach similar to that of one-trial associative tests in a field experiment. Although their training task involved multiple trials, they gave fox squirrels different spatial and nonspatial relational proximal cues that could be used to predict the locations of nuts buried by experimenters. The squirrels used spatial over nonspatial information to solve the task, even when both were available, a result similar to the results of laboratory one-trial associative experiments just reviewed.

1.22.4.2.3 Open-room radial maze

In an open-room radial maze procedure, Hilton and Krebs (1990) tested two storing parid species, two nonstoring parid species, and a nonstoring greenfinch in an open-room analog of the radial maze. They found decreasing performance as the retention interval increased from 30 s to 24 h. The food-storing tits (marsh and coal tits) performed above chance after 24 h, although the extent to which their performance exceeded chance was modest. In contrast, neither the nonstoring tits (blue and great tits) nor the finches performed above chance after 24 h.

Kamil et al. (1994) tested four corvids who vary in dependence on stored food in their version of an open-room analog of the radial maze. They found that the two species most dependent on stored food, Clark's nutcrackers and pinyon jays, acquired the task to higher levels than the less dependent species, Mexican and Western scrub jays. When retention intervals of 30–300 min were tested (in ascending order), the species differences tended to disappear as the retention interval got longer. Only the most dependent species, the nutcrackers, performed above chance after a 24-h retention interval, although, as in the marsh and coal tits, their performance was only modestly better than chance.

Gould-Beierle (2000) also tested four corvid species – nutcrackers, pinyon jays, Western scrub jays, and jackdaws – on a version of the open-room radial maze task. She included both a reference memory and a working memory component by having 12 holes in the floor, four of which were never correct while the other eight were used in the usual way as working memory locations. She found that pinyon jays and scrub jays performed better than nutcrackers

and jackdaws in both the working and reference memory aspects of the procedure. When looking at the first four searches in the maze, however, the nutcrackers performed as well as the two jay species in working memory and there were no species differences in reference memory. The performance of the scrub jays was not expected and suggests further exploration into the spatial memory abilities of this species. Perhaps combining both a working and reference memory task simultaneously affects spatial memory differentially in these species.

Barkley and Jacobs (2007) used an open-room task similar to a radial maze analog. They trained two species of kangaroo rat in a task in which the animal was shown four locations (randomly chosen out of 128) and then tested for their ability to remember the four 24 h later. One species was the scatter-hoarding Merriam's kangaroo rat (*Dipodomys merriami*), a species that hoards intensively. The other was the leaf-eating specialist Great Basin kangaroo rat (*D. microps*), which relies less on scatter-hoarding than Merriam's. Merriam's kangaroo rat performed considerably better than the Great Basin kangaroo rat on this task.

1.22.4.2.4 Operant tasks

A number of investigators have used several different operant tasks to measure differences in memory ability among storing species and between storing and nonstoring species. The most commonly used procedure has been spatial delayed nonmatching- or matching-to-sample. In this task, each trial consists of two parts: the presentation of the sample followed by the presentation of a choice test. Thus, for example, Olson (1989, 1991) had two keys on the front wall of an operant chamber. Each trial began with the illumination of one of those keys, chosen at random on each trial. After the bird had pecked at that key and moved to the back of the box to peck at another, single key located there (to break up any patterns of settling in front of the to-be-correct key), the bird was presented with two keys and rewarded only for pecking at the key that had not been pecked at earlier in the trial (nonmatching). Olson (1989) tested Clark's nutcrackers, scrub jays, and pigeons (*Columba livia*). Although all three learned the task with equal facility, the nutcrackers outperformed the other two species when the task was made more difficult by either titrating the delay between sample and choice test or by introducing multiple samples to be remembered.

These results were extended in a subsequent study (Olson et al., 1995) with nutcrackers, pinyon jays, scrub jays, and Mexican jays. In this study, a computer monitor and touch screen were used. When the delay interval was titrated, the nutcrackers performed at much higher levels than the other three species. After completing this spatial nonmatching test, the birds were then tested on an almost exactly equivalent nonspatial task. In this experiment, the samples could be either red or green and the bird had to remember the color rather than the location. Under these conditions, the ordering of the species changed completely, and none of the species differences were statistically significant (**Figure 5**).

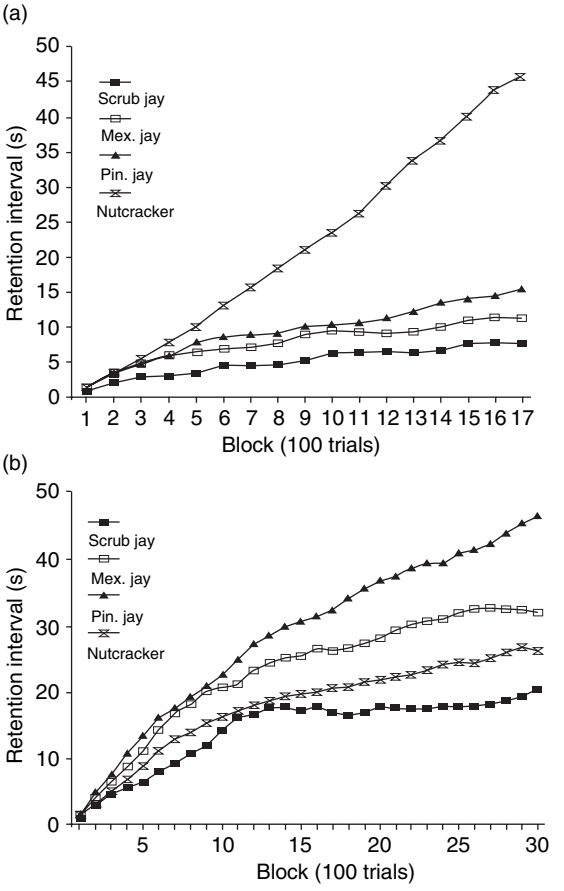

Figure 5 (a) Performance of scrub jays, Mexican jays, pinyon jays, and nutcrackers during spatial nonmatching-to-sample titration. (b) Performance of each species during color nonmatching-to-sample titration. Data are presented as averages of blocks of 100 trials. From Olson DJ, Kamil AC, Balda RP, and Nims PJ (1995) Performance of four seed-caching corvid species in operant tests of nonspatial and spatial memory. *J. Comp. Psychol.* 109: 173–181; used with permission from the American Psychological Association.

Healy and Krebs (1992) studied matching-to-sample in marsh tits and great tits, using a choice apparatus attached to the birds' home cage. The birds took a seed from the correct location, which was signaled both by location and by a visual object, then returned to their home cage to consume the object. They were then given a choice test, and the two species performed very similarly. The only significant different between the species was superior performance by the storing marsh tits early in acquisition of the task. Healy (1995) used a more traditional nonmatching-to-sample (NMTS) test on a computer monitor with four parid species, two storing species (coal and marsh tits) and two nonstoring species (blue and great tits). The birds performed well at retention intervals as long as 100 s, but there were no differences between the storers and nonstorers. This may have been due to the presence of spatial and nonspatial cues. It is also possible that storing and nonstoring tits perform similarly during matching-to-sample type procedures.

1.22.5 Neural Substrates

The central role of spatial memory in the recovery of scatter-hoarded food raises a number of questions about neural substrates. Which areas of the brain are used during cache recovery? What types of species differences in neural structure are associated with the evident differences between species in performance on cache recovery and other tests of spatial memory? In this section we review the literature relevant to these questions.

1.22.5.1 Role of the Hippocampus in Spatial Memory

O'Keefe and Nadel (1978) first proposed a central role for mammalian hippocampus in spatial memory. This hypothesis has been confirmed by experiments in many different laboratory tasks (*See* Chapters 1.33, 2.11). Most of these experiments, however, have been carried out in mammals, while most research on spatial memory in scatter-hoarders has been carried out in birds. What is known about the avian hippocampus (**Figure 6**)?

In this context, it is interesting to note that there is a radically new view of brain evolution and the structure of the avian cerebrum, a view that emphasizes the large number of avian–mammalian homologies (Jarvis et al., 2005). This view has led to a proposal for a radical revision of the nomenclature for avian cerebrum, a nomenclature that "better reflects these functions and the homologies between avian and mammalian brains" (Jarvis et al., 2005: 2). Research with scatter-hoarding birds and mammals is consistent with this revision. The dorsomedial region of the avian telencephalon has been shown to be homologous to the mammalian hippocampal formation in many regards. This includes connectivity (Krayniak and Siegel, 1978; Casini et al., 1986; Szkeley and Krebs, 1996), distribution of neuropeptides and neurotransmitters (Erichsen et al., 1991; Krebs et al., 1991; Gould et al., 2001), generation of long-term potentiation (Shapiro and Wieraszko, 1996) and a theta rhythm (Siegel et al., 2000), electrophysiology (Siegel et al., 2002), and *N*-methyl-D-aspartate (NMDA) receptor activation (Shiflett et al., 2004) and immediate early gene expression (Smulders and DeVoogd, 2000b; Shimizu et al., 2004) during spatial tasks. Behaviorally, lesions to pigeon hippocampus disrupt performance on a variety of spatial memory tasks such as learning spatial representations in homing (reviewed in Bingman et al., 2005), spatial reversal learning (Good, 1987), spatial alternation (Reilly and Good, 1987), and spatial delayed matching-to-sample (Good and Macphail, 1994).

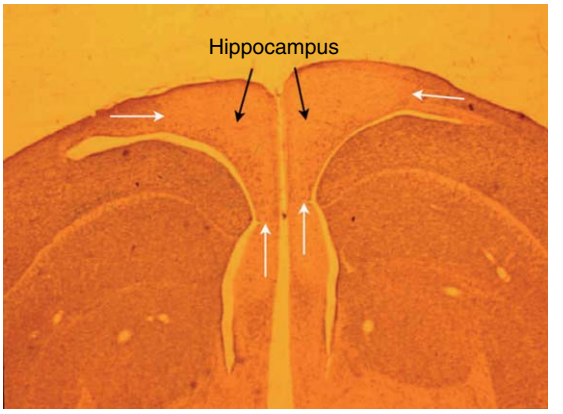

Figure 6 A photomicrograph of a coronal section through the avian hippocampus, with boundaries indicated by the white arrows. (Photograph by Kristy Gould.)

1.22.5.2 The Hippocampus in Food-Storing Birds

In the case of food-storing birds, hippocampal lesions disrupt cache retrieval. Krushinskaya (1966) lesioned the dorsomedial and dorsolateral sections of the hippocampus of Eurasian nutcrackers after they had stored

food in a dirt-floored laboratory room. When given the opportunity to recover, lesioned birds retrieved 13% of their caches while nonlesioned controls recovered around 90% of theirs. Although Krushinskaya's lesion methods were crude, and she may have inadvertently damaged areas outside of the hippocampus, later research has confirmed the role of hippocampus in cache recovery and spatial memory using lesion techniques on black-capped chickadees during both food storing (Sherry and Vaccarino, 1989) and delayed spatial matching-to-sample tasks (Hampton and Shettleworth, 1996). Temporary inactivation of the hippocampus in black-capped chickadees also produces memory impairment in a spatial associative task (Shiflett et al., 2003), indicating hippocampal involvement in storing and retrieving spatial information in the short term.

These results strongly suggest that the species differences in spatial memory and cache recovery should be reflected in differences in hippocampal structure. Comparative studies of avian hippocampus have found that species that store food have a larger relative hippocampal size than those that do not (Krebs et al, 1989; Sherry et al., 1989; Garamszegi and Eens, 2004; Lucas et al., 2004; but see Brodin and Lundberg, 2003). Correlations are also found between food storing behavior, spatial memory performance, and relative hippocampal volume for food-storing birds within corvids (Healy and Krebs, 1992; Basil et al., 1996) and parids (Hampton et al., 1995; Healy and Krebs, 1996), as well as in food-storing rodents within the kangaroo rat family (Jacobs and Spencer, 1994).

There are also population differences in hippocampal volume within species. Black-capped chickadees that live further north, in harsher climates (e.g., Alaska), store more food, perform better on spatial tasks, and have a larger hippocampus than birds living further south (e.g., Colorado) (Pravosudov and Clayton, 2002; but see Brodin et al., 1996). Similar population differences may exist in other species. For example, Pravosudov and de Kort (2006) analyzed the brains of a large number of scrub jays, which have been classified as storing fewer seeds (Balda and Kamil, 1989) and performing less accurately during many spatial memory tasks (e.g., Balda and Kamil, 1989; Olson, 1991, see previous); they have been found to have a smaller hippocampus than other food-storing corvids (Basil et al., 1996). Their data indicated a significantly larger relative hippocampal volume than the scrub jays in Basil et al. (1996). This difference in results may be due to methodological differences (paraffin-embedded vs. frozen tissue). On the other hand, the scrub jays used in the two studies came from different regions (northern Arizona and northern California), and there may be population differences within scrub jays in hippocampal size correlated with natural history.

1.22.5.3 Experience, Seasonality, and Neurogenesis in Birds

There are also important interactions between early environment, seasonality, and hippocampal growth. In at least some food-storing birds, early experience with food storing contributes to the development and ultimate size of adult hippocampus. When juvenile food-storing parids are given the opportunity to store food, they perform better on tests of spatial memory (Clayton, 1995, 2001) and develop larger hippocampi with more neurons and an increased cell proliferation rate compared to food-storing parids that are not allowed to store food (Clayton, 1996; Patel et al., 1997). Juveniles given the opportunity to perform noncaching spatial memory tasks also perform better and have a larger hippocampus than those that were not (Clayton, 1995). The developing hippocampus seems to be sensitive to experience with tasks that require the recall of spatial locations, at least in food-storing parids. However, food-storing experience during adulthood does not change the volume or number of hippocampal neurons (Cristol, 1996). This all suggests that early experience with food storing leads to the development of a larger adult hippocampus with more neurons (Healy and Krebs, 1993, Healy et al., 1994) and a high cell proliferation rate (Patel et al., 1997).

Seasonal changes in the neural tissue associated with birdsong in species that sing seasonally are well known (Nottebohm, 1981). Similar phenomena have been demonstrated in birds that cache/recover seasonally. Barnea and Nottebohm (1994) studied hippocampal neurogenesis in adult black-capped chickadees and found a seasonal difference in neuronal recruitment, with more new neurons in October than any other time of year. This corresponds to a time of seasonal diet change, from insects to seeds, with many of the seeds being stored (see Pravosudov, 2006, for discussion of a bimodal peak in food storing among parids). Barnea and Nottebohm did not, however, find a seasonal difference in total number of hippocampal neurons. They hypothesized that seasonal recruitment is part of a neuronal replacement process important for the acquisition of new spatial

memories. As seeds begin to be stored in October, new memories are established, requiring new neurons. Without a change in total neuron number, however, there must be apoptosis occurring as the new neurons are recruited.

Smulders et al. (1995) reported a seasonal change in the relative volume of the hippocampus in black-capped chickadees, with the peak in October. This seemed to complement the results of Barnea and Nottebohm (1994). Smulders et al. (2000), however, concluded that this change in volume was related to an increase in the total number of neurons in the hippocampus. Barnea and Nottebohm did not find seasonal changes in total neuron number, only in the number of new neurons. Smulders and DeVoogd (2000a) hypothesized that the overall increase in neurons they found was the mechanism allowing greater processing of spatial information in the fall. The more neurons, the more spatial information can be processed. This differs from Barnea and Nottebohm's hypothesis of neuron replacement with no net gain in number of neurons.

Hoshooley and Sherry (2004) attempted to distinguish between the hypotheses of Barnea and Nottebohm (1994) and Smulders et al. (2000) by determining if the seasonal changes in chickadee hippocampus were a result of more 'new' neurons or an increase in the actual 'production' of neurons. They found no seasonal change in hippocampal volume, total neuron number, or neuron production, which suggests enhanced survival of new neurons in the fall, not an increase in neuron production. Smulders (2006), however, has pointed out that the birds used by Hoshooley and Sherry (2004) were held in captivity for up to 2 weeks before they were sacrificed and that captivity can cause decreases in neurogenesis (Barnea and Nottebohm, 1994) and hippocampal volume (Smulders and DeVoogd, 2000a) in birds.

There appear to be two mechanisms affecting hippocampal size in food-storing parids. First, food storing experience early in life increases adult hippocampal volume by influencing the total number of neurons and the extent of cell proliferation. Second, in adults, when demand for spatial memory increases because of food-storing, either the number of hippocampal neurons increases or the number of new neurons that survive increases, resulting in a larger population of new hippocampal neurons to process new memories being formed. Further work will be necessary to fully understand the reasons for the increase in neuronal recruitment found by Barnea and Nottebohm (1994).

A possible complication is that cell proliferation is correlated with spatial memory and social status in mountain chickadees (*Parus gambeli*; Pravosudov and Omanska, 2005). Subordinate mountain chickadees performed worse on spatial memory tasks (Pravosudov et al., 2003) and also had lower cell proliferation rates (Pravosudov and Omanska, 2005) than their dominant counterparts. Individual birds that performed better on spatial memory tasks also had higher cell proliferation rates, suggesting a strong correlation between proliferation and spatial memory. However, no differences were found in hippocampal volume or total neuron number.

Other hippocampal differences have been found between food-storing and nonstoring birds. This includes larger calbindin-immunoreactive neurons in the hippocampus of food-storing than nonstoring corvids and parids (Montagnese et al., 1993) and significantly lower levels of NMDA-binding receptor sites in the hippocampus of food-storing parids (Stewart et al., 1999). How these differences might be related to food-storing is unclear. However, blocking NMDA receptors when black-capped chickadees are learning a one-trial spatial association task prevents the retrieval of the food after either 3 or 24 h. It also blocks learning about a new spatial location within the context of an already learned array of locations (Shiflett et al., 2004). This suggests that the avian hippocampus plays a role in linking new spatial locations into preexisting spatial memories (Smulders, 2006) and that NMDA receptor activation is important only in processing spatial information over the long term. Food-storing birds have fewer hippocampal NMDA receptor sites, which seems contradictory to these results. But this highlights the complexity of the relationship between the NMDA system and food-storing and the need for future work in this area.

1.22.5.4 Role of the Hippocampus in Mammals

In food-storing mammals, three studies have addressed species and seasonal differences in hippocampal neuroanatomy. Lavenex et al. (2000a,b) found no seasonal variations in hippocampal volume, total neuron number, or cell proliferation rates in the adult scatter-hoarding eastern gray squirrel (*Sciurus carolinensis*), an interesting contrast with the results from birds (Smulders et al. 1995, 2000) in terms of seasonal changes in volume and neuron number. Barker et al. (2005) compared the yellow pine chipmunk, both a

larder- and scatter-hoarder, to the scatter-hoarding eastern gray squirrel during the fall when both species were actively collecting and storing food for winter. Gray squirrels had three times the number of proliferating cells in the dentate gyrus of the hippocampus, but no significant difference in the number of new neurons compared to the yellow pine chipmunk. There was a nonsignificant trend suggesting gray squirrels had more new neurons, and Barker et al. (2005) hypothesized that the greater number of proliferating cells provided a larger population from which to recruit new neurons into the hippocampus.

The Barker et al. (2005) results were quite different from those of Lavenex et al. (2000a) in terms of cell proliferation rates, but there were two major methodological differences. While Barker et al. used free-living animals sacrificed within 2 h of capture, Lavenex et al. used animals that had been in captivity for days before sacrificing. In addition, Barker et al. analyzed endogenous proteins that are indicators of neurogenesis, proteins that would be conserved at time of capture regardless of stress due to capture. Lavenex et al. assessed neurogenesis with a mitotic marker, which can be affected by stress of captivity (Barker et al., 2005). The results of Barker et al. (2005) were also different from those of Hoshooley and Sherry (2004), in that cell proliferation was related to spatial memory, but not the number of new neurons. These differences may also be the result of differences in stress due to captivity. It is also possible that there are different mechanisms producing hippocampal seasonal changes in mammals and birds.

1.22.5.5 Other Brain Areas

Brain areas other than the hippocampus play important roles in processing spatial information. However, the contribution of these areas to the recovery of scatter-hoarded food has not been investigated very thoroughly. These areas include the parahippocampal region (or Wulst in birds), the prefrontal cortex (or caudolateral nidopallium in birds), the septum, and visual areas. All of these brain regions have connections with the hippocampus in both mammals and birds and their contribution to spatial memory in mammals has been extensively studied. But we have little understanding of their contribution to spatial memory in birds or to scatter-hoarding in general for either rodents or birds. A handful of studies show general differences in the volume of two of these structures in food-storing birds. Gould et al. (2001) show that the medial substance P receptor field within the parahippocampal area of the food-storing black-capped chickadee is larger than that found in the nonstoring blue tit and great tit. Shiflett et al. (2002) showed that the septum is larger in chickadees than in blue and great tits. What these results mean in relation to food-storing is not clear, but research investigating brain regions connected with the hippocampus and their contributing role to spatial memory should be continued.

1.22.5.6 Cognitive Pleiotropy

Like genes, cognitive abilities can affect more than one trait. Spatial memory, for example, can facilitate territoriality or migration as well as cache recovery. This complicates the analysis of the relationship between natural history and cognition/neuroanatomy. If evolution has favored larger hippocampal volumes in some species, there must be strong advantages to such investment for those species, given the high cost of maintaining neural tissue (Attwell and Laughlin, 2001). But the hippocampus undoubtedly plays a significant role in behaviors other than relocating stored food. For example, Volman et al. (1997) looked at hippocampal volume in two species in each of two genera of woodpeckers. In *Melanerpes*, they found a larger hippocampus in a scatter-hoarding species than a larder-hoarder. But in *Picoides*, they found generally large hippocampal volumes even though neither *Picoides* species scatter-hoards. They suggest that factors other than scatter-hoarding may influence hippocampal size.

One such factor is migration. Healy et al. (1996) demonstrated that experience with migration has an impact on the size of the hippocampus in Garden warblers (*Sylvia borin*), who normally migrate from Europe to tropical Africa. They found that warblers at least 1 year old that have experience migrating have a larger hippocampus after at least one migration trip than 3-month-old, naive birds. In contrast, no age effect was found in nonmigratory Sardinian warblers (*S. melanocephala momus*), who had relatively small hippocampi, suggesting that it is the migratory experience and not some other maturational factor that affects hippocampus size.

Mettke-Hofmann and Gwinner (2003) extended these results with behavioral measures. They found better long-term spatial memory in migratory garden

warblers than nonmigratory Sardinian warblers. Taken together, these studies suggest a picture for these migratory and nonmigratory congeners similar to that found for storing and nonstoring parids by Clayton and her colleagues (reviewed in the section titled 'Memory for cache contents'). The connection between migration, spatial memory, and hippocampal structure is further indicated by the research of Cristol et al. (2003).

1.22.6 Conclusions

The study of spatial memory in scatter-hoarding animals has enriched the scientific understanding of animal cognition. The duration, capacity, and dynamism of this memory have driven impressive, stimulating research into both ultimate-evolutionary and proximate-neurophysiological explanations. The most important impact of this research has probably been its contribution toward integrating biological and psychological approaches to animal cognition, combining concepts and designs from psychology with those from biology in a broadly evolutionary framework, leading to a better understanding of the complex relationships between natural history, cognition, and brain structure and function.

At another level, the cache recovery context has proved an extremely valuable setting for experiments on animal cognition. As our review has hopefully demonstrated, experiments on caching and recovery have extended ideas about the memorial capacities of animals. Many interesting questions about cache memory remain, questions such as the role of interference in forgetting, how information about the emptying of cache sites affects cache site memory, and exactly how cache site locations are encoded. In addition, caching and recovery are also providing an extremely useful context in which to study other important aspects of animal cognition such as episodic-like memory and social cognition (*See* Chapter 1.23).

1.23 What Do Animals Remember about Their Past?

L. H. Salwiczek, A. Dickinson, and N. S. Clayton, Cambridge University, Cambridge, UK

1.23.1 Introduction

Episodic memory refers to the ability to remember specific personal happenings from the past. Ever since Tulving first made the distinction between episodic memory and other forms of declarative memory in 1972, most cognitive psychologists and neuroscientists have assumed that episodic recall is unique to humans, in part because our reminiscences are accompanied by the subjective awareness of remembering (e.g., Tulving, 1983; Suddendorf and Corballis, 1997; Wheeler, 2000; *See also* Chapters 1.02, 1.04, and 1.21). Tulving argues that, like many animals, his pet cat can acquire and retrieve all kinds of information about events that have happened in the past, but only in a way that is devoid of any awareness of remembering such events. So while his cat may know that she caught a mouse, what she does not recall is the personal experience of having caught that mouse. To be fair, humans also have many instances of knowledge acquisition in which we do not remember the episode in which we acquired that information. For example, although most of us know when and where we were born, we do not remember the birth itself or the episode in which we were told when our birthday is.

According to Tulving, the retrieval of semantic factual knowledge and episodic memories can be differentiated in terms of the remember-know distinction. To *know* that the Psychological Laboratory was opened in Cambridge in 1912 is semantic knowledge, whereas *remembering* having attended a comparative cognition lecture at Cambridge University is an episodic memory. Remembering and knowing are thought to be two separate subjective states of awareness, the former being an awareness of reliving past events in the mind's eye (what he later called mental time travel; Tulving, 2000), whereas the latter only involves an awareness of knowledge without any requirement to travel mentally back in time to reexperience the past (Gardiner and Richardson-Klavehn, 2000).

In humans, these episodic memories are often recalled vividly and contain a rich representation of the past event. Furthermore, the memories may appear quite suddenly, and out of the blue. In his autobiographical novel *Remembrance of Things Past,* Marcel Proust (1922) described such a moment of episodic recall:

> And suddenly the memory returns. . . . The taste was that of the little crumb of madeleine which . . . my aunt Léonie used to give me, dipping it first in her own cup of real or of lime-flower tea. And once I had recognized the taste of the crumb of madeleine soaked in her decoction of lime-flowers which my aunt used to give me . . . immediately the old grey house upon the street, where her room was, rose up like the scenery of a theatre to attach itself to the little pavilion, opening on to the garden, which had been built out behind it for my parents (the isolated segment which until that moment had been all that I could see); and with the house the town, from morning to night and in all weathers, the Square where I

> used to be sent before lunch, the streets along which I used to run errands, the country roads we took when it was fine.

One of the cardinal features of episodic memory is that it operates in what Tulving (2002) calls "subjective time," namely that remembering the event is always accompanied by an awareness of traveling back to the past time in which the experiences were recorded (see also Hampton and Schwartz, 2004). Episodic memory differs from all other kinds of memory in being oriented to the past, and specifically in the past of the owner of that memory. So while some factual memories do involve a datable occurrence, they are fundamentally different from episodic memories. Indeed, as William James so aptly wrote:

> Memory requires more than the mere dating of a fact in the past. It must be dated in *my* past. (James, 1890: 650)

Tulving (2002) argues that episodic remembering requires a specific form of self-consciousness, *chronesthesia,* that enables an individual to address her own, personally experienced past, which "does not reside in memory traces as such; it emerges as the phenomenally apprehended product of episodic memory system" (Tulving, 2000: 17), much like the piece of madeleine dipped in linden tea enabled Proust to consciously relive the past as a simultaneous part of his present. Many cognitive neuropsychologists have argued that this ability to travel back in time in the mind's eye to reexperience the past is unique to humans; animals, by contrast, are stuck in the seemingly eternal present (e.g., Tulving, 1983; Suddendorf and Corballis, 1997; Roberts, 2002). So according to Tulving (1983), his pet cat does not recall the personal experience of having caught the mouse, nor is she aware that the event is explicitly located in her past.

Language-based reports of episodic recall suggest not only that the retrieved experiences are explicitly located in the past but that they are also accompanied by the conscious experience of one's recollections (e.g., Wheeler, 2000), of feeling that one is the author of the memory, what Tulving (1985) called *autonoetic consciousness*. It is this feature of episodic recollection that William James referred to when describing what he called the "warmth and intimacy" of one's episodic memories (James, 1890).

This phenomenological definition makes it impossible to assess the claim that episodic memory is unique to humans, because there are no agreed nonlinguistic behavioral markers of these kinds of conscious experiences in nonhuman animals (Griffiths et al., 1999), and therefore we have no way of assessing whether Tulving's cat, or any other animal, does or does not experience an awareness of the passing of time and of reexperiencing one's own memories while retrieving information about a specific past event. This dilemma can be resolved to some degree, however, by using Tulving's original definition of episodic memory (Tulving, 1972), according to which he identified episodic recall as the retrieval of information about where a unique event occurred, what happened during the episode, and when it took place. The advantage of using this definition is that the simultaneous retrieval and integration of information about these three features of a single, unique experience may be demonstrated behaviorally in animals. We refer to this ability as *episodic-like memory* (Clayton and Dickinson, 1998) rather than episodic memory, because we have no way of knowing whether or not this form of remembering is accompanied by the various phenomenological aspects that accompany conscious recollection in humans.

1.23.2 Animal Studies

Some of the earliest evidence that animals may be capable of episodic-like recall came from studies of rats foraging in a radial arm maze (*See* Chapter 1.22). In a paper entitled "Remembrance of places passed: Spatial memory in rats," Olton and Samuelson (1976) argued their laboratory rats could remember which arms had already been chosen and/or which had not in order to forage efficiently by avoiding those arms they had visited previously. Another potential example of episodic-like memory came from studies of visual short-term memory in which rhesus monkeys (*Macaca mulatto*) had to choose, for example, either the previously presented stimulus or the novel stimulus in a delayed matching or nonmatching to sample task (Mishkin and Delacour, 1975). In both of these studies, the animals may have solved the task by remembering the specific past event – about which arms had been visited in the case of the rats, and which stimuli had been seen in the case of the monkeys. There is a simpler alternative, however, namely that the animals could have based their decision of where to search in the maze or which stimulus to choose in the matching tasks on familiarity rather than recall; for example, they could simply have learned to avoid stimuli that look familiar, arms in the case of a rat in the radial maze and objects in the

case of the monkey performing the matching task (see Griffiths et al., 1999).

There is growing evidence that familiarity and episodic recall are separate cognitive processes, both psychologically (Mandler 1980; Jacoby and Dallas, 1981; Kelley and Jacoby, 2000) and neurobiologically (Aggleton and Brown, 1999, 2006; Wheeler, 2000), and that they have different retrieval dynamics (e.g., Yonelinas, 2001; Yonelinas et al., 2002, 2005, for humans; Fortin et al., 2004, for rats). For example, Yonelinas (2001) has argued that the receiver operating characteristic (ROC) of human recognition memory consists of two components. The first is a *familiarity* component, which is mediated by a standard signal-detection process, whereas the second is an *episodic recollection* component that reflects a high-threshold process in which recollection only occurs once the strength of the episodic memory trace exceeds a threshold. Given this analysis, there is no need to appeal to anything more than the discriminative control exerted by the familiarity of an arm in the radial maze task or of the sample stimulus in a delayed matching task.

Fortin and colleagues used Yonelinas' analysis to determine whether rats were capable of episodic recollection using an odor recognition paradigm (Fortin et al., 2004). Importantly, the rats produced an asymmetrical ROC curve that is characteristic of the conjoint control of recognition by familiarity and episodic recollection. Moreover, their assessment of the two processes through the ROC analysis allowed the authors to dissociate the two processes, by both brain lesions and retention interval (*See* Chapter 1.21).

Clayton and Dickinson (1998) adopted a different approach to the question of whether or not animals other than humans are capable of episodic recall. Rather than applying a theoretically derived analysis, they considered cases in nature in which an animal might need to rely on episodic recall as opposed to other forms of memory. They suggested that the food-caching behavior of Western scrub-jays (*Aphelocoma californica*) might be one such example, because this species of bird hides both perishable food items (e.g., insect larvae) and nonperishable food items (e.g., nuts) for later consumption (for other potential candidates, see discussion by Clayton et al., 2001a). A suite of studies have shown that Western scrub-jays, like many other food-caching animals, have highly accurate and long-lasting spatial memories for the locations of their caches (Bednekoff et al. (1997) for Western scrub-jays; see review by Shettleworth (1995) for food-caching animals in general; *See also* Chapter 1.22). As these jays rely on their caches for survival in the wild, the selection pressure for remembering which caches were hidden where and how long ago might have been particularly strong (Griffiths et al., 1999), particularly since they cache year round (Curry et al., 2002). Furthermore, the birds also cache reliably in the laboratory, providing both ethological validity and experimental control (Clayton, 1999).

Rather than identifying episodic-like memory by its retrieval characteristic, Clayton and colleagues focused on the behavioral criteria for episodic-like memory, namely that the animal must be capable of remembering what happened where and when on the basis of a single past experience and in a way that cannot be explained in terms of relative familiarity. Clayton et al. (2003a) argued, however, that this criterion was insufficient; rather, an animal's *episodic-like* memory must fulfill three criteria: content, structure, and flexibility. In terms of the content of an episodic-like memory, we have argued that it is the 'when' component that is critical, since episodic memory is the only kind of memory to be explicitly located in the past. Furthermore, the what-where-and-when components form an integrated structure, and this feature of episodic memory is important because it permits discrimination between similar episodes that occurred at different times and possibly different places. Finally, the third criterion is one of flexibility, namely that the information can be represented in memory in a form that allows it to be used in a number of different ways, depending on the context. This flexibility arises from the fact that episodic memories are embedded within a larger declarative system that also encodes factual knowledge (e.g., Tulving and Markowitsch, 1998), and consequently the information can be updated and generalized across situations (*See* Chapters 1.04 and 1.21).

1.23.3 The Critical Components of Episodic-Like Memory

In the following section we discuss each of these three key features of episodic-like memory in turn in order to assess the evidence that some nonhuman animals do have episodic-like memory and, if so, which ones. We shall start our analysis by reviewing what is known about the memories of food-caching jays and then discuss subsequent studies that have been conducted on other animals, primarily rodents and primates.

1.23.3.1 The Content Criterion: The Importance of Pastness

Episodic memory is the only memory to be oriented in time (Tulving, 2000), and more precisely, in subjective time. Semantic and other memories do contain information that was acquired in the past, but without any notion of when they had been acquired, and thus these memories are timeless. As we argued in the introduction, having an awareness of the passage of time ('pastness') is a critical feature of episodic memory, one that distinguishes it from all other forms of memory, so it is therefore essential that any demonstration of episodic-like memory must show that the animal remembers when a particular event occurred in the past as well as what happened where (Clayton, 2004).

1.23.3.1.1 The what-where-and-when memories of food-caching Western scrub-jays

When investigating food-caching by Western scrub-jays as a natural candidate for episodic-like memory in animals, Clayton and Dickinson reasoned that, as these birds do not eat rotten insects, the recovery of perishable items is only valuable as long as they are still fresh. Consequently, a jay should remember not only the location of a cached food item but also the content (perishable or nonperishable food item), in addition to keeping track of the time since caching. Clayton and Dickinson (1998) gave the jays a series of trials in which they cached both their preferred food wax worms (wax moth larvae), and the less-preferred peanuts in two sand-filled ice cube trays, both of which were made visuospatially distinct and trial-unique by structures of children's building blocks (Lego Duplo) attached to the sides of the trays. Consequently, the jays cached in different pairs of trays on different trials so that each caching episode was unique (**Figure 1**). Although the birds had no cue predicting whether or not the wax worms were perished other than the passage of time, the birds quickly learnt that wax worms were available and fresh when recovered 4 h after caching, but rotten after 124 h, while peanuts were always fresh (Clayton and Dickinson, 1998).

Having received four pairs of training trials, the birds were given a pair of test trials, in which the caches were removed prior to recovery and the trays were filled with fresh sand to ensure that the birds could not use any cues emanating directly from the hidden food. The birds' search patterns at recovery demonstrated that they did remember which caches they had hidden in which particular trays and when, because they looked primarily in the places in which they had hidden the wax worms when the food had been cached 4 h ago, but redirected their search to peanut sites when the food had been cached 124 h ago. Note that the recoveries after both short and long retention intervals (RIs) always occur at the same time of day (4 h after caching on the same day as caching or 5 days after caching), and therefore neither circadian rhythms nor the state of hunger at the time of recovery could provide cues to guide the jays' searching behavior (see de Kort et al. (2005) for further discussion).

Figure 1 Sweetie Pie, one of the Western scrub-jays in Clayton's colony, is about to cache one of the wax worms in one of the visuospatially unique caching trays. Photo courtesy of Ian Cannell and Dean Alexis, University of Cambridge, UK, with permission.

At issue, however, is whether the birds really remembered the specific past caching episodes or whether they simply knew what had been cached where and when. In order to search in the correct cache sites that were unique to that specific caching event, the jays had to retain information about which caches they had placed where. However, it is possible that rather than remembering how long ago they had cached, the birds relied on familiarity judgments with the caching trays in order to decide whether to search for worms or peanuts. When caching had occurred just 4 h previously, the trays are presumably much more familiar than when caching occurred 124 h ago, and so the jays might have used a conditional rule, "if the trays look familiar search for worms, but if the trays look relatively unfamiliar search for peanuts."
