such a crime is likely to vividly recollect the time and place of the crime, as well as the events leading up to and following the event. In addition, there may be visceral emotional responses, such as a racing heart and sweating palms, that are evoked by aspects of the robbery – such as the sight of a man in a ski mask on a snowy day years after the crime. The victim might also form the opinion that convenience stores are dangerous places after the experience. Hence, the armed robbery filters through several memory systems, leaving its trace in memories about where and when the episode occurred, the emotional consequences of the event, and factual knowledge about the event, among others.

The memory system that is the focus of this chapter is that concerned with emotional information. Emotions, of course, come in several varieties – fear, love, anger, joy, and so on. However, the most productive neurobiological analysis of emotional learning has been in the context of aversive emotions such as fear. There has been considerable work in both human and animals on the anatomy and physiology of the memory system for fear. This focus on fear memory has been driven by many factors, including the isomorphism of fear responses in humans and animals, the rapid acquisition and long-term stability of fear memory, and the primacy of fear memory in the context of behavioral systems adapted to defense and self-preservation. Moreover, from a clinical perspective, dysfunction in emotional memory systems is at the heart of the most prevalent psychiatric disorders in humans. Specifically, anxiety disorders including posttraumatic stress disorder, panic disorder, and specific phobias are rooted in pathological fear memories. The aim of this chapter is to explore the emotional memory system, focusing on the contribution of experimental studies in animals to fostering our understanding of the nature and properties of emotional learning and memory, particularly for aversive events, in humans. The approach that is followed in this chapter is to use studies of brain function and anatomy to inform the properties of emotional memory and, similarly, to leverage psychological theory and animal behavior to inform the nature of the brain systems underlying emotional learning and memory. This behavioral neuroscience perspective on the emotional learning and memory systems in animals has had great influence on modern thinking about the neurobiology of memory, in a general sense. This chapter will not consider the extensive literature on the cellular, genetic, and molecular mechanisms underlying learning, which are the focus of other chapters in this volume.

3.24.2 Behavioral Models for Exploring the Neural Substrates of Emotional Learning

Before considering in depth the neural systems underlying emotional learning and memory, it is important to understand the paradigms and methods used to investigate aversively motivated learning and memory in the laboratory. The experimental investigation of emotional learning has its roots in Watson and Rayner's classic demonstration of fear learning in the human infant, Little Albert (Watson and Rayner, 1920). In this case study of human fear learning, Watson presented Albert with a live, white rat and subsequently hammered an iron rod to produce a loud, startling sound that sent Albert into tears. After several conditioning trials, Albert came to fear the rat and burst into tears and attempted to avoid the rat when presented with the animal, even in the absence of the loud noise. Watson and Rayner (1920) argued that emotional responses could be conditioned in much the same way as discrete motor or salivary responses, as described by Pavlov. This provided an important demonstration of the use of Pavlovian procedures to study emotional learning and laid the groundwork for subsequent studies in both humans and animals of the nature and properties of aversively motivated learning.

Although Watson and Rayner's examination of Little Albert was a noteworthy proof of concept that fear could be established through conditioning procedures, the successful analysis of emotional learning and memory systems required the development of behavioral tasks that could be adapted to laboratory animal subjects and brought under rigorous experimental and parametric control. In most cases, these tasks were developed in efforts to understand the psychological properties of learning and memory systems (rather than brain substrates *per se*), whether in the context of motor skill acquisition, appetitive learning, or aversively motivated learning, for example. Indeed, the work that emerged from psychological laboratories in the early to mid-twentieth century proved to be crucial for understanding the process and content of learning. These advances in psychological learning theories were essential to adapting behavioral tasks to the analysis of learning and memory systems in the brain.

3.24.2.1 Instrumental Conditioning Paradigms

The types of learning tasks used in analyzing the psychological and neural substrates underlying emotional learning can be classified in general terms according to their associative contingencies. Broadly speaking, one class of task requires that the animal learn that the delivery of an aversive stimulus is a consequence of its behavior. These tasks therefore involve an instrumental contingency and are variously referred to as instrumental conditioning or operant conditioning tasks. In the context of aversive learning, animals are often instrumentally trained to avoid a noxious stimulus, such as the delivery of footshock on an electrified grid floor. Hence, one might arrange that a conditioned stimulus (CS) will signal the occurrence of a footshock unconditioned stimulus (US). In some tasks, such as a shuttle-box avoidance task in rats, the animal can avoid the aversive US if it learns to move from one side of the box to the other when the CS is initiated. In this case the animal learns an active response to avoid shock. Active avoidance tasks may take several forms, from one-way active avoidance (in which the animal always shuttles in one direction from a consistently dangerous compartment to a consistently safe compartment) to two-way or shuttle avoidance (in which either compartment might be associated with shock and the animal learns to shuttle, in either direction, on alternate trials). Other active avoidance tasks might take advantage of entirely different response requirements, such as wheel-running avoidance, in which rabbits step in a running wheel to avoid shock, or conditioned taste avoidance, in which animals learn to avoid a novel taste that is followed by gastrointestinal malaise induced with an emetic such as lithium chloride.

In other instrumental avoidance tasks, such as inhibitory avoidance conditioning, the animal learns that making a response, such as walking from an illuminated compartment to a darkened compartment of a chamber, will result in shock delivery. In this case, the animal learns to avoid footshock by inhibiting its tendency to move to the dark side of the apparatus when it is returned to the illuminated chamber. Thus, the animal learns a passive avoidance response in this situation. There are many variants of passive avoidance tasks, including step-through passive avoidance of the sort just described, or step-down avoidance, in which movement from a small, elevated platform to a larger arena is punished with footshock. Animals that have learned to press a bar for food will suppress that response if it comes to yield footshock. Similarly, thirsty animals will avoid licking a water spout if contacts with the spout lead to a shock. In another variant of passive avoidance training, rats are placed in a chamber that houses an exposed, electrified shock probe. Upon contacting the probe, the animal receives a shock and subsequently avoids the probe. In addition to avoiding contact with the probe, the animal will spray bedding or any other substrate at the probe in an effort to bury it. Defensive burying is an ethologically relevant avoidance behavior observed by animals in response to noxious stimuli in their environments.

In every instrumental task described, the animal learns that its behavior has consequences for the likelihood of experiencing an aversive event. In one case, the animal learns that its behavior causes the aversive event and then learns to withhold that response in the future (i.e., passive avoidance tasks), and in another case the animal learns that its behavior terminates an aversive stimulus, and it can avoid the aversive event by making a behavioral response (i.e., active avoidance tasks). Thus, in passive avoidance tasks, the probability of various approach behaviors is decreased by punishment, yielding passive avoidance. In active avoidance tasks, the probability of an active avoidance response is increased through negative reinforcement (removing an aversive stimulus). In both cases, it is important to appreciate that although the task is orchestrated to reinforce one behavioral response or another, the instrumental association between a stimulus and a response (the so-called stimulus–response or S–R association) is certainly not the only thing learned in the situation. Of course, for successful performance in such tasks, animals must learn associations between stimuli (stimulus–stimulus or S–S associations, such as the CS–US association), associations between behavioral responses and their outcomes (response–outcome or R–O associations), and any other information incidental to task performance that defines the episode in the stream of the animal's experience. So, simple conditioning tasks are often much more complicated than they would appear to be at first glance.

3.24.2.2 Pavlovian Conditioning Paradigms

The other major class of aversive conditioning tasks that has been adapted to study emotional memory systems does not require the instrumental contingency that is at the heart of avoidance conditioning

tasks. In classical or Pavlovian conditioning, just as in instrumental conditioning, animals learn an association between stimuli and their consequences, such as an auditory CS and a footshock US that it predicts. However, in Pavlovian conditioning, the animal's behavior is inconsequential to the delivery of either stimulus; CSs and USs are delivered irrespective of the animal's behavior, and the animal cannot engage in behavior to avert or avoid the US. In this sense, Pavlovian conditioning simplifies the analysis of the underlying brain systems because it eliminates some of the associative processes that operate in the context of instrumental conditioning tasks (namely, instrumental S–R and R–O associations).

Pavlovian conditioning tasks designed to characterize emotional learning and memory, such as learning fear, typically utilize noxious USs such as electric shock applied to the feet or, in some cases, electric current delivered through fine wires implanted in the neck or around the eye. Other aversive USs that are effective for conditioning fear include loud sounds, such as bursts of white noise (Watson actually used a loud sound to condition fear of rats in Little Albert), air puffs, illness induced by emetics such as lithium chloride, and inhalation of carbon dioxide. These aversive USs can be signaled by a variety of CSs including lights, sounds (most typically pure tones or white noises), olfactory stimuli, or even the places or contexts in which the animal encounters the US. What tends to vary across different Pavlovian fear conditioning tasks is the behavioral (or autonomic) response used to index fear. The choice of response system depends on many factors, not the least of which is the animal species used in the experiments. In rats and mice, a variety of response measures have been used. In a naturalistic setting, rodents show a hierarchy of defensive behavior in response to predatory threat. When a predator is near, but not yet in contact with, the prey, a rat or mouse will exhibit freezing behavior, which is characterized by nearly complete immobility, as a means to avoid detection by the predator. In the laboratory, freezing behavior is readily conditioned to places in which aversive USs are delivered (Blanchard and Blanchard, 1969). Interestingly, unlike other notable forms of Pavlovian conditioning, the learned fear response (the conditioned response or CR) does not take the form of the activity burst that is generated by the shock US. Running, jumping, and vocalization characterize the activity burst of a rat to footshock; this collection of responses resembles a rat's circa-strike response to a predatory attack. It is widely believed that the activity burst reflects the sensory properties of the shock US, whereas the freezing response is a function of the affective (fear-engendering) properties of the aversive event. Hence, many studies of fear conditioning in rodents rely on freezing behavior as an index of fear. In addition to freezing, rats exhibit a number of other behavioral and autonomic responses that can be used to index fear. For instance, they show less recuperative behavior to a painful formalin injection into their paw because of fear-induced hypoalgesia. Fear is also associated with increased heart rate and blood pressure and the release of stress hormones such as glucocorticoids.

Another popular measure for indexing fear is the change in the acoustic startle reflex that is observed in the presence of a fear-provoking stimulus (Brown et al., 1951). In the fear-potentiated startle paradigm, rats or mice are exposed to a series of loud noise bursts to index their acoustic startle amplitudes. After this phase they are exposed to Pavlovian fear conditioning procedures in which a visual CS is paired with a footshock US. To assess the fear engendered by the CS, the rats are once again exposed to the acoustic startle stimuli, but now in the presence of the visual CS on some trials. Under these conditions, the acoustic startle response is greatly elevated on trials in which the fearful CS is present relevant to trials without the CS. Fear, then, is indexed indirectly by potentiation of the startle response. Another indirect measure of fear described by Estes and Skinner is the suppression of appetitive responding in the presence of a fearful CS (Estes and Skinner, 1941). In this case, animals were first instrumentally trained to press a bar for a food reward. When the animals were reliably pressing the bar for food, they underwent (typically in another chamber) fear-conditioning procedures. The animals were then once again allowed to respond instrumentally for food. When presented with the fearful CS in this situation, instrumental responding during the CS dropped considerably relative to intervals before or after delivery of the CS. This bar-press suppression by a fearful CS has historically been used to index the conditioned emotional response (CER), which is synonymous with the conditioned fear response.

3.24.2.3 Naturalistic Conditioning Paradigms

In addition to these traditional models for studying emotional learning, there are some less widely used,

yet more naturalistic, paradigms that have been used for studying aversively motivated learning. For example, social defeat by a dominant conspecific appears to yield a conditioned fear state that shares many of the properties of fear motivated by artificial aversive stimuli, such as footshock (Potegal et al., 1993). In this paradigm, typically conducted in Syrian hamsters, a younger, subordinate animal (the intruder) is introduced into the cage of an older, dominant animal (the resident), which arranges a social interaction whereby the resident behaves aggressively toward the intruder, chasing and biting the subordinate animal. Subsequent to this antagonistic interaction, the intruder exhibits submissive behavior around the dominant animal as well as other, nonthreatening conspecifics. Although the pattern of behavior that emerges from social defeat does not include freezing behavior, there are other commonalties with conditioned fear responses such as a reduction in pain sensitivity (hypoalgesia). Clearly, negative social interactions can yield an aversive state that conditions fear to other conspecifics and even the places where defeat occurs (Razzoli et al., 2006).

Of course, one function of fear is not only to motivate defensive behavior but also, at least in the case of overt fear responses, to communicate an individual's emotional state to nearby conspecifics. This might serve to protect genetically related individuals from external threats bearing on one member of the group. Learned fear through social transmission has been demonstrated in both mice and rats. For instance, mice that witness a conspecific being attacked by biting stable flies will subsequently exhibit hypoalgesia and attempt to bury themselves (to avoid being bitten) when exposed to flies whose mouthparts have been removed (to prevent biting) (Kavaliers et al., 2003). Animals that were never exposed to flies did not exhibit these responses. Social transmission of fear may also influence subsequent aversively motivated learning. In a recent study, rats were housed in pairs, and then one member of the pair was removed and subjected to fear conditioning (Knapska et al., 2006a). After the fear-conditioning episode, the conditioned animal was allowed to interact with its naïve cage-mate. During the interaction, the nonshocked cage-mate exhibited behaviors similar to that of the shocked rat and subsequently acquired a conditioned avoidance response faster than rats whose cage-mate left home but did not undergo fear conditioning. Collectively, these studies suggest that fear can be socially transmitted, can be learned, and can influence subsequent behavior to novel aversive events. Fear learning would appear to promote defensive behavior in not only the individual experiencing an aversive stimulus but also others with whom that animal interacts.

3.24.3 Historical Perspective on Brain Mechanisms of Emotional Learning

To appreciate modern work on the neural mechanisms of aversively motivated learning, it is worthwhile to trace the development of work linking emotion to the brain. There is no doubt that our modern appreciation of the brain circuits involved in aversive learning and memory emerged from early observations on the effects of brain damage on emotional behavior in humans and animals. Emotional learning in humans will be covered in depth elsewhere, but it is worthwhile mentioning one human case as a prelude to the discussion of work in animals. Prior to the nineteenth century, there had been an explosion of detailed descriptions of human brain anatomy, but only small gains in appreciating the function of various brain areas in psychological function. Perhaps the most influential one was the discovery of profound emotional changes in a man named Phineas Gage, whose brain was penetrated by an iron spike in a railway construction accident in 1848. Amazingly, Gage survived the injury to his head, but he was not the same person after recovering from the wound. The surgeon that oversaw Gage's case noted that Gage's personality showed marked changes after the injury. Relative to his gentle demeanor prior to the accident, he angered easily, used profanity, and could not maintain interpersonal relationships after his accident. Emotions, it would appear, had their roots in the brain. Gage's case would not inform the question of brain systems involved in emotional learning and memory *per se*, but it did set the groundwork for understanding the brain mechanisms of emotion, which was then actively pursued in experimental studies in animals.

The experimental investigation of emotional changes after brain injury in animals was heralded by Goltz's work in dogs (Goltz, 1892). Goltz surgically removed large portions of the dog cerebral cortex (a decortication) and noted profound changes in emotional reactivity after the animals recovered from the procedure. He found that any disturbance of the animal, however small, provoked an acute rage

that included barking, biting, deflection of the pinnae, and piloerection among other responses. The animals appeared to assume an emotional state that was only provoked in normal animals by highly aversive stimuli. Cannon and Britton later termed this behavioral state 'sham rage,' to distinguish it from the emotional reaction displayed by normal animals. The importance of Goltz's work was to begin a series of more systematic functional neuroanatomical studies that sought to localize emotional centers in the brain.

In parallel with Goltz's work in Germany, Brown and Schäfer, working in London, described profound alterations in emotional reactivity following temporal lobe lesions in monkeys (Brown and Schafer, 1888). Klüver and Bucy subsequently extended this work by making more discrete lesions and recording detailed behavioral observations of their operated animals (Klüver and Bucy, 1937). Both groups found that temporal lobe resections, which damaged both cortical and subcortical tissue, produced marked behavioral changes, including hyperorality, hypersexuality, visual agnosia, and notably, a loss of fear. For example, monkeys with temporal lobe lesions readily consumed novel and normally avoided foods, such as meat, and they would mouth inedible objects including metallic screws. Moreover, monkeys that once cowered in the presence of humans readily approached and contacted their caretakers after surgery. This work heralded the study of the neural substrates of emotion and focused intense interest on the role of the temporal lobes in the mediation of fear.

Papez, and later MacLean, built on the functional studies in animals and proposed what were to become highly influential neuroanatomical models of emotion systems in the brain (Papez, 1937; MacLean, 1949). Papez used anatomical methods to trace axonal connections between brain structures. He found that brain structures involved in generating emotional responses were highly interconnected and circuitous. His anatomical circuit for emotion included a prominent role for the hippocampus (a medial temporal lobe structure), the anterior thalamus and mammillary bodies in the diencephalon, cingulate lobe of the neocortex, and the major fiber tracts connecting these structures (fornix and mammilothalamic tract). MacLean expanded on the Papez circuit to include other brain structures in the emotional circuit, including the septum and amygdala, in what he termed a larger limbic system that he implicated in emotion. Central to MacLean's theory was the triune brain, which he contended described a systematic pattern of brain evolution along three neural axes: primitive, regulatory centers in the brain stem (the reptilian R-complex); emotional centers in the subcortical limbic system; and higher cognitive centers in the neocortex.

Although the Papez circuit and related limbic system had a potent influence on thought concerning the neural basis of emotion, it is now generally understood that there is no singular emotional center in the brain. Even specific emotions, such as fear, appear to involve brain circuitry that is not constrained by the anatomical circuits described by Papez and MacLean. In the context of aversive learning and memory, for example, it has become clear that a critical brain structure is the amygdala, a temporal lobe structure that was omitted from the Papez circuit. The central role of the amygdala in fear emerged from early work focusing on the consequence of temporal lobe damage on emotional reactivity. Specifically, Weiskrantz found that the loss of fear that Klüver and Bucy described in monkeys with temporal lobe lesions was the consequence of damage to the amygdala (Weiskrantz, 1956). Indeed, recent work has shown that a selective loss of amygdala neurons results in a fear reduction similar to that observed by Klüver and Bucy (Zola-Morgan et al., 1991; Meunier et al., 1999; Kalin et al., 2004). Numerous other studies have demonstrated reduced fear (taming) after amygdala damage in several mammalian species, including rats, cats, rabbits, dogs, and humans (Goddard, 1964). Moreover, electrical stimulation of the amygdala in animals and amygdaloid seizures in humans are associated with autonomic and behavioral changes characteristic of fear (Gloor, 1960; Gloor et al., 1982; Iwata et al., 1987; Davis, 1992). Hence, consensus emerged from these studies that the amygdaloid complex has an indispensable role in the regulation of fear.

3.24.4 Neural Mechanisms of Instrumental Avoidance Conditioning

The discovery of the central role for the amygdala in fear heralded an era of systematic examination of the neural substrates of aversively motivated learning and memory tasks in animals (Sarter and Markowitsch, 1985). Moreover, the observation by Watson and Rayner that fearful emotions could be conditioned in humans led to considerable interest in

how acquired states of fear and anxiety might influence normal and pathological behavior (Watson and Rayner, 1920). Hence, the mid-twentieth century witnessed a convergence of neuroanatomical work on emotion centers in the brain with psychological work on the properties of emotional learning that provided the foundation for systematic studies of the neural circuitry and mechanisms involved in learning about fearful experiences. Several investigators set out to further quantify this function by employing learning and memory tasks. The earliest work in this domain used instrumental avoidance conditioning tasks to investigate the neural mechanisms of learned emotions. And although there has been considerable debate concerning the nature of avoidance learning (Bolles, 1972; Fanselow, 1997), active and passive avoidance conditioning tasks have remained an important method for characterizing an animal's propensity to alter its behavior to avoid aversive stimuli.

3.24.4.1 Active Avoidance Conditioning

The earliest studies to examine the neural substrates of fear-motivated learning used instrumental avoidance tasks, in which animals could avoid an aversive stimulus by making the appropriate behavioral response. Not surprisingly, the amygdala was the focus of this early work, given the important role it had been shown to play in emotional behavior. In the first study of its kind, Brady and colleagues trained cats in a footshock-motivated shuttle avoidance task and found that large amygdala aspirations impaired the acquisition, but not the retention, of the avoidance response (Brady et al., 1954). Subsequent studies extended the active avoidance conditioning deficits after amygdala damage to rats. These deficits were reported in two-way active avoidance (McNew and Thompson, 1966; Campenot, 1969; Bush et al., 1973; Yeudall and Walley, 1977; Schutz and Izquierdo, 1979) and wheel-turning avoidance (Robinson, 1963).

Of course, the amygdala is a heterogeneous structure composed of several anatomically distinct nuclei (Krettek and Price, 1974; Krettek and Price, 1978; Pitkanen et al., 1997; McDonald, 1998; Swanson and Petrovich, 1998; Sah et al., 2003). The basolateral complex of the amygdala is the primary cortical interface of the amygdala and consists of the lateral, basolateral, and basomedial nuclei. These nuclei in turn project heavily to the central nucleus of the amygdala, which is the primary interface of the amygdala to hypothalamic and brainstem structures involved in generating various fear responses. Many of the earlier studies, with some exceptions, damaged the amygdala in its entirety without attention to the different contributions individual amygdaloid nuclei make to avoidance learning and memory. However, some of the early studies attempted to examine the contribution of individual nuclei to avoidance learning. For example, discrete electrolytic lesions to the basolateral complex of the amygdala impaired the acquisition and retention of a shuttle-box avoidance in cats (Horvath, 1963), one-way active avoidance in rats (Werka et al., 1978), and two-way avoidance in rats (Coover et al., 1973). The central nucleus of the amygdala was also shown to be critical for the acquisition, but not retention, of one-way (Werka et al., 1978) and two-way (Roozendaal et al., 1993) active avoidance. Importantly, selective neurotoxic lesions of the central nucleus of the amygdala that spare axonal fibers of passage result in active avoidance conditioning deficits (Sanchez Riolobos, 1986). Interestingly, however, cellular markers of neuronal activity in the amygdala indicate that avoidance training engages primarily the lateral and basolateral nuclei of the amygdala, with little evidence for central nucleus activation (Savonenko et al., 1999; Radwanska et al., 2002; Knapska et al., 2006b). This pattern of activity is consistent with recent work that indicates that the basolateral, but not central nucleus, of the amygdala is particularly involved with instrumental avoidance under some conditions (Killcross et al., 1997; Amorapanth et al., 2000).

In contrast to the amygdala, damage to the hippocampus, the fornix (the major subcortical projection tract of the hippocampus), or the entorhinal cortex (the major cortical interface of the hippocampus) typically produces a facilitation of active avoidance learning (Myhrer, 1975; Weiner et al., 1998; Pouzet et al., 1999; Guillazo-Blanch et al., 2002). As will be discussed next, the enhancement in active avoidance conditioning might be the result of two factors. First, hippocampal lesions increase locomotor activity in a variety of test situations (Douglas, 1967; Blanchard et al., 1977; Maren and Fanselow, 1997). Increases in locomotor activity are likely to foster the emission of escape responses in response to shock during avoidance training and are thus permissive to the acquisition of avoidance responses. Second, hippocampal lesions produce impairments in the acquisition of contextual fear, while having minimal effects on fear to discrete CSs (e.g., Phillips and LeDoux, 1994). Contextual fear tends to retard acquisition of two-way active avoidance insofar as it generates freezing behavior (which

competes with escape and avoidance responding), and it encourages passive avoidance of the compartment of the apparatus that was associated with shock on each subsequent trial. Hence, hippocampal rats unencumbered by contextual fear, accruing CS fear normally, and primed to emit active avoidance responses, outperform normal rats in active avoidance tasks. The hippocampal system does not appear to play a direct role in supporting avoidance learning but, rather, modulates performance in a way that is constrained by the contextual demands of the task.

Gabriel and colleagues have conducted one of the most systematic neural analyses of instrumental avoidance learning in rabbits performing wheel-running responses in a discriminative avoidance task (Gabriel, 1993). In this task, one auditory conditional stimulus (CS+) signals the onset of footshock, whereas a different auditory conditional stimulus (CS−) does not. Rabbits come to respond discriminatively to the two cues, only making stepping responses in a running wheel to avoid footshock in response to the CS+. Consistent with work in rats and cats in other avoidance conditioning tasks, lesions or pharmacological inactivation of the amygdala impair the acquisition of discriminative avoidance conditioning in rabbits (Poremba and Gabriel, 1997a, 1999, 2001). Damage to the lateral and central nuclei of the amygdala appears to be particularly predictive of avoidance deficits in rats with amygdala lesions (Poremba and Gabriel, 1997a). Indeed, discrete lesions of the central nucleus severely impair acquisition of discriminative avoidance learning without affecting instrumental responding for an appetitive reward (Smith et al., 2001). And as noted in earlier reports, the amygdala appears to be particularly important during the acquisition of instrumental avoidance behavior, insofar as reversible inactivation of amygdala neurons with muscimol, a $GABA_A$ receptor agonist, in well-trained rabbits does not impair avoidance responding (Poremba and Gabriel, 1999).

Electrophysiological recordings in a number of interconnected structures reveal that there is a systematic engagement of neuronal populations in encoding the conditioning contingencies and mediating the performance of well-learned behavior (Gabriel, 1993). Earliest to engage during avoidance conditioning are the basolateral amygdala, mediodorsal nucleus of the thalamus, and anterior cingulate cortex; later avoidance performance in well-trained animals is correlated with discriminative neuronal activity in the anterior thalamic nuclei and the posterior cingulate cortex (Gabriel et al., 1991; Maren et al., 1991). Both thalamic structures are critically involved in acquisition and maintenance of avoidance behavior (Gabriel et al., 1989; Steinmetz et al., 1991). Auditory information that drives neuronal firing to the CSs during avoidance training reaches the amygdala, thalamus, and cingulate cortex by way of the auditory thalamus (Poremba and Gabriel, 1997b). Amygdala lesions or inactivation, in addition to impairing acquisition of avoidance responses, impair electrophysiological correlates of avoidance conditioning that develop in the auditory thalamus, particularly the medial division of the medial geniculate nucleus, the anterior and mediodorsal thalamic nuclei, and the anterior and posterior cingulate cortices (Poremba and Gabriel, 1997a; Poremba and Gabriel, 1999; Poremba and Gabriel, 2001; Smith et al., 2001). Electrophysiological correlates of avoidance conditioning have also been observed in the central and basolateral nuclei of rats during both active (Rorick-Kehn and Steinmetz, 2005) and passive (Chang et al., 2005) avoidance.

As in other active avoidance conditioning tasks, damage to the hippocampal formation improves the acquisition of instrumental avoidance conditioning in rabbits (Gabriel and Sparenborg, 1986; Gabriel et al., 1987). Interestingly, hippocampal areas, particularly the subiculum, appear to have an inhibitory influence on anterior thalamic neuronal activity; accordingly, subicular lesions facilitate both CS-elicited spike firing in the thalamus and behavioral performance (Gabriel and Sparenborg, 1986; Gabriel et al., 1987). As suggested earlier, the hippocampus appears to be particularly germane to encoding contextual representations during conditioning. Indeed, hippocampal neurons exhibit highly context-dependent spike firing when auditory CSs acquire multiple meanings (Freeman et al., 1996). Lesions placed in the entorhinal cortex, which is the primary cortical interface of the hippocampus, impairs context-dependent behavioral performance and CS-elicited neuronal activity (Freeman et al., 1997).

Collectively, the results from instrumental avoidance conditioning tasks suggest that the central and basolateral nucleus of the amygdala are involved in acquiring active avoidance responses but are not required for their retention. It has been argued that two processes contribute to the acquisition of avoidance responses (Mowrer, 1947). First, animals acquire Pavlovian fear of the CS and subsequently learn to terminate the CS by making an instrumental avoidance response (see Bolles, 1972, for an alternative interpretation). According to this view, avoidance responses are reinforced by fear reduction when the CS is terminated. Once learned, performance

is maintained by the instrumental contingency, and conditional fear to the CS plays a relatively minor role in supporting performance (Mineka and Gino, 1980). Hence, one explanation for the differential role of the amygdaloid nuclei in the acquisition and retention of instrumental avoidance is that lesions made before training disrupt acquisition because they interfere with Pavlovian fear conditioning, whereas lesions made after training have little effect because Pavlovian fear is not required to sustain performance at that point in training (Maren, 1998).

3.24.4.2 Passive Avoidance Conditioning

Unlike active avoidance tasks, the instrumental contingency in a passive avoidance task is arranged to punish active behavioral response and encourage shock avoidance through inhibition of responding. Similar to active avoidance learning, several studies have indicated a critical role for the amygdala in the acquisition and retention of this form of learning. Large, bilateral amygdala lesions impair the acquisition of a variety of passive avoidance responses in rats (McNew and Thompson, 1966; McIntyre and Stein, 1973; Bresnahan et al., 1976; Nagel and Kemble, 1976; Russo et al., 1976; Liang et al., 1982; Jellestad and Bakke, 1985), mice (Slotnick, 1973), and cats (Horvath, 1963; Ursin, 1965). Smaller electrolytic lesions centered on the basolateral nucleus (Coover et al., 1973; Grossman et al., 1975; Werka et al., 1978) or central nucleus (Grossman et al., 1975; Werka et al., 1978) of the amygdala reproduce these passive avoidance deficits. In contrast, only excitotoxic lesions of the central or lateral nuclei, but not the basolateral nucleus, have been reported to impair step-through inhibitory avoidance (Tomaz et al., 1992); this is an interesting contrast to other studies that find that basolateral, but not central, lesions influence active avoidance responses (Killcross et al., 1997; Amorapanth et al., 2000). In addition to acquisition deficits, impairments in the retention of a passive avoidance response after amygdala lesions have also been reported (Nagel and Kemble, 1976; Liang et al., 1982; Parent et al., 1994, 1995), and reversible inactivation of the amygdala with lidocaine, a voltage-gated sodium channel blocker (Parent and McGaugh, 1994), or muscimol (Holahan and White, 2004a,b) impairs the retention of inhibitory avoidance.

Given the importance of the amygdala, particularly the lateral and central nuclei, in passive avoidance, it is reasonable to consider the possibility that the memory for some aspect of passive avoidance training resides within the amygdala. Passive avoidance conditioning depends on both Pavlovian associations between context and shock and instrumental associations between approach behavior and its aversive outcome (Randall and Riccio, 1969). Unlike active avoidance conditioning, it is likely that Pavlovian associations play a key role in maintaining passive avoidance behavior (most passive avoidance tasks involve only a single training trial) (Randall and Riccio, 1969). As discussed earlier, considerable evidence shows that the central and lateral nuclei of the amygdala are involved in encoding and storing Pavlovian fear memories (e.g., Maren and Quirk, 2004). Therefore, disruption of these structures would be expected to impair the acquisition and expression of passive avoidance behavior. Spared passive avoidance performance that is observed after damage to the basolateral nucleus may be maintained by conditioned fear, which can survive these lesions under some conditions (Nader et al., 2001; Anglada-Figueroa and Quirk, 2005). Nonetheless, basolateral nucleus lesions do impair the acquisition of fear conditioning in other studies (Goosens and Maren, 2001), and these lesions disrupt the expression of conditioned fear when made after conditioning (Anglada-Figueroa and Quirk, 2005). Thus, the contribution of individual amygdaloid nuclei to both the acquisition and retention of passive avoidance warrants further attention, particularly in relation to the effects of these manipulations on Pavlovian fear conditioning.

In addition to the amygdala, the hippocampus plays an important role in the acquisition and retention of passive avoidance conditioning. Hippocampal lesions or electrical stimulation disrupt the acquisition and consolidation of passive avoidance memory (Blanchard and Fial, 1968; Winocur and Bindra, 1976; Munoz and Grossman, 1981; Kesner and Hardy, 1983). Moreover, reversible inactivation of the hippocampus with tetrototoxin, a voltage-gated sodium channel blocker, impairs the acquisition, consolidation, and retrieval of passive avoidance memories (Lorenzini et al., 1996; Ambrogi Lorenzini et al., 1997). The important role of the hippocampus in passive avoidance conditioning is likely due to the prominent role contextual conditioning plays in standard passive avoidance paradigms. That is, step-through and step-down versions of the task, which

are the most commonly used passive avoidance paradigms, essentially consist of an animal-initiated context-shock conditioning trial. The Pavlovian association between context and shock is an important component to passive avoidance performance, insofar as forced extinction of the shock context after avoidance conditioning degrades conditional responding (Randall and Riccio, 1969). Of course, the instrumental approach-shock contingency is also important in shaping passive avoidance, and delay of shock after animals enter the dangerous context (which degrades the response-outcome contingency) reduces passive avoidance performance (Randall and Riccio, 1969). Indeed, the hippocampal contribution to encoding contexts (which is discussed later), as opposed to processing the aversive shock event, appears to play a critical role in the influences of hippocampal manipulations on passive avoidance memory (Malin and McGaugh, 2006). Recent work shows that the representation of contexts by the hippocampus depends, in part, on activity in the amygdala (Roozendaal and McGaugh, 1997; Huff and Rudy, 2004; Huff et al., 2006; Malin and McGaugh, 2006).

Because passive avoidance conditioning can be acquired in a single trial, it has been become one of the most extensively used tasks to explore the pharmacology of emotional learning and memory. Indeed, a variety of pharmacological manipulations within the amygdala can bidirectionally influence (either enhancing or impairing) the retention of passive avoidance memory (Gallagher et al., 1977; McGaugh, 2000, 2004). In this regard, there is substantial evidence that the amygdala is also involved in consolidating memories for aversive experiences outside the amygdaloid circuitry (Cahill and McGaugh, 1998), and the majority of work indicates that the basolateral nucleus of the amygdala in particular is instrumental in this function (Roozendaal and McGaugh, 1997; Roozendaal et al., 1998). It has been argued that the amygdala may not be involved in the local storage of memories for aversive events but, rather, is preferentially concerned with modulating aversive memory in other brain structures (Cahill et al., 2001). However, the roles for the amygdala in Pavlovian association formation and memory consolidation are dissociable. For example, posttraining inactivation of the amygdala with muscimol produces deficits in the retention of inhibitory avoidance conditioning, but not Pavlovian fear conditioning (Wilensky et al., 2000). Therefore, the nature of the amygdala's involvement in aversive learning, whether it is local memory storage or remote memory consolidation, depends importantly on the associative structure of the conditioning situation and the behavioral measures used to index memory (Kapp et al., 1978; Maren, 2003b).

3.24.4.3 Defensive Burying and Shock-Probe Avoidance

Similar to traditional passive avoidance tasks, large lesions of the hippocampus or amygdala lesions impair avoidance of an electrified probe once the probe has been contacted (Treit and Menard, 1997). Neither lesion, however, affects how much time animals spend burying the probe after they have received shock. Small lesions of the amygdala centered on the central nucleus do not affect probe avoidance but do affect immobility that occurs after contact with the electrified probe (Roozendaal et al., 1991). Interestingly, lesions or inactivation of the amygdala, despite reducing probe avoidance during the conditioning session, do not affect subsequent avoidance of the probe during retention testing (Lehmann et al., 2000, 2003). Although this has been interpreted to indicate that the amygdala is not necessary to form probe-shock associations, another possibility is that instrumental contingencies related to the training procedure maintain avoidance in the absence of associative fear of the probe (Maren, 2003b).

3.24.5 Neural Mechanisms of Pavlovian Fear Conditioning

In addition to instrumental avoidance conditioning tasks, Pavlovian fear conditioning has been used extensively to examine the brain substrates of emotional learning and memory (LeDoux, 2000; Maren, 2001; Fanselow and Poulos, 2005; Davis, 2006). Studies of the neural mechanisms of Pavlovian fear conditioning have focused on the contribution and interaction of several interconnected structures, including the amygdala, hippocampus, and prefrontal cortex (McIntosh and Gonzalez-Lima, 1994, 1998). Sensory information reaches each of these structures via both thalamic and cortical routes. To understand the neural basis of fear conditioning, we will consider the contribution of each of these brain areas to various fear conditioning paradigms. This review will focus on the anatomy and physiology of these forms of learning, insofar as the synaptic and cellular basis

of fear conditioning is considered in detail elsewhere (*See* Chapter 4.11). The majority of the work described was conducted in rats, and work in other species will be identified where appropriate.

3.24.5.1 Conditioned Freezing

It has long been appreciated that aversive stimuli evoke freezing behavior in several animal species, particularly rodents. Robert and Caroline Blanchard pioneered the use of freezing behavior as an index of conditioned fear (Blanchard and Blanchard, 1969). Not surprisingly, they were also the first to systematically examine the neural systems involved in the acquisition and retention of conditioned freezing. In early work, they demonstrated a role for the amygdala in the acquisition of conditioned freezing (Blanchard and Blanchard, 1972a). In this case, they used a contextual fear conditioning procedure in which footshocks were delivered in a specific environmental context, and freezing behavior in that context served as the measure of conditional fear. They found that large, bilateral amygdala lesions completely eliminated shock-elicited freezing behavior, as well as unconditional freezing to a cat (Blanchard and Blanchard, 1972a). Interestingly, they also found in related studies that damage to the hippocampal formation produced a similar loss in contextual fear conditioning (Blanchard et al., 1970, 1977; Blanchard and Blanchard, 1972b), but such lesions also elevated motor activity in a number of test situations. Nonetheless, as will be discussed shortly, the hippocampus proves to have a special role in learning about contextual stimuli, and this role comes to influence the acquisition of contextual fear. The use of freezing behavior as an index of learned fear has become the most widely used paradigm for studying the neural mechanisms of emotional learning and memory. This is due in large part to the ease of measuring freezing behavior and the simplicity of the training regimen (appetitive training to establish an operant baseline is not required). For this reason, the most published literature is on this paradigm, and this will be reflected in the extensive coverage of conditioned freezing in this section.

Building on the Blanchards' original work, several laboratories in nearly countless studies have confirmed the critical role for the amygdala in both the acquisition and expression of conditioned freezing behavior using selective lesions of individual amygdaloid nuclei. For example, selective lesions of the basolateral complex, particularly the lateral nucleus, produce severe deficits in both the acquisition and expression of conditioned freezing to discrete CSs (whether auditory, visual, or olfactory) and contexts (LeDoux et al., 1990; Ambrogi Lorenzini et al., 1991; Maren et al., 1996a; Cousens and Otto, 1998; Maren, 1998, 1999b; Amorapanth et al., 2000; Antoniadis and McDonald, 2000; Cahill et al., 2000; Goosens and Maren, 2001; Nader et al., 2001; Blair et al., 2005). It is noteworthy that lesions of the basolateral amygdala made long after conditioning (from a month to over a year) produce a complete retrograde amnesia for conditioned fear manifested as a loss of conditioned freezing (Maren et al., 1996a; Gale et al., 2004). Reversible pharmacological inactivation of the basolateral amygdala with agents such as muscimol (a $GABA_A$ receptor agonist) or lidocaine (a voltage-gated sodium channel blocker) also eliminates the acquisition and expression of conditioned freezing (Helmstetter, 1992a; Helmstetter and Bellgowan, 1994; Muller et al., 1997; Wilensky et al., 1999; Wilensky et al., 2000; Maren et al., 2001; Goosens and Maren, 2003; Blair et al., 2005). Furthermore, the amygdala plays a prominent role in the ontogeny of fear conditioning in rats (Moriceau and Sullivan, 2005, 2006; Moriceau et al., 2006).

An important observation is that deficits in conditioned freezing after basolateral complex lesions can be overcome with extensive training so long as overtraining occurs in a brain-damaged animal; basolateral lesions made after extensive overtraining still yield complete deficits in conditioned freezing (Maren, 1998, 1999b). This argues that although the basolateral complex of the amygdala, including the lateral nucleus of the amygdala, is critical for the acquisition of conditioned freezing, another brain region can compensate for loss of the basolateral complex under some conditions. One possibility is that the central nucleus of the amygdala, which receives a major projection from the basolateral complex (Krettek and Price, 1978; Paré et al., 1995; Savander et al., 1995), has a critical role in the acquisition and expression of conditioned freezing (Paré et al., 2004). This possibility has been supported in preliminary work (Zimmerman et al., 2005).

The possibility that the central nucleus has a critical role in fear conditioning is not novel. Indeed, it has long been appreciated that the central nucleus of the amygdala has a critical role in fear behavior. For example, electrical stimulation of the

central nucleus produces behavioral responses similar to those evoked by stimuli paired with shock (Applegate et al., 1983; Iwata et al., 1987; Kapp et al., 1992). Lesions of the central nucleus of the amygdala, like those of the basolateral complex, prevent the acquisition and expression of conditioned freezing in rats (Amorapanth et al., 2000; Goosens and Maren, 2001; Nader et al., 2001), although there is some evidence of spared fear conditioning with pharmacological manipulations of the central nucleus during conditioning (Goosens et al., 2003; Goosens and Maren, 2003). As mentioned earlier, lesions placed in central amygdala efferents produce selective deficits in certain fear responses such as conditioned freezing in the case of the periaqueductal gray (LeDoux et al., 1988; Kim et al., 1993a; De Oca et al., 1998; Amorapanth et al., 1999) or arterial pressure in the case of the lateral hypothalamus (Iwata et al., 1986b; LeDoux et al., 1988). Because lesions in the central nucleus of the amygdala impair all these fear responses (LeDoux et al., 1988), the evidence suggests that the central nucleus is the final common pathway for the generation of learned fear responses.

There is extensive sensory convergence in both the basolateral complex and central nucleus in the amygdala (Krettek and Price, 1974, 1978; Pitkanen et al., 1997; McDonald, 1998; Swanson and Petrovich, 1998; Sah et al., 2003). In the past, the possibility that associations between sensory inputs occurred exclusively in the basolateral complex, particularly the lateral nucleus, rather than the central nucleus had been emphasized (LeDoux, 1993a,b, 1994, 1995, 2000; Maren, 1996, 1999a,b, 2001, 2003a; Fanselow and LeDoux, 1999; Fendt and Fanselow, 1999). However, it has recently been appreciated, given both anatomical considerations and spared learning in rats with basolateral complex lesions, that the central nucleus has a more important role in fear conditioning than previously thought (Paré et al., 2004). A recent series of experiments indicates that many of the molecular processes believed to operate in the service of long-term memory storage are required in the central nucleus to acquire conditional fear (Wilensky et al., 2006). The important role for the central nucleus in the acquisition of conditioned affective states has also been emphasized in appetitive conditioning paradigms and in conditioned suppression (Cardinal et al., 2002; Balleine and Killcross, 2006). As a result, there is mounting evidence that the central nucleus and basolateral complex might perform different functions in aversive conditioning, at least under some conditions.

Sensory inputs to the amygdala arise from a number of areas, including the medial thalamus (LeDoux et al., 1984; Doron and LeDoux, 2000a,b), hippocampal formation (Ottersen, 1982; Aggleton, 1986; Canteras and Swanson, 1992; Maren and Fanselow, 1995), rhinal cortices (Aggleton, 1986; McDonald and Mascagni, 1997; Shi and Cassell, 1999), and spinal cord (Ma and Peschanski, 1988; Cliffer et al., 1991; Burstein and Potrebic, 1993; Newman et al., 1996). Consistent with this anatomy, single neurons in the basolateral complex and central nucleus of the amygdala respond to auditory, visual, and somatic (shock) stimuli (Applegate et al., 1982; Pascoe and Kapp, 1985a,b; Kapp et al., 1992; Romanski et al., 1993), which indicates that the amygdala is a locus of convergence for information about CSs and USs. Thus, the amygdala is anatomically situated to integrate information from a variety of sensory domains. Extensive pharmacological evidence indicates that synaptic plasticity in the amygdala contributes to both the acquisition and extinction of conditioned freezing (Maren et al., 1996b, 2003; Lee and Kim, 1998; Rosen et al., 1998; Bailey et al., 1999; Weisskopf et al., 1999; Goosens et al., 2000; Nader et al., 2000; Schafe et al., 2000, 2005; Fendt, 2001; Lee et al., 2001, 2006; Malkani and Rosen, 2001; Bauer et al., 2002; Lamprecht et al., 2002; Moita et al., 2002; Rodrigues et al., 2002, 2004; Goosens and Maren, 2003, 2004; Apergis-Schoute et al., 2005; Maren, 2005b; Rumpel et al., 2005; Merino and Maren, 2006; Wilensky et al., 2006).

As mentioned earlier, it is well documented that amygdala damage disrupts not only learned fear but also innate fear under some conditions. For example, rats with amygdala lesions do not exhibit freezing or analgesia in the presence of a cat (Blanchard and Blanchard, 1972a; Fox and Sorenson, 1994); they do show attenuated unconditional analgesia and heart rate responses to loud noises (Bellgowan and Helmstetter, 1996; Young and Leaton, 1996), and they exhibit reduced taste neophobia (Nachman and Ashe, 1974). Amygdala damage does not disrupt all unconditional fear responses, however. Amygdala lesions do not affect open arm avoidance in an elevated plus maze (Treit et al., 1993; Treit and Menard, 1997), unconditional analgesia (Watkins et al., 1993), or unconditioned freezing to a predator odor (Wallace and Rosen, 2001), or after ejaculation (Choi and Brown, 2003). Thus, although amygdala damage may reduce unlearned fear responses under some conditions, it does not appear that a general loss of fear accounts for the memory impairments

observed after lesions or inactivation of the amygdala, as has been suggested by some (Cahill et al., 2001, 1999).

Electrophysiological recordings of amygdaloid neuronal activity support a role for the amygdala in representing conditional fear memories (Maren and Quirk, 2004). Auditory fear conditioning induces short-latency plasticity in amygdala neurons (Quirk et al., 1995, 1997; Armony et al., 1998; Collins and Paré, 2000; Maren, 2000a; Pelletier et al., 2005). This plasticity takes the form of enhanced spike firing elicited by acoustic CSs. Fear conditioning also increases the amplitude of synaptic potentials in lateral amygdala neurons recorded either intracellularly (Rosenkranz and Grace, 2002) or extracellularly (McKernan and Shinnick-Gallagher, 1997; Rogan et al., 1997). The short latency of learning-related changes in spike firing is consistent with plasticity in thalamo-amygdala projections, specifically, projections from the medial division of the medial geniculate nucleus. Amygdala neurons exhibit plasticity earlier in training than auditory cortical neurons, further suggesting that direct thalamo-amygdala projections, rather than cortico-amygdala projections, mediate neuronal plasticity in the lateral amygdala (Quirk et al., 1997). Although spike-firing changes with conditioning are only correlative, it is difficult to determine if they represent fear memories or are consequent to changes in fear and arousal engendered by auditory CSs. A recent study, however, indicates that learning-related changes in the amygdala are independent of conditioned freezing behavior, suggesting that they reflect the associative properties of CSs paired with shock (Goosens et al., 2003). Electrophysiological plasticity also develops in both the auditory thalamus (Weinberger et al., 1972; Supple and Kapp, 1989; Edeline and Weinberger, 1991a,b; McEchron et al., 1996), and the auditory cortex (Edeline et al., 1993; Edeline and Weinberger, 1993; Weinberger, 1995) after auditory fear conditioning. The latency of CS-elicited plasticity in the lateral amygdala is not consistent with transmission of plasticity from the cortex (Quirk et al., 1997; Maren, 2000a); however, transmission of plasticity from the auditory thalamus cannot be ruled out (Weinberger and Bakin, 1998; Cahill et al., 1999). Although thalamic plasticity might modulate the memory formation in the amygdala during fear conditioning (Apergis-Schoute et al., 2005; Parsons et al., 2006), evidence suggests that cellular activity in the amygdala is necessary for both fear conditioning and auditory thalamus plasticity (Maren et al., 2001).

As mentioned earlier, the hippocampus is also involved in conditioned freezing under some conditions. In particular, there is extensive evidence that the hippocampus is involved with encoding the contexts in which aversive stimuli occur (Maren et al., 1998; Anagnostaras et al., 2001; O'Reilly and Rudy, 2001; Sanders et al., 2003). Several investigators have found that lesions of the hippocampus produce rather selective deficits for the acquisition of fear to contextual stimuli, as opposed to discrete CS (Sutherland and McDonald, 1990; Selden et al., 1991; Phillips and LeDoux, 1992, 1994, 1995; Kim et al., 1993a). However, others have not found deficits in the acquisition of contextual fear conditioning after hippocampal damage (Maren et al., 1997; Cho et al., 1999). This has led to the suggestion that contextual fear can be mediated by discrete stimuli within the conditioning chamber (such as the smell of the chamber) (Maren et al., 1997; Rudy and O'Reilly, 1999; Rudy et al., 2002). Interestingly, the amount of training appears to be critical for obtaining deficits in the acquisition of contextual fear insofar as deficits are obtained with limited, but not more extensive, training (Wiltgen et al., 2006). Hippocampal lesions also impair the consolidation of contextual fear memory when made within a month of fear conditioning (Kim and Fanselow, 1992; Maren et al., 1997; Anagnostaras et al., 1999). Although dorsal hippocampal lesions tend to spare auditory fear conditioning, neurotoxic lesions that include the subiculum or ventral hippocampus produce deficits in auditory fear conditioning in many cases (Maren, 1999c; Maren et al., 1997; Richmond et al., 1999; Maren and Holt, 2004). Nonetheless, considerable evidence indicates that contextual and auditory fear conditioning is mediated, at least in part, by dissociable neural systems (Rudy et al., 1999; Venton et al., 2006).

In addition to its role in encoding contextual representations, the hippocampus is involved in contextual memory retrieval (Holt and Maren, 1999; Maren and Holt, 2000; Maren, 2005a). Although the hippocampus is not necessary to retrieve context memories *per se* (e.g., Kim and Fanselow, 1992), it is necessary for using contextual information to retrieve the meaning of an ambiguous CS. For instance, in two related paradigms, latent inhibition and extinction, animals are exposed to a phase of CS-alone presentations either before (in the case of latent inhibition) or after (in the case of extinction) fear conditioning. With these procedures, the CS acquires two different meanings: it predicts a fearful US in the

conditioning phase but does not predict the US during the latent inhibition or extinction phase of training. Importantly, considerable work indicates that both latent inhibition and extinction are context dependent, and contexts are used to inform the animal what a CS means in a particular context (Bouton, 1993). Lesion or reversible inactivation of the dorsal or ventral hippocampus disrupt the context dependence of latent inhibition and extinction and also disrupt the context dependence of lateral amygdala spike firing after extinction (Holt and Maren, 1999; Corcoran and Maren, 2001, 2004; Corcoran et al., 2005; Ji and Maren, 2005; Bouton et al., 2006; Hobin et al., 2006; Maren and Chang, 2006). Based on this work, it appears that the amygdala is involved in associating CSs and USs, and the hippocampus encodes contextual representations and uses those representations to tag CS–US associations to enable their retrieval under conditions in which the CS memory has become ambiguous.

In addition to the hippocampus, considerable attention has been directed at the role of the prefrontal cortex in the extinction of fear conditioning (Quirk et al., 2006). It has been reported that lesions or pharmacological manipulations in the prefrontal cortex impede the recall of extinction without effecting extinction *per se* (Morgan et al., 1993; Quirk et al., 2000; Hugues et al., 2006; Sierra-Mercado et al., 2006). Moreover, prefrontal neurons increase their activity to CSs that have undergone extinction (Milad and Quirk, 2002), an effect that may be regulated by the amygdala (Garcia et al., 1999). Despite the explosion of interest in prefrontal cortical contributions to fear extinction, not all investigators report that prefrontal cortical lesions influence the extinction of conditional fear (Gewirtz et al., 1998; Garcia et al., 2006). Additional work is required to fully understand the contribution of the hippocampus, prefrontal cortex, and amygdala to fear extinction.

3.24.5.2 Conditioned Suppression of Appetitive Responding

As noted earlier, the amygdala has a critical role in the acquisition and expression of Pavlovian fear conditioning as indexed by conditioned freezing. Insofar as it has been argued that conditioned fear contributes to conditioned suppression of appetitive responding (Estes and Skinner, 1941), one would expect a similarly important role for the amygdala in this form of responding. Consistent with this possibility, Kellicutt and Schwartzbaum demonstrated a critical role for the amygdala in the acquisition of a conditioned emotional response, which they assessed by measuring bar-press suppression to an auditory CS previously paired with shock (Kellicutt and Schwartzbaum, 1963). This study used large lesions of the amygdala that were not specific to particular nuclei, but nonetheless it was the first to establish that fear learning requires the amygdala. More recent studies have also found that large lesions of the amygdala or electrical stimulation of the amygdala disrupts conditioned bar-press suppression (Lidsky et al., 1970; Spevack et al., 1975; Kopchia et al., 1992; Mintz and Wang-Ninio, 2001). Importantly, fiber-sparing excitotoxic lesions of amygdaloid nuclei also disrupt the acquisition of conditioned suppression to auditory CSs, such as lick suppression (Selden et al., 1991).

Subtotal lesions of the amygdala, focused on either the basolateral complex or the central nucleus of the amygdala, have also been reported to produce deficits in the acquisition of bar-press suppression (Killcross et al., 1997). In an unconventional paradigm, rats initiated delivery of two different CSs on each of two bars (one bar yielded a CS+ that signaled footshock, and the other bar yielded a CS− that did not signal shock). The paradigm was designed to yield measures of both instrumental avoidance (preferential pressing on CS− bar) and conditioned suppression (reduction in appetitive responding on trials in which the animal delivered a CS+). In this paradigm, both types of lesion impaired conditioned suppression early in training, but ultimately animals with basolateral complex lesions acquired the response. In contrast, animals with basolateral lesions were unable to acquire instrumental avoidance, whereas rats with central nucleus lesions were unimpaired on this measure of aversive conditioning. Based on these results, it has been argued that there is a functional dissociation between the central nucleus and basolateral complex of the amygdala, with the central nucleus mediating Pavlovian conditioned aversive states required for appetitive suppression and the basolateral complex mediating specific sensory representations of biologically relevant outcomes required for instrumental choice (Blundell et al., 2001; Cardinal et al., 2002; Balleine et al., 2003; Balleine and Killcross, 2006).

However, as we have seen, there are considerable data supporting a role for both the central and basolateral nuclei in the acquisition and expression of

Pavlovian conditioned freezing. These data argue that a serial circuit in the amygdala underlies fear memory. A critical factor in revealing dissociations between the central nucleus and the basolateral complex in aversive conditioning may be the extent of training. For instance, deficits in conditioned suppression are equally robust early in training in rats with central or basolateral complex lesions but recover with additional training in some cases (Killcross et al., 1997; Lee et al., 2005). Moreover, as mentioned earlier, deficits in conditioned freezing in rats with basolateral complex lesions, but not central nucleus lesions, recover with additional training (Zimmerman et al., 2005). Hence, these amygdaloid nuclei may operate cooperatively and in a serial manner early in fear conditioning, but functionally dissociate after more extensive training. It remains to be determined how central or basolateral complex lesions affect the expression of conditioned suppression when made after extensive training.

The potent influence of amygdala lesions on the acquisition of conditioned suppression is not a general effect of damage to limbic system structures. For example, electrolytic or excitotoxic lesions of the hippocampus do not impair the acquisition of conditioned bar-press suppression (Wilson et al., 1995; Frohardt et al., 2000; Talk et al., 2002) or lick suppression (Selden et al., 1991) to auditory CSs. Lesions of the septo-hippocampal cholinergic system do not themselves affect the acquisition of conditioned suppression but may alter the competition between discrete CSs and contextual cues in gaining control of behavior (McAlonan et al., 1995; Calandreau et al., 2006). Interestingly, damage to the dorsal noradrenergic bundle, which is one of the major forebrain sources of the catecholaminergic neurotransmitter, norepinephrine, impairs the acquisition of conditioned suppression (Cole and Robbins, 1987). An important issue is whether deficits in bar-press suppression with any neural intervention are secondary to disruptions in conditioned freezing behavior, for example. That is, rats may suppress appetitive responding in the presence of a fear CS because that CS elicits freezing behavior, which competes with licking for water or pressing for food. However, there is evidence that bar-press suppression can occur in rats that otherwise do not show conditioned freezing behavior. Rats with lesions of the midbrain periaqueductal gray, which completely eliminate the expression of conditioned freezing responses (De Oca et al., 1998), while sparing other indices of conditional fear, such as increases in arterial pressure (LeDoux et al., 1988), do not effect bar-press suppression (Amorapanth et al., 1999). This suggests that fear-induced suppression of appetitive responding is not dependent on conditioned freezing in all circumstances.

Relatively little work has been done on the neurophysiological correlates of conditioned suppression. However, a recent study in rats has revealed that auditory CSs paired with footshock produced changes in CS-elicited firing in the dorsal portion of the lateral amygdala (Repa et al., 2001). Interestingly, in some lateral nucleus neurons, these changes occurred before the appearance of conditioned suppression, suggesting that neuronal changes in the amygdala precede appearance of the behavioral CR. In ventral regions of the lateral nucleus, another population of cells was slower to exhibit learning-related changes but showed persistent learning-related activity, even after the behavioral fear response had been extinguished. The development of learning-related changes in amygdala spike firing during the acquisition of conditioned lick suppression has also been shown in monkeys (Rolls, 2000; Paton et al., 2006).

3.24.5.3 Conditioned Hypoalgesia

In addition to conditioned freezing, considerable work has examined the consequences of emotional learning and memory for pain sensitivity. As first described by Bolles and Fanselow (Bolles and Fanselow, 1982), fear has an important role in modulating endogenous opiate levels, thereby influencing pain sensitivity. Hypoalgesia after fear conditioning has been demonstrated in numerous studies (Fanselow and Bolles, 1979), and several investigators have explored the neural mechanisms underlying this effect. As with conditioned freezing, amygdala lesions or pharmacological manipulations prevent the acquisition and expression of conditioned hypoalgesia to contexts that have been paired with footshock (Helmstetter, 1992b; Helmstetter, 1993; Helmstetter and Bellgowan, 1993; Watkins et al., 1993; Good and Westbrook, 1995; Harris and Westbrook, 1995). Also like freezing, the periaqueductal gray is the primary descending target of the amygdala that is required for the expression of conditioned hypoalgesia (Helmstetter and Landeira Fernandez, 1990; Helmstetter and Tershner, 1994; Harris and Westbrook, 1995; Bellgowan and

Helmstetter, 1998; Helmstetter et al., 1998; Tershner and Helmstetter, 2000).

3.24.5.4 Fear-Potentiated Acoustic Startle

Another important model system for analyzing the neural mechanisms of Pavlovian fear conditioning is the fear-potentiated acoustic startle paradigm (Davis, 1992, 2006; Davis and Whalen, 2001). Similar to conditioned freezing, lesions placed in the amygdala, including excitotoxic lesions in the basolateral complex or central nucleus, produce severe impairments in the acquisition and expression of fear-potentiated startle to a visual CS in rats (Hitchcock and Davis, 1986; Sananes and Davis, 1992; Kim and Davis, 1993; Campeau and Davis, 1995b; Lee et al., 1996). Similarly, pharmacological inactivation of either the central nucleus or basolateral complex of the amygdala prevents the acquisition and expression of fear-potentiated startle (Kim et al., 1993b; Walker and Davis, 1997a; Walker et al., 2005). Both thalamic and cortical afferents of the amygdala transmit sensory information to the amygdala for the acquisition and expression of potentiated startle (Rosen et al., 1992; Campeau and Davis, 1995a; Shi and Davis, 1999, 2001). Extensive pharmacological evidence indicates that synaptic plasticity in the amygdala contributes to both the acquisition and extinction of fear-potentiated startle (Miserendino et al., 1990; Falls et al., 1992; Gewirtz and Davis, 1997; Walker and Davis, 2000; Lu et al., 2001; Josselyn et al., 2001; Lin et al., 2001, 2003a,b; Walker et al., 2002; Chhatwal et al., 2006).

In addition to learning-induced potentiation of acoustic startle, ambient illumination (bright light) can lead to nonassociative increases in acoustic startle (Davis, 1998). Unconditioned increases in potentiated startle also involve the amygdala, but interestingly there is a double dissociation in the circuitry for conditioned and unconditioned potentiated startle. Inactivation of the central nucleus of the amygdala affects conditioned increases in startle without influencing unconditioned increases in startle, whereas inactivation of the bed nucleus of the stria terminalis (which receives input from the amygdala) produces the converse pattern of results (Walker and Davis, 1997a). Inactivation of the basolateral complex of the amygdala influences both conditioned and unconditioned potentiated startle.

Although fear-potentiated startle is a widely used measure of fear conditioning, it displays some properties that differentiate it from other indices of conditioned fear. Unlike many of the other measures of conditioned fear, the magnitude of fear-potentiated startle decreases with increases in US magnitude. This decrease in the amplitude of the acoustic startle response is not predicted by formal models of learning and appears to be due to competition with freezing behavior. That is, lesions of the periaqueductal gray that eliminate freezing behavior permit the expression of potentiated acoustic startle by CSs trained with high US intensities (Walker et al., 1997; Walker and Davis, 1997b). Another factor that differentiates the acoustic startle response from other measures of fear is the timing of the conditioned response relative to the CS. Whereas freezing or hypoalgesic responses are tonic and expressed for minutes after the delivery of a brief CS, acoustic startle is only potentiated within a narrow time window that envelopes the expected time of US delivery (Davis et al., 1989; Burman and Gewirtz, 2004). These factors prove valuable for the analysis of temporal relationships that modulate fear expression but also suggest that the neural network involved in the expression of fear-potentiated startle is quite different from that involved in the expression of other fear responses.

3.24.5.5 Cardiovascular Conditioned Responses

In addition to somatic responses, learned fear is associated with the expression of many autonomic and hormonal responses. The most extensively studied autonomic correlates of fear conditioning are changes in heart rate and blood pressure to fearful CSs. Kapp was one of the first to systematically examine the neural basis of heart rate CRs in rabbits during Pavlovian fear conditioning. He found that the central nucleus was critical for the acquisition and expression of heart rate CRs (bradycardia in this case), but not unconditioned responses to either the auditory CS or periorbital shock US (Kapp et al., 1979). Considerable electrophysiological work has revealed that single neurons in the central nucleus exhibit plasticity during the acquisition of heart rate conditioning (Applegate et al., 1982; Pascoe and Kapp, 1985a,b). Subsequent work has shown that cell-specific lesion of the central nucleus, and the auditory afferent areas in the thalamus, also disrupt the acquisition and expression of heart rate conditioning in rabbits (Gentile et al., 1986; Jarrell et al., 1986a,b; McCabe et al., 1992, 1993). Foreshadowing recent work implicating the prefrontal cortex in fear

CRs, there is considerable evidence suggesting a role for prefrontal and cingulate cortices in the acquisition of conditioned bradycardia in rabbits (Buchanan and Powell, 1982; Powell, 1992; Powell et al., 1994).

Another brain structure that has been implicated in cardiovascular conditioning in rabbits is the cerebellar vermis, including the medial cerebellar cortex (Supple and Leaton, 1990a,b; Supple and Kapp, 1994). This finding is somewhat surprising because although the cerebellum has an established role in Pavlovian conditioning of discrete motor responses (Christian and Thompson, 2003), it has typically not been implicated in emotional CRs (Lavond et al., 1984; Lee and Kim, 2004). Most of these studies, however, have focused on the lateral cerebellar cortex and its projections to the interpositus nucleus. Moreover, previous studies in rats had indicated a role for the cerebellar vermis in unconditioned fear reactions but found little evidence of the vermis in conditioned fear (Supple et al., 1987, 1988). However, recent work suggests the vermis may have a role in conditioned freezing in rats (Sacchetti et al., 2002, 2005). This raises the possibility that the vermis has a role not only in the cardiovascular components of learned fear responses but also in other somatic fear CRs.

An important role for the auditory thalamus and amygdala has also been observed for heart rate and arterial pressure CRs in rats (LeDoux et al., 1984, 1986; Iwata et al., 1986a; Sananes and Campbell, 1989). In this case, both the lateral and central nuclei of the amygdala are critical for hear rate conditioning (LeDoux et al., 1990; Romanski and LeDoux, 1992). The projections from the amygdala that are involved in the expression of heart rate CRs are distinct from those involved in the other fear CRs that have been discussed. The expression of cardiovascular CRs involves both the lateral and peri-fornical regions of the hypothalamus (Iwata et al., 1986b; LeDoux et al., 1988; Furlong and Carrive, 2007).

3.24.5.6 Social Defeat and Social Transmission of Fear

Laboratory studies of fear conditioning using artificial stimuli under rigid parametric control are highly useful for analyzing the neural substrates of emotional learning and memory. Fear conditioning, of course, is a form of learning with relevance to an animal's niche and is the product of interactions with members of other species (e.g., predators) and even members of the same species (e.g., aggressive conspecifics). For example, in Syrian hamsters social defeat by a resident, dominant conspecific has been shown to yield later submissive behavior in the defeated individual that has some similarities with conditioned fear (Potegal et al., 1993). Interestingly, pharmacological inactivation of the amygdala in the subordinate animal during the aggressive encounter impairs the development of fear-related submissive behavior (Jasnow and Huhman, 2001; Jasnow et al., 2004a,b). In addition, augmenting molecular pathways that foster amygdala plasticity facilitate the development of submissive behavior that follows social defeat (Jasnow et al., 2005). Although the neurobiological analysis of this form of social fear conditioning is relatively young, it is interesting that it too requires the amygdala.

Conditioned fear is not only the product of certain social interactions but is also the source itself for generating fear in conspecific animals that have not themselves experienced aversive stimuli. There are multiple routes by which fear in one individual might be communicated to another. In rodents, olfactory stimuli and ultrasonic vocalizations are potent in this regard (Blanchard and Blanchard, 1989). Lesions of the amygdala, but not hippocampus, prevent the acquisition of fear-conditioned ultrasonic vocalizations (Koo et al., 2004; Lee and Kim, 2004). Moreover, both conditioned and unconditioned vocalization after discharges are sensitive to central amygdala damage (Borszcz and Leaton, 2003). The fact that conditional fear-induced vocalizations depend on the amygdala is not surprising insofar as all the Pavlovian fear CRs we have discussed depend on the amygdala.

However, an interesting new discovery is that the amygdala of a naïve observer appears to be engaged by the fearful behavior of a conspecific that has undergone an aversive fear-conditioning procedure (Knapska et al., 2006a). In this case, molecular markers of cellular activity (c-fos expression) were upregulated in several amygdaloid nuclei of rats merely exposed to a cage-mate that had undergone fear conditioning, even though the observers themselves never experienced the aversive conditioning procedure. This is similar to the activation of the human amygdala that has been observed by verbal warnings of potential fear experiences without actual presentations of an aversive stimulus (Phelps et al., 2001). Interestingly, subsequent emotional learning and memory in the observer rats, which was assessed in a shock-motivated shuttle avoidance task, was facilitated. This suggests that a brief social interaction

with a cage-mate that undergoes an aversive learning experience promotes aversive learning in an otherwise naïve animal. Apparently, fear conditioning has an important role in promoting adaptive defensive behavior in both the individual experiencing an aversive event, as well as others that are in proximity to the affected individual. In both cases, amygdala activity appears essential.

3.24.6 Conclusions

Animal models have proved incredibly informative for understanding the neural basis of emotional learning and memory. In fact, animal work has provided the groundwork for understanding the neural systems underlying emotional memory in humans. Consistent with the results that have emerged from animal studies, several investigators have now revealed an important role for the human amygdala in fear conditioning (Davidson and Irwin, 1999). Patients with amygdala pathology do not exhibit Pavlovian fear conditioning to either visual or auditory cues paired with loud noise (Bechara et al., 1995; LaBar et al., 1995), and patients with amygdala damage fail to recognize fear in facial expressions (Adolphs et al., 1995, 1999; Young et al., 1995). Functional neuroimaging has extended these lesion studies by revealing amygdala activation to visual or vocal expressions of fear (Morris et al., 1996; Phillips et al., 1997; Whalen et al., 1998; Whalen et al., 2004) and during Pavlovian fear conditioning (Buchel et al., 1998; LaBar et al., 1998; Morris et al., 1998; Morris and Dolan, 2004). Thus, the neural mechanisms of fear conditioning appear to exhibit homology across several mammalian species.

Of course, it is also important to stress that the amygdala does not encode every aspect of an aversive learning experience. For example, humans with amygdala damage exhibit intact declarative memory for a fear-conditioning experience, despite failing to exhibit conditional fear responses to stimuli paired with loud noise (Bechara et al., 1995). Similarly, rats with amygdala lesions avoid a compartment in which they have received footshock, despite failing to exhibit conditional freezing to the contextual cues associated with shock (Vazdarjanova and McGaugh, 1998). These results indicate that multiple memory systems are engaged during relatively simple learning and memory tasks. Thus, the amygdala operates to encode certain aspects of an emotional event, whereas other brain structures including the hippocampus and prefrontal cortex encode other aspects of the event that together integrate a robust representation of the emotional experience.

3.25 Hormones and Memory

J. M. Juraska and M. J. Rubinow, University of Illinois, Champaign, IL, USA

3.25.1 Introduction and Scope

Hormones are ubiquitous and important. Even though the topic of hormonal effects is considered somewhat marginal in the study of memory, every experiment described in these volumes (at least in mammals) has been subject to hormonal modulation. Occasionally, these influences were noted and manipulated (*See* Chapters 3.26, 3.27); most often they were not. Hormones usually were not the most important determining factor in memory, which may account for much of the field's ability to overlook them. It is safe to assert that no hormone is secreted primarily for its effects on learning and memory. However, a complete understanding of the learning of any task, as well as the memory that an individual forms, does require an understanding of hormones.

Hormones are chemicals secreted into the bloodstream, which carries them to target tissue. All hormones have multiple effects both on the body and directly on the brain, and they generally act as integrators of bodily functions. Hormones are only effective if there is an appropriate receptor with which they chemically interact. Once this hormone–receptor interaction occurs, it facilitates other chemical reactions that change the physiology of the cell. These alterations in physiology can include which genes are active. To add to the complications, hormones often interact with more than one type of receptor. These receptors are dynamic in that their numbers, and even their presence, can change depending on the amount of the hormone that has been available recently, the presence of other hormones, and the age of the organism. This means that hormones usually act in interaction with other factors, which complicates their study. It also complicates any simple generalization about the effect or role of any given hormone.

This chapter is an overview of this recently burgeoning field. It is not, and indeed it cannot be,

exhaustive because of the breadth and depth of this field. Our primary focus is on ovarian and adrenal steroids, as the bulk of the research has centered on these. There is an emphasis on recent data. We concentrate on mammals not only because of our own expertise but also to be concordant with most of the other chapters in this volume series. Neurohormones, substances that are secreted in the brain and that act on the brain, will not be covered. The review is not aimed at neuroendocrinologists. Rather, the audience is assumed to be investigators and students interested in memory in humans and other mammals – behavioral neuroscientists and psychologists.

3.25.2 Gonadal Steroid Hormones

Clearly, the hormones secreted by the gonads – the testes in males and the ovaries in females – have a primary role in the behavioral aspects and physiology of reproduction. Their effects on learning and memory may be indirect by-products of this role. Although this may be the origin of the effects, the gonadal steroids influence many situations that appear to have little relationship to reproduction.

Although the gonadal steroids are characterized as 'male' (testosterone, androgens) or 'female' (estrogen, progesterone), they are closely related chemicals, as are all of the steroid hormones (**Figure 1**). The steroids are produced from one another, and as a result, steroid-producing glands secrete small amounts of many steroids, in addition to the principal secretions. This further complicates interpretation of steroid effects.

3.25.2.1 Ovarian Steroids

3.25.2.1.1 Effects on cognitive behaviors – animal models

Estrogen and progesterone are the two primary steroid hormones secreted by the ovaries. Of the two, estrogen is by far the most heavily investigated in learning and memory. There appear to be several reasons for this. One is that the secretion of estrogen starts the estrous/menstrual cycles (**Figure 2**), and progesterone is not secreted without estrogen first being present, which gives it a secondary role. Another is that estrogen has been found to increase spine and synaptic density in a portion of hippocampus (see section 3.25.2.1.3.) with or without progesterone. The series of studies by Woolley, McEwen, and colleagues (e.g., Woolley et al., 1990) legitimized the investigation of estrogenic effects on cognitive tasks. Prior to these studies, the role of the estrous cycle and estrogen had only been investigated in active and passive avoidance tasks (reviewed in Dohanich, 2002). Finally, the medical implications of the drop in estrogen, and its replacement, at menopause have stimulated research (see section 3.25.2.1.5).

During the estrous cycle, both estrogen and progesterone rise and peak during the proestrus phase and then drop to low levels during the estrous phase (**Figure 2**). This drop is precipitous, occurring in less than 24 h in rodents, the major animal model for learning and memory. **Table 1** shows some of the mnemonic effects of the phase of the cycle. The effects tend to be subtle, which means that no differences will be found if the task is made easier, for

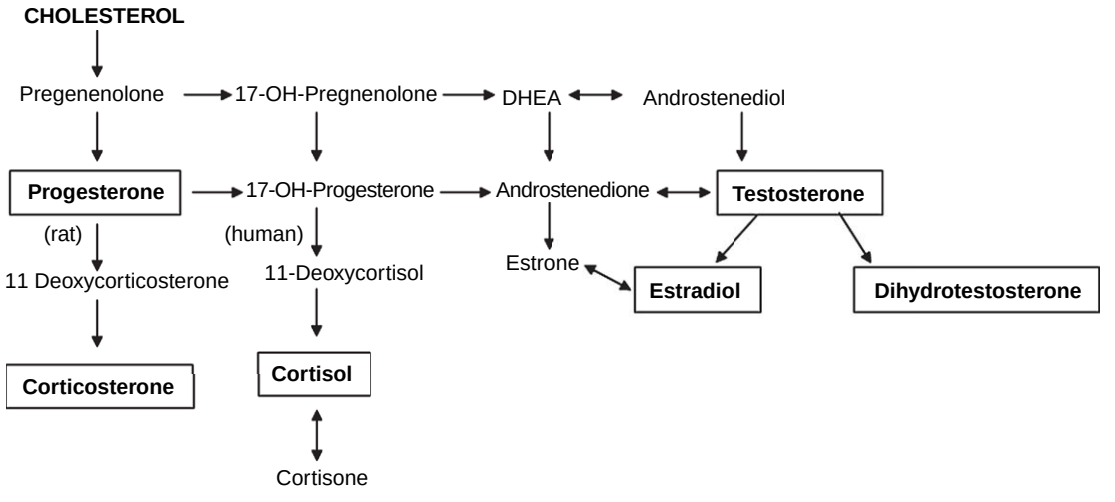

Figure 1 The synthesis pathways of the steroid hormones, illustrating their close interrelationships.

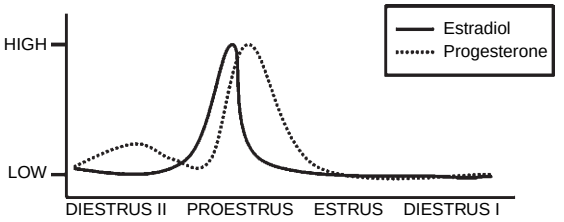

Figure 2 A schematic of the rise and fall of estrogen and progesterone during the 4- to 5-day estrous cycle. The menstrual cycle has the same pattern of rise and fall of hormones, with portions of the cycle temporally extended over 28 days.

example, by using a curtain with cues surrounding the water maze (Berry et al., 1997). Effects also tend to be lost if learning of the task is spread over several cycles (Stackman et al., 1997). Thus the water maze, which can be learned in a single day, has often been employed. The tasks that are facilitated by high hormones (proestrus) or having hormones (intact) defy simple classification. This is a point to which we will return. The studies in **Table 1** illustrate that the cycle of intact female lab rodents would affect the results of learning and memory experiments if this half of the population had been included. The effects of the cycle, which have been investigated by removing the ovaries and then replacing hormones, are due mostly to estrogen itself.

Table 2 shows the results of replacing estrogen (sometimes with progesterone) in females following removal of the ovaries. This can either be done acutely, usually with injections that mimic the cycle, or chronically, with pellets containing estrogen implanted under the skin, which allows the use of tasks that take longer to learn, such as the radial arm maze. In general, the effects are somewhat stronger than in the cycle, perhaps because of the supraphysiological doses that are often employed. Estrogen facilitates the performance of many cognitive tasks, but there are exceptions, and a generalization about what types of tasks are facilitated by estrogen has not been obvious. Some variability is caused by the dose, the pharmacokinetics of the method of replacement, and the length of time between the removal of the ovaries and replacement. The stressfulness of the task is also a factor (see section 3.25.3.5). There are some discrepancies between rats and mice. Still, even for data gathered on rats, there is no simple story.

There have been several attempts at a unifying explanation or construct for the role of estrogen in cognitive behavior. The first explanation, derived from estrogen's effects on hippocampal spines during proestrus and with replacement (Gould et al., 1990; Woolley et al., 1990), was an enhancement of spatial ability (Desmond and Levy, 1997), but this was negated by performance on the water maze, where high levels of estrogen resulted in poorer performance (Warren and Juraska, 1997; Chesler and Juraska, 2000). In a thorough review, Dohanich (2002) articulated the distinction in terms of working and reference memory, with estrogen aiding working memory while mildly hindering reference memory. This accounts for the negative effects on the water maze and on reference memory (unbaited arms) in the radial arm maze and the positive effects on working memory (baited arms) in the radial arm maze (Fader et al., 1999). The working/reference memory distinction did fail to explain the place/response

t-maze findings of Korol and Kolo (2002), in which estrogen facilitated place learning, but not response learning, even though both are reference memory. Korol and Kolo (2002) proposed that estrogen predisposed hippocampal (place) strategies. However, the water maze data do not fit into this scheme, especially when the standard reference version of the water maze is impeded by high estrogen (Warren and Juraska, 1997; Chesler and Juraska, 2000), while a working memory version of the maze is facilitated (Sandstrom and Williams, 2001). Further, estrous cycle effects on the reference memory version of the water maze are influenced by task stressfulness (Rubinow et al., 2004; see also section 3.25.3.5). Daniel (2006) has further elaborated the hippocampal view by proposing that estrogen enhances performance on tasks that involve relational representations and a flexible use of memory. This enlarged construct is supported by the author's own work with a cued operant discrimination that is not a spatial task (Daniel et al., 2002), and this view can handle the above paradox in water maze

paradigms. Another interesting proposal is by Sava and Markus (2005), who present evidence that estrogen increases the breadth of cue selection. This formulation can also account for much of the existing data, including the impairing effects of high estrogen on contextual fear conditioning (Markus and Zecevic, 1997). Thus, it is not just the type of task but the amount and placement of cues within the task that influence the effect of estrogen. This formulation also may extend the effects of estrogen beyond the hippocampus into neural areas involved in attention.

3.25.2.1.2 Effects on cognition during aging – animal models

Table 3 lists the studies that examined hormonal effects in females that were middle aged or older. Aging females, until recently rarely tested in the study of aging, have become a focus of attention as a model for the hormonal effects of human menopause. This research area has become important enough that there is a considerable literature on primates. Some primate species have menstrual cycles, but researchers usually do not wait for menopause to occur, rather, removing the ovaries in middle age. The ovaries are also often removed in aging rodents because, although the estrous cycle stops in female rodents in middle age, unlike human menopause, the ovaries continue to secrete estrogen and progesterone in a noncyclic fashion. This has been most thoroughly documented in rats (reviewed in Warren and Juraska, 2000), and two estropausal states have been described. One, termed constant estrus, is characterized by moderate amounts of estrogen and progesterone secretion. The other is constant diestrus (sometimes called pseudopregnancy), in which progesterone secretion is high, but estrogen is moderate to low. We have verified the hormonal bases of these stages in our own work on aged females (Markham and Juraska, 2002).

As can be seen in Table 3, replacement estrogen is often beneficial for the performance of cognitive tasks in aging females across the species that have been examined. The question in this part of the literature is less on how to characterize what type of tasks estrogen benefits and more on the parameters of the replacement that are most beneficial: chronic or cyclic administration, the length of time after the loss of estrogen during which replacement is still beneficial, the type of estrogen that is optimal, and the role of progesterone. All of these issues are under

Table 3 Effects of estrogen in females from middle through old age

investigation, and none are considered settled. There is some evidence that progesterone tends to impede the beneficial effects of estrogen in aged rats, both in intact females in different estropausal states (Warren and Juraska, 2000) and when given with estrogen following ovariectomy (Bimonte-Nelson et al., 2006), but more work is warranted.

It is important to note that the effects of estrogen in adult females of reproductive age are often not the same as the effects during aging. Comparisons between ages are especially powerful if the studies were run by the same investigator with parameters held as constant as possible. We have found that adult females showed a small deficit in the acquisition of the water maze when estrogen and progesterone were high both at proestrus and when replaced following ovariectomy (Warren and Juraska, 1997; Chesler and Juraska, 2000), but estrogen replacement in aged rats, with or without progesterone, facilitated performance on the same task (Markham et al., 2002). Likewise, Bimonte and Denenberg (1999) found that estrogen facilitated performance on the water radial arm maze in adult females, whereas Bimonte-Nelson et al. (2003a) found that both endogenous and exogenous estrogen impeded performance on the task in aged females. There also is evidence for changes in the subcellular localization of estrogen receptors in the hippocampus of the aged female rat (Adams et al., 2004). These examples indicate that young adult female rats cannot serve as a model for aging.

3.25.2.1.3 Neural mechanisms

The inquiry into the role of estrogen in cognition became a major field after Woolley et al. (1990) found that dendritic spines increased on a portion of the dendritic tree of CA1 pyramidal neurons during proestrus (high estrogen and progesterone), and Gould et al. (1990) found the same spine changes after estrogen replacement. The increases were large (20–30%), happened over the course of 3–4 days, and were subsequently seen in the density of synapses in the region (Woolley and McEwen, 1992).

How does high estrogen translate into new spines that may affect the processing of the hippocampus, and thus behavior? Estrogen has several paths to influencing neuronal functions (**Figure 3**). Most of its actions are through two known receptor subtypes, estrogen receptor (ER) α and β, that are widely distributed in the nervous system – including areas that are involved in cognitive behavior. Most receptors are in the cell and act by altering gene expression. In addition, there are ERs in the neuronal membrane that are influenced quickly by estrogen (**Figure 3**) (reviewed by Boulware and Mermelstein, 2005). ERα has been found in dendritic spines in hippocampal CA1 (Milner et al., 2001). Estrogen is also known to increase glutamate *N*-methyl-D-aspartate (NMDA) receptors in CA1 (Weiland, 1992). Interestingly, there are several ties to cholinergic input, including a study finding that a muscarinic receptor antagonist placed in the medial septum blocked the estrogen-mediated rise in NMDA receptors in the hippocampus and the improvement on the radial arm maze (Daniel et al., 2006). In addition, in cell culture estrogen decreases the inhibitory transmitter GABA, and treatment with a blocker of GABA synthesis mimics estrogenic increases in dendritic spines on hippocampal CA1 neurons (Murphy et al., 1998). Further details of intracellular signaling are reviewed by Woolley (2007). Less directly, estrogen levels modulate growth factors in the hippocampus such as BDNF (Gibbs, 1998).

All of this makes a compelling story for the interrelationship between estrogen, hippocampal dendritic spines, and behavior. It is impossible to deny that the

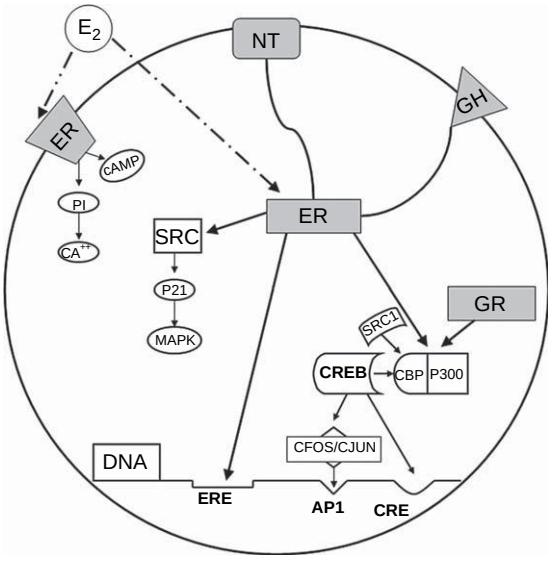

Figure 3 The intracellular mechanisms for estrogen (E_2) interactions with the estrogen receptor (ER). These interactions include several proteins that are second messengers such as cAMP, PI, SRC, and CREB (which also is influenced by the glucocorticoid receptor [GR]). Ultimately, response elements on the DNA are activated. Neurotransmitter receptors (NT) and growth hormone receptors (GH) interact with the estrogen receptor. Adapted from David Rubinow, 2006, with permission.

hippocampus is playing an important role in the effects of estrogen on behavior. However, there has been far less work on estrogenic effects on other important neural areas, such as the cerebral cortex, that may complicate easy correlations. Also, there are some dissociations between estrogen-induced spine increases and behavioral effects. One comes from our own laboratory, in which we have consistently failed to find increases in spine density at proestrus in the hippocampus (Warren et al., 1996; Markham et al., 2005). We should add that we handle all of the rats in our experiments extensively, which interferes with estrogen-induced spine increases (Garza-Meilandt et al., 2002, 2006), as does behavioral training (Frick, et al., 2004). In spite of this, we find increased long-term potentiation (LTP) (presumably NMDA dependent) during proestrus (Warren et al., 1995) and estrogenic influences on behavior (e.g., Warren and Juraska, 1997). There also is a dissociation between increases in dendritic spines and NMDA receptors in aging. Adams et al. (2001) found that, unlike young female rats, aged females do not have increased hippocampal spines when given estrogen, but they do have an increase in NMDA receptors. It is possible that estrogenic influences on NMDA receptors, as often reflected in spines, are more important for behavior than the spines themselves. It is also reasonable to assume that other neural areas, in addition to the hippocampus, are involved in the behavioral response to estrogen. Recent evidence that estrogen increases spines in the prefrontal cortex of aged female rhesus macaques (Hao et al., 2006) underscores this possibility.

3.25.2.1.4 Nonmnemonic effects

Given that estrogen plays a critical role in reproduction and a modulatory role in cognition, it is not surprising that it influences other aspects of behavior as well. It has long been known that estrogen increases activity in rodents, and much of its influence on simple tasks such as active and passive avoidance appears partially caused by this (reviewed by Beatty, 1979). The confound with activity would seem to be controlled to some degree in tasks in which a good deal of activity is called for, such as the radial arm maze and the water maze. Indeed, swimming speed in the water maze does not appear to be influenced by estrogen in any of the studies that have measured it.

Estrogen may interact with several motivational factors. Estrogen does influence pain perception, but the direction of influence varies considerably between inbred and outbred strains of both rats and mice, so no simple generalization is possible (Mogil et al., 2000). Thus the use of several strains in a task serves as converging evidence. Food motivation can also be influenced by estrogen, as estrogen decreases food intake and weight (Wade, 1975). It is not understood how this may interact with various learning tasks. Again, the convergence of tasks using food and nonfood motivation is critical. Another potential confound is the stressfulness of a task because of interactions between stress hormones (especially the corticosteroids) and the gonadal steroids. This is covered in section 3.25.3.

3.25.2.1.5 Humans

The naturally occurring menstrual cycle affects cognitive behavior, as does exogenous estrogen, which is often given to postmenopausal women. The generalization has been made that estrogen facilitates tasks on which females have an advantage over males (e.g., verbal tasks) and impedes tasks on which males have the advantage (e.g., spatial tasks) (Hampson, 1990a). As more tasks have been tested, this generalization has given way to a more complex view (Janowsky et al., 1998; Maki et al., 2002; Hampson et al., 2005). The differences in the effect of estrogen between young, cycling, and postmenopausal women are not as readily evident as they are between young and old rats, perhaps because women in early postmenopause are not as aged as females in the rat studies. In both cycling and menopausal human populations, estrogen tends to enhance verbal tasks (Hampson, 1990b; Kimura, 1995; Sherwin, 1998; Wolf and Kirschbaum, 2002). Even in nonreplaced postmenopausal women, endogenous estrogen levels have a positive correlation with verbal memory (Hogervorst et al., 2004). There also is work indicating that estrogen facilitates motor skills (Hampson, 1990b; Szekely et al., 1998; Maki et al., 2002) in young women. On the other hand, tests of spatial ability tend to be more variable, with negative correlations between estrogen and spatial ability in cycling (Hampson and Kimura, 1988) and elderly women (Drake et al. 2000), as well as positive effects in cycling (Janowsky et al., 1998) and postmenopausal women (Kimura, 1995). It may be that 'spatial' tasks are not really a unitary category. Adding to the range of effects are studies showing that estrogen inhibits perceptual object priming and a fragmented-object discrimination (Maki et al., 2002; Hampson et al., 2005). It is evident that, like the

nonhuman animal literature, it is difficult to make generalizations about the role of estrogen, and there are examples of failure to find differences (e.g., Gordon and Lee, 1993), presumably because of methodological differences between studies and the relatively modest size of the effects.

It is not known whether estrogen increases the number of dendritic spines in the human hippocampus, as it can in the rat. Certainly the range of tasks influenced by estrogen indicates that more than one neural area is involved. fMRI studies indicate that estrogen alters the pattern of cortical activation (e.g., Shaywitz et al., 1999), implicating a cortical contribution.

Contrary to the many positive effects of estrogen that have been found in naturally cycling and in nonrandomized, postmenopausal estrogen users, the Women's Health Initiative Memory Study found an increase in dementia/mild cognitive impairment when women aged 65 or older were given either estrogen plus progesterone or estrogen alone (Shumaker et al., 2004). However, in a study from Denmark, randomized replacement of both types in women younger than 65 years resulted in less cognitive impairment than controls after 65 years of age (Bagger et al., 2005). This distinction is supported by studies showing that initiation of replacement around the time of menopause aids verbal memory, whereas replacement after 65 years of age does not (reviewed by Maki, 2006). It has been suggested that changes in both the blood–brain barrier and immune system in the aging brain could change the neural response to estrogen (Sohrabji and Bake, 2006).

3.25.2.2 Androgens

The testes are the principal source of androgens, and testosterone is the most abundant androgen secreted. Testosterone binds to the androgen receptor, as does one of its principal metabolites, dihydrotestosterone. Estrogen is another metabolite of testosterone (**Figure 1**), and it acts through the estrogen receptors (see section 3.25.2.1.3). Perhaps because male production of testosterone does not change radically after puberty (relative to the female cycle and menopause), there is far less work on its effects on cognitive behavior or even on its cellular mechanisms. There is a large literature on its role in forming the male brain and behavior during early development of rodents. However, this literature is confounded with a significant problem for any behavior that depends on the cerebral cortex or hippocampus. Neonatal anesthetics (necessary for neonatal castration) result in neuronal death in the rat cortex and hippocampus, and the loss is larger in males than in females (Nunez et al., 1998, 2000; Nunez and Juraska, 2000). Performance in the water maze is also impeded (Nunez et al., 2000). Therefore, only manipulations of testosterone in males that are past puberty are reviewed here.

In adult rats, castration often impairs performance, and testosterone replacement brings performance back to the level of intact controls in several tasks: delayed alternation (Kritzer et al., 2001), object recognition (Ceccarelli et al., 2001), radial arm maze (Daniel et al., 2003), inhibitory avoidance (Edinger and Frye, 2004), and delayed matching to position (Gibbs, 2005). Because testosterone is readily converted to estrogen, it is possible that some of these effects are the result of this conversion, but there is no consensus on this. For example, on similar tasks, Kritzer et al. (2001) found that both testosterone and estrogen reversed the effects of castration on a delayed alternation task, whereas Gibbs (2005) examined a delayed matching-to-sample task and found that testosterone, but not estrogen, brought delayed performance back to controls. Thus, even small differences between tasks can alter whether androgenic or estrogenic effects are responsible.

There is evidence that testosterone can affect several neural areas relevant to cognition. Castration decreases spine density on CA1 hippocampal pyramidal neurons, as does removal of the ovaries in females. Testosterone and one of its androgenic metabolites, dihydrotestosterone (**Figure 1**), reverse the decrease to control male levels, whereas estrogen is without effect in males (Leranth et al., 2003). There is also evidence that both the loss and replacement of testosterone changes markers of acetylcholine levels in the cortex and hippocampus (Nakamura et al., 2002) and dopamine levels in the cortex (Kritzer, 2003).

Little work has been done in aged male rats, but there are indications that testosterone can improve performance on a water radial arm maze to levels better than aged controls and similar to young adult males (Bimonte-Nelson et al., 2003b). Dihydrotestosterone did not have this effect, implying that testosterone was acting through conversion to estrogen. Testosterone did not reverse aging effects on the standard water maze, however (Goudsmit et al., 1990), so broad generalizations about the antiaging effects of testosterone cannot be made.

In human males, the lack of a cycle or natural cessation of secretion makes studies more difficult. Correlational studies across both young men and women indicate that highest spatial and mathematical ability correlated with the low range of testosterone in men but the high range in women (Gouchie and Kimura, 1991; Moffat and Hampson, 1996). The degree to which testosterone is converted to estrogen appears to benefit verbal memory in men (Kampen and Sherwin, 1996). Confirmation of these correlational results occurs in studies where extra testosterone has been administered and has improved performance of visual-spatial tasks in older, but not younger, men (reviewed in Janowsky, 2006). Supplemented older men also show improvements in spatial memory that are not caused by conversion to estrogen, and verbal memory improvements that are the result of increases in estrogen (Janowsky, 2006).

3.25.3 Adrenal Steroids

Glucocorticoids are the steroid hormones produced by the adrenals. The primary adrenal steroid is cortisol in humans and other primates, and its close relative corticosterone in rats (both abbreviated CORT; **Figure 1**). CORT release is regulated by the hypothalamic-pituitary-adrenal axis, which exhibits a circadian rhythm, with plasma CORT peaking around the onset of the active period (morning for humans; prior to dark cycle onset in rats). CORT release is also increased under stress. In addition to multiple actions in the periphery coordinating the body's energetic priorities under stress, CORT readily passes the blood–brain barrier and acts on specific receptors throughout the brain. The well-characterized brain glucocorticoid receptors are classified as mineralocorticoid (MR) or glucocorticoid (GR). As with the estrogen receptor, newer studies have provided evidence for membrane glucocorticoid receptors (Makara and Haller, 2001; Johnson et al., 2005), which likely account for some of the fast actions of CORT. GRs, though most concentrated in hypothalamic and pituitary areas, which regulate the hypothalamic-pituitary-adrenal axis, are ubiquitous in the brain. By contrast MRs – initially characterized by their affinity for aldosterone – are most concentrated in the hippocampus, where they lack aldosterone specificity and exhibit very high affinity for CORT, approximately 10× greater than that of colocolized GRs. Hippocampal MRs are largely occupied at basal levels, whereas GRs are activated only at the circadian peak and under stress (De Kloet et al., 1998). As discussed below (in section 3.25.3.1.1), the dynamic between MR and GR occupation may be one of the critical factors determining the way CORT affects cognitive processes. Several excellent reviews provide more detailed discussion of CORT actions in the brain (e.g., De Kloet et al., 1998).

Literally thousands of studies on humans and experimental animals attest to the potent influence of stress hormones on learning and memory, but the direction of these cognitive effects – enhancing or impairing – depends on several factors, including the subject's age and sex, the timing of stress exposure, brain memory systems involved in a given task, and whether the stressor is acute or chronic. Each of these mediating factors is discussed here. Perhaps a more basic – and a long-acknowledged – variable involves the amount of stress hormones released: How much stress is optimal for enhancing cognition?

3.25.3.1 Acute Exposure: Effect of Amount

This question was addressed as early as 1908, when Yerkes and Dodson published their landmark paper, 'The relation of strength of stimulus to rapidity of habit formation,' in which they reported the effects of utilizing different shock intensities in a discrimination task on the rate of learning in mice (Yerkes and Dodson, 1908). Their results showed that, for moderate and difficult discriminations, shock intensity affected performance according to an inverted-U function, with lowest and highest shock intensities impairing the rate of learning, and intermediate intensities enhancing learning. The suggestion that a moderate level of arousal represents the optimal peak for performance along an inverted-U function has come to be known as the 'Yerkes–Dodson principle.' Glucocorticoids are likely to at least partially underlie this phenomenon, as CORT levels – which certainly represent one measure of arousal – also exhibit an inverted-U relationship to performance, at least for some types of tasks (see below). The same appears true of the other major adrenal stress hormone, epinephrine (Gold and Van Buskirk, 1975). Although our discussion here is focused on glucocorticoids, those studies that examined effects of behavioral stressors, rather than manipulations specific to glucocorticoids, may be presumed to involve adrenal catecholamine as well as glucocorticoid effects (*See* Chapters 3.26, 3.27, for discussion of epinephrine effects on memory).

3.25.3.1.1 Animal models

Studies of experimental animals (Pugh et al., 1997; Sandi and Rose, 1997; Sandi et al., 1997; Conrad et al., 1999) demonstrate nonlinear relationships between CORT levels and memory formation, which typically take the form of an inverted-U function: optimal mnemonic effects are seen with moderate CORT levels, and either no effect or memory impairment is seen at very low and very high CORT levels. In rats, this phenomenon is often seen in studies with hippocampal-dependent tasks (Pugh et al., 1997; Sandi et al., 1997; Conrad et al., 1999). For example, male rats trained in the spatial water maze task with water temperature of 19° C had higher levels of posttraining plasma CORT and exhibited better memory the following day than rats trained in 25° C water. When rats trained at these temperatures were administered posttraining CORT, performance benefits were only seen in the rats trained in warmer water, suggesting that when the rats trained in cold water were given CORT on top of already elevated levels, they were pushed past the peak of CORT's mnemonic effects for this task (Sandi et al., 1997).

Electrophysiological studies likewise demonstrate an inverted-U relationship of CORT levels to hippocampal function, as seen in studies of LTP, long-term depression (LTD), and primed burst potentiation (Diamond et al., 1992; Kerr et al., 1994; Pavlides et al., 1995). LTP studies that manipulated MR and GR binding with selective agonists and antagonists provided strong evidence for the theory that MR occupation accounted for the rising part of the inverted-U curve, and GR occupation for the falling part (Pavlides et al., 1996; Pavlides and McEwen, 1999). However, several behavioral studies that manipulated MR and GR effects suggest a dissociation between the mechanism underlying the inverted-U seen for behavior versus for electrophysiology (e.g., Conrad et al., 1999) and generally implicate GRs rather than MRs in beneficial effects on memory consolidation (Sandi, 1998; Roozendaal, 2000).

3.25.3.1.2 Human studies

Perhaps the most direct evidence for an inverted-U relationship between CORT and human memory comes from a recent study that applied cold-pressor stress (immersion of one hand in ice water) immediately following the reading of a relatively neutral story, and tested memory for the story 1 week later. Among male subjects, individual salivary CORT response to the cold-pressor stress showed a significant quadratic relationship to subsequent recall performance (different results for the female subjects in this study are discussed below in section 3.25.3.5; Andreano and Cahill, 2006).

Less direct evidence from human studies demonstrates the way that seemingly minor endogenous factors can alter CORT effects on cognition. A recent meta-analysis found mixed effects of hydrocortisone administration prior to learning, until the studies were broken down by time of day: The studies that administered hydrocortisone in the afternoon, when basal CORT is relatively low tended to find enhancing effects on subsequent memory, whereas studies that gave hydrocortisone in the morning, near the circadian peak, were generally impairing to memory formation (Het et al., 2005). The same finding was reported in a direct study of time-of-day effects in glucocorticoid administration (Maheu et al., 2005).

The social significance of high stress levels negatively affecting memory is quite broad, including the suggestion that glucocorticoid therapy may be helpful in impairing memory formation following traumatic experience (De Quervain, 2006; Schelling et al., 2006) and the finding that experimentally induced stress increases susceptibility to false recognition memory (Payne et al., 2002).

3.25.3.2 Timing

Studies with experimental animals show that the timing of stress hormone administration in relation to different stages of learning, memory, and performance of a task is another key to whether the effects are beneficial or harmful. Task-associated stress (e.g., lower water maze temperature or higher shock intensity) and CORT manipulations administered prior to learning suggest generally enhancing effects of CORT on learning (Sandi et al., 1997; Cordero et al., 1998; Conrad et al., 1999), at least for male rats performing hippocampal-dependent tasks. Memory consolidation is also enhanced by CORT: Immediate posttraining administration of stress hormones, which eliminate performance effects and are thought to mimic endogenous stress effects on memory consolidation, enhances subsequent performance in male rats (Roozendaal, 2000). However, stress hormones administered prior to retrieval testing or during the delay interval between training and testing impair memory retrieval (De Quervain et al., 1998; Roozendaal, 2002). Although most of these studies also used hippocampal-dependent tasks, numerous studies by Roozendaal, McGaugh, and colleagues have provided elegant

demonstration that both enhancing and impairing glucocorticoid effects on these tasks depend on the modulatory influence of the basolateral amygdala (Roozendaal, 2003; McGaugh, 2004).

Timing of stress exposure is also important in human studies. For example, the meta-analysis cited above that found that pretraining CORT exposure interacted with time of day also looked at several studies that administered CORT prior to retention testing, and in all cases, memory impairment resulted (Het et al., 2005). This makes some intuitive sense, as preretention testing (unlike post- or peritraining) stress would not be expected to influence central processes associated with the task itself.

3.25.3.3 Chronic Effects

Until now, our discussion has examined the effects of acute glucocorticoid exposure. In many ways, chronic exposure is quite different. In rats, monkeys, and other experimental animals, deleterious effects are most often reported in studies of spatial and working memory, mediated by the hippocampus and prefrontal cortex, respectively (see excellent review in Wolf, 2003). Although it is not feasible to administer glucocorticoids long-term in human studies, chronic stress effects on cognition have special relevance for people who have undergone long-term glucocorticoid exposure, either because of a medical condition requiring long-term corticosteroid medication or in people with conditions such as Cushing's syndrome or major depression, both of which are associated with chronic elevations in plasma CORT. Studies of these populations have described cognitive deficits in hippocampal and neocortical function (Forget et al., 2000; Starkman et al., 2001; Bourdeau et al., 2005).

In both humans and rats, chronic stress-related cognitive impairments are paralleled by anatomical changes. In rats, chronic stress effects are best documented in the hippocampus and include dendritic atrophy in area CA3 (Watanabe et al., 1992), decreased neurogenesis in the dentate gyrus (Cameron and Gould, 1994), and sometimes CA3 neurotoxicity (Sapolsky, 2000). Chronic stress also induces dendritic atrophy in the prefrontal cortex (Cook and Wellman, 2004). In humans, volume reductions associated with chronic glucocorticoid exposure (e.g., in major depression and Cushing's disease) are most often seen in the hippocampal formation, but also in the prefrontal cortex (Starkman et al., 1992; Duman et al., 1999; Wolf, 2003). At the other end of the spectrum, long-term glucocorticoid deprivation, as in Addison's disease (Maehlen and Torvik, 1990) or experimental adrenalectomy (Conrad and Roy, 1993), can induce hippocampal dentate granule cell loss and memory deficits.

Chronic stress effects on amygdala structure and function are markedly different from those seen in the hippocampus and prefrontal cortex. Also, cognitive effects of both chronic and acute stress interact potently with sex and ovarian hormones and change with lifespan age. Each of these interacting variables is reviewed in the following sections.

3.25.3.4 Memory System

When deleterious effects of acute stress are seen, they are, as with chronic stress, most often seen in relation to hippocampal or prefrontal function. For example, acute stress can impair or block LTP in both the hippocampus and prefrontal cortex, at levels that may enhance amygdalar LTP (reviewed in Diamond et al., 2004). Furthermore, a study that examined dendritic morphology in both the hippocampus and amygdala following chronic stress found that losses in the hippocampus were accompanied by dendritic growth in the basolateral amygdala (Vyas et al., 2002). Behavioral studies with rats suggest that high levels of stress hormones may also bias the relative use of different memory systems, from hippocampal-dependent strategies toward caudate nucleus–dependent strategies, and this shift appears to be mediated by the basolateral amygdala (Packard and Wingard, 2004).

The dose-dependent effects of acute CORT exposure discussed above (see section 3.25.3.1) also appear to be memory system dependent. The inverted-U function describing acute CORT effects on memory and plasticity is best supported for hippocampal function. By contrast, acute and even chronic CORT can enhance amygdala-dependent memory in a linear fashion (reviewed in Conrad, 2005). In the case of prefrontal function, evidence from human and nonhuman primates suggests a general deleterious effect of acute stress on working memory (reviewed in Wolf, 2003). Thus, glucocorticoid effects on cognition are sensitive to several factors (e.g., amount, timing) in locally specific manners.

3.25.3.5 Sex and Ovarian Steroids

Oddly enough, a growing literature describes quite different and frequently opposite effects of stress in male versus female rats. Luine and colleagues have done extensive research on chronic stressor effects in males and females, and on the modulating effects of ovarian hormones in females (reviewed in Bowman et al., 2006). Generally, they observe that the same chronic stress regimen that is deleterious to spatial memory in male rats is enhancing to female rats. This enhancement is abolished by ovariectomy, suggesting that estrogen has an important role in this striking interaction of sex and stress. Further, chronic stress effects on CA3 dendrites are both attenuated and different (occurring in the basilar rather than the apical tree) in female rats (Galea et al., 1997).

Striking sexual dimorphisms have also been found in studies of acute stress. For example, acute stressors that enhance eyeblink conditioning in male rats are impairing to female rats (Shors, 2004). Endogenous ovarian hormone fluctuations across the estrous cycle interact with acute stress effects in a parallel fashion (Wood et al., 2001; Rubinow et al., 2004). For instance, in a study comparing water maze performance of estrous versus proestrous rats using warm (30° C) or cold (19° C) water temperatures, we found a significant interaction such that overall performance was impaired in proestrous rats in the cold water maze and enhanced in the warm maze, while estrous rats (similar to male rats) showed the opposite pattern (Rubinow et al., 2004).

Human studies of acute stress that have examined the factor of sex also report significant interactions. For example, salivary CORT in response to a psychological stressor showed a strong negative association with word list recall among young men but showed no such relationship among young women (Wolf et al., 2001b). Another recent study found that acute psychological stress enhanced fear conditioning in men but produced no effect or impairment in women. The same study showed different salivary CORT responses in men versus women (Jackson et al., 2006). Finally, in the study discussed above (see section 3.25.3.1.2), which found an inverted-U relationship between cold-pressor salivary CORT response and subsequent recall in men, women showed no clear relationship between salivary CORT and subsequent memory. However, unlike the results of Jackson et al. (2006), this study found similar CORT responses to stress in men and women (Andreano and Cahill, 2006). Further complicating this story are studies showing that sexually dimorphic effects of stress on cognition change across the lifespan.

3.25.3.6 Interactions with Age

In a series of studies on acute stress effects on eyeblink conditioning across the lifespan of male and female rats, Hodes and Shors (2005, 2006) found that sexually dimorphic effects of stress on this task (favoring males) were limited to adulthood. Prior to puberty and in old age, stress exposure produced no effects on conditioning in either sex, whereas during puberty, stress enhanced performance for both males and females. Other laboratories using different stress and task paradigms showed different kinds of alterations in stress effects in old age. For example, chronic stress remains impairing to aged male rats, but the enhancing effects in adult females are lessened in old age (Bowman, 2005).

In humans, Wolf and collaborators found sexually dimorphic effects of CORT on working memory that were reversed in old age: Young men were impaired under CORT, whereas young women were unaffected; among the elderly, aged men were unaffected, but aged women were impaired (Wolf et al., 1998, 2001a).

Taken as a whole, these findings defy easy explanation. Leaving aside the vast and important literature on the lasting effects of developmental stress on cognition, findings that discrete episodes of stress exposure have markedly different effects on cognition across the male and female lifespan further point to the complexity of glucocorticoid effects on cognitive processes.

3.25.4 Other Hormones

The peptide hormones, which are composed of a string of amino acids, are the other major class of hormones besides the steroids. In fact, most mammalian hormones are peptides, and many of them have been shown to influence learning and memory. We highlight those hormones that have been most investigated.

3.25.4.1 Oxytocin and Vasopressin

Oxytocin and vasopressin are structurally similar and secreted from the same subregion, the intermediate zone, of the pituitary gland. They also are secreted as

neurotransmitters in the central nervous system. As demonstrated by intracerebral injections and in gene knockout mice, these hormones can influence many types of learning, including social recognition (Argiolas and Gessa, 1991; Alescio-Lautier et al., 2000; Winslow and Insel, 2004). However, these effects may be part of the role of the peripheral hormones, because neither peptide appears to directly cross the blood–brain barrier, although they can influence the properties of the barrier (Meisenberg and Simmons, 1983). The neurotransmitter actions of these peptides and of cholecystokinin (CCK, below) are not within the purview of this chapter. Peripheral injections of vasopressin and oxytocin often facilitate learning (e.g., Dietrich and Allen, 1997), but several investigators have hypothesized that this occurs through interactions with stress hormones (Sahgal, 1984; McGaugh, 1989). Therefore, a direct role for oxytocin and vasopressin as hormones, as opposed to neurotransmitters, in learning and memory has not been clearly established.

3.25.4.2 Cholecystokinin

Like oxytocin and vasopressin, CCK is released both centrally as a neurotransmitter and peripherally as a hormone. However, peripheral CCK, which is released from the duodenum of the small intestine during eating, does modulate learning and memory. In fact, posttraining eating itself enhances memory consolidation (Huston et al., 1974; Flood et al., 1987). Similar to epinephrine (*See* Chapter 3.26), CCK interacts with its receptors on the vagus nerve, which synapses on the brainstem nucleus of the solitary tract. Both vagotomy (Flood et al., 1987) and lesions of the stria terminalis (Flood et al., 1995), which projects from the nucleus of the solitary tract to the amygdala, abolish CCK effects on memory.

Other gastrointestinal hormones, including bombesin and gastrin-releasing peptide, also enhance memory consolidation, but these effects appear to be mediated by CCK release, as an antagonist for peripheral CCK receptors blocks these effects (Morley et al., 1994).

3.25.5 Summary and Conclusions

Hormone effects on memory function range from mild to potent, but hormonal milieu always plays a role, even when it is not experimentally manipulated. The majority of studies directly examining hormone effects on cognition have looked at ovarian and adrenal steroids.

The effects of estrogen resulting from the rat estrous cycle or when replaced following removal of the ovaries vary from memory enhancement, to impairment, to lack of effect. Attempts at a unifying explanation for such wide-ranging results continue to be refined, but as yet no single construct accounts for all the data. Important factors have been hypothesized to include the degree of hippocampal involvement in a task, whether a task requires working or reference memory, the involvement of relational representations, task stressfulness, and the breadth of cue selection available. Estrogenic effects on cognition are paralleled by anatomical and physiological changes, but behavioral findings are sometimes dissociated from these other measures.

Data on ovarian hormone effects on learning and memory in aged females are also variable but differ in several ways from findings with young adults. Thus, it is important to use aged subjects when modeling aging.

Human studies tend to find positive effects of estrogen on verbal and fine motor tasks, but effects on spatial cognition are more variable across studies. Postmenopausal hormone replacement has been correlated with positive effects, but results from controlled studies suggest that replacement may only be beneficial when initiated close to the onset of menopause and can be harmful if initiated past the age of 65.

Glucocorticoid effects on cognition are powerful but, like estrogen effects, also variable. Glucocorticoid effects can be enhancing or impairing, depending on the amount of acute exposure, and interact with a number of other variables including the timing of exposure in relation to different stages of learning, memory consolidation and recall, whether stress or glucocorticoid exposure is chronic, memory system(s) involved, and both the sex and age of subjects. All of these factors can alter and in some cases reverse the direction of glucocorticoid effects in experimental animals and in humans.

Many other hormones have been investigated with respect to cognition, including testosterone and the peptide hormones oxytocin, vasopressin, and CCK. Mnemonic effects of all these hormones are often positive when they are seen. Nevertheless, the effects of these and other peripheral hormones are also complex and interact with other variables including other hormone systems.

3.26 Memory Modulation

J. L. McGaugh and B. Roozendaal, University of California at Irvine, Irvine, CA, USA

3.26.1 Introduction

Brain systems have many tasks to perform in enabling the formation of memories. New information must be encoded and stored in ways that enable the information subsequently to be retrieved and expressed in behavior. Understanding the cellular mechanisms and brain systems responsible for enabling and orchestrating these various complex tasks is the aim of research on the neurobiology of learning and memory. A key role in such orchestration is played by systems that modulate the consolidation of memories of recent experiences. Our memories are not all created equally strong: Some experiences are well remembered, while others are remembered poorly, if at all. Understanding the neurobiological processes and systems that contribute to such differences in the strength of our memories is a special quest of research on memory modulation. Not only do modulatory systems influence neurobiological processes underlying the consolidation of new information, but more recent evidence indicates that these systems also affect other mnemonic processes, including memory extinction, memory recall, and working memory.

Research on memory modulation was stimulated by findings reported a little over half a century ago that, in rats, retention of a recently learned response was impaired by administration of electroconvulsive shock (ECS) (Duncan, 1949; Gerard, 1949). These findings were the first to provide compelling evidence supporting the hypothesis proposed half a century earlier (Müller and Pilzecker, 1900) that neural memory traces activated by new experiences perseverate in a fragile state and gradually become consolidated. Subsequent studies using ECS and other treatments to impair brain functioning shortly after training provided extensive evidence that such treatments impair memory by interfering with time-dependent processes involved in memory consolidation (McGaugh, 1966; McGaugh and Herz, 1972). The findings of such studies also revealed that susceptibility to posttraining modulating influences

is a common feature of animal memory: Posttraining treatments affect memory in mollusks, fish, insects, and birds, as well as rodents and primates (Cherkin, 1969; Agranoff, 1980; Menzel, 1983; Kandel, 2001).

In providing evidence that new memories remain fragile for a while before becoming consolidated, the findings of Duncan and Gerard suggested the possibility that memory consolidation might also be enhanced by stimulating brain functioning. In support of this implication, many studies subsequently reported that, in rats, retention is enhanced by injections of stimulant drugs, including strychnine, the GABAergic antagonists picrotoxin and bicuculline, pentylenetetrazole, and amphetamine, administered shortly after training, and that such treatments are generally ineffective when administered several hours after learning (Breen and McGaugh, 1961; McGaugh and Petrinovich, 1965; McGaugh, 1966, 1973; Doty and Doty, 1966; Evangelista and Izquierdo, 1971; McGaugh and Herz, 1972; Grecksch and Matthies, 1981; Carr and White, 1984; Brioni and McGaugh, 1988; Castellano and Pavone, 1988). Such a time-dependent susceptibility thus clearly suggests that the drugs affected memory by modulating the consolidation of recently acquired information.

In studies of the effects of treatments modulating learning and memory it is essential to distinguish the effects of the treatments on memory from the effects of the treatments on, e.g., attentional, motivational and motor processes that may directly affect the behavior used to make inferences about memory. The use of posttraining treatments to alter brain functioning shortly after training has provided an effective technique for excluding such performance effects in investigating the effects of modulatory treatments on memory consolidation (McGaugh, 1966, 1989; McGaugh and Herz, 1972).

3.26.2 Endogenous Modulation of Consolidation

Memory consolidation appears to be a highly adaptive function because, as noted above, evidence of consolidation is found in a wide variety of animal species. But why do our long-term memories and those of other animals consolidate slowly? There seems to be no *a priori* reason to assume that neurobiological mechanisms are not capable of consolidating memory quickly. Considerable evidence suggests that the slow consolidation of memories may serve a highly important adaptive function by enabling endogenous processes activated by an experience, and thus occurring shortly after the event, to modulate memory strength. In a paper published shortly after those reporting that posttraining drug administration can enhance memory consolidation (e.g., Breen and McGaugh, 1961; McGaugh, 1966), Livingston suggested that stimulation of the limbic system and brainstem reticular formation might promote the storage of recently activated brain events by initiating a "neurohormonal influence (favoring) future repetitions of the same neural activities" (Livingston, 1967, p. 576). Kety subsequently offered the more specific suggestion that adrenergic catecholamines released in emotional states may serve "to reinforce and consolidate new and significant sensory patterns in the neocortex" (Kety, 1972, p. 73). Although the specific details of current findings and theoretical interpretations differ in many ways from those early views offered by Livingston and Kety, recent findings are consistent with their general hypotheses.

3.26.3 Modulating Influences of Adrenal Stress Hormones

Emotionally arousing experiences are generally well remembered (Christianson, 1992; McGaugh, 2003). As William James (1890) noted, "An experience may be so exciting emotionally as to almost leave a scar on the cerebral tissue" (James, 1890, p. 670). The susceptibility of memory consolidation processes to modulating influences induced after learning provides the opportunity for neurobiological processes activated by emotional arousal to regulate the strength of memory traces representing important experiences (McGaugh, 1983; McGaugh and Gold, 1989). Extensive evidence indicates that stress hormones released by the adrenal glands, epinephrine and cortisol (corticosterone in rodents), by emotionally arousing experiences modulate memory consolidation (McGaugh and Roozendaal, 2002). It is well established that, in rats and mice, hormones of the adrenal medulla and adrenal cortex are released during and immediately after stressful stimulation of the kinds used in aversively motivated learning tasks (McCarty and Gold, 1981; McGaugh and Gold, 1989; Aguilar-Valles et al., 2005), and that removal of these stress hormones by adrenalectomy generally results in memory impairment (Borrell et al., 1983, 1984; Oitzl and de Kloet, 1992; Roozendaal et al., 1996b; Roozendaal, 2000).

3.26.3.1 Epinephrine

Gold and van Buskirk (1975, 1978) were the first to report that, in adrenally intact rats, systemic posttraining injections of the adrenomedullary hormone epinephrine enhance long-term retention of inhibitory avoidance. As found in previous studies of the memory-enhancing effects of stimulant drugs, the epinephrine effects were dose dependent and time dependent. Moderate doses of posttraining epinephrine enhanced retention performance, whereas lower doses or higher doses were less effective. Furthermore, as was found with stimulant drugs, memory enhancement was greatest when epinephrine was administered shortly after training (**Figure 1**). Comparable effects were obtained in subsequent experiments using many different types of training tasks commonly used in experiments with rats and mice, including inhibitory avoidance, active avoidance, discrimination learning, and appetitively motivated tasks (Izquierdo and Dias, 1985; Sternberg et al., 1985; Introini-Collison and McGaugh, 1986; Liang et al., 1986; Costa-Miserachs et al., 1994). Additionally, numerous studies have shown that peripherally administered amphetamine, which increases the release of epinephrine from the adrenal medulla, also enhances memory consolidation when given shortly after training (Martinez et al., 1980).

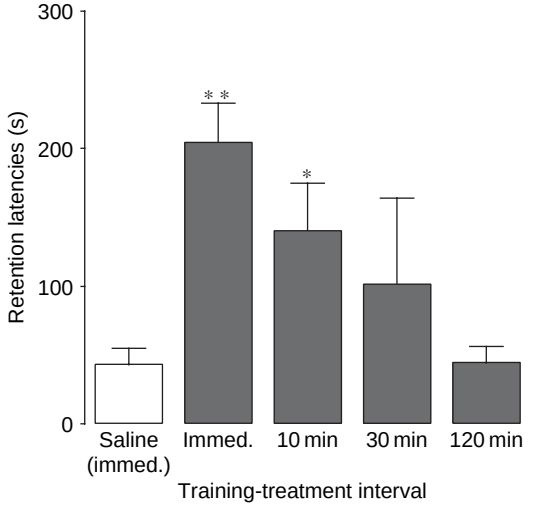

Figure 1 Posttraining systemic injection of epinephrine induces time-dependent memory enhancement. Epinephrine (0.1 mg/kg, ip) enhanced 24-h retention performance on an inhibitory avoidance task when injected either immediately or 10 min after training but was ineffective when given 30 or 120 min after training. Results represent retention latencies (mean + SEM) in seconds. *, $p < .05$; **, $p < .01$ as compared with the saline group. From Gold PE and van Buskirk R (1975) Facilitation of time-dependent memory processes with posttrial epinephrine injections. *Behav. Biol.* 13: 145–153.

Epinephrine effects on memory consolidation appear to be initiated, at least in part, by the activation of β-adrenoceptors located in the periphery, as this hormone does not readily cross the blood–brain barrier (Weil-Malherbe et al., 1959). Sotalol, a β-adrenoceptor antagonist that does not readily enter the brain, blocks the enhancing effects of peripherally administered epinephrine on memory for inhibitory avoidance training (Introini-Collison et al., 1992). Epinephrine effects are most likely mediated by activation of β-adrenoceptors located on vagal afferents that project to the nucleus of the solitary tract (NTS) in the brain stem (Schreurs et al., 1986), which sends noradrenergic projections to forebrain regions involved in memory consolidation, including the amygdala (Ricardo and Koh, 1978). Furthermore, the NTS regulates noradrenergic activity of the forebrain via indirect projections to noradrenergic cell groups in the locus coeruleus (Williams and Clayton, 2001). Vagotomy attenuates the memory-enhancing effects induced by systemic administration of 4-OH-amphetamine, a peripherally acting derivative of amphetamine that induces epinephrine release (Williams and Jensen, 1991). The evidence that inactivation of the NTS with the sodium channel blocker lidocaine prevents epinephrine effects on memory consolidation, as well as the finding that the β-adrenoceptor agonist clenbuterol infused into the NTS posttraining enhances memory, very strongly suggests that epinephrine effects on memory consolidation are mediated via activation of the NTS (Williams and McGaugh, 1993). Additionally, the finding that, in rats as well as human subjects, posttraining electrical stimulation of vagal afferents enhances memory consolidation provides further evidence that projections mediated by the ascending vagus are involved in regulating memory consolidation (Clark et al., 1995, 1999; Ghacibeh et al., 2006).

Thus, the NTS appears to be an interface between peripheral adrenergic activation and brain processes regulating memory consolidation. However, posttraining peripheral administration of β-adrenoceptor agonists that are able to enter the brain, including dipivefrin and clenbuterol, also enhance memory consolidation. The memory enhancement induced by dipivefrin and clenbuterol is blocked by the β-adrenoceptor antagonist propranolol, which readily

enters the brain, but not by the peripherally acting antagonist sotalol (Introini-Collison et al., 1992). Considered together, these findings indicate that the modulatory effects of epinephrine on memory consolidation are initiated by activation of peripheral β-adrenoceptors, but that memory consolidation is also modulated by direct activation of β-adrenoceptors within the brain. As discussed below, noradrenergic activation of the basolateral region of the amygdala (BLA), arising from noradrenergic cell groups in the NTS and locus coeruleus, is critically involved in mediating the effects of epinephrine, as well as those of many other neuromodulatory systems, on memory consolidation (Roozendaal, 2007).

Other findings suggest that epinephrine may also influence memory consolidation by enhancing glycogenolysis in the liver (Messier and White, 1984, 1987; Gold, 1995). Posttraining peripheral administration of glucose produces dose- and time-dependent effects on memory comparable to those produced by epinephrine (Gold, 1986). Additionally, doses of epinephrine and glucose that are optimal for enhancing retention induce comparable levels of plasma glucose (Hall and Gold, 1986). β-Adrenoceptor antagonists do not block glucose effects on memory (Gold et al., 1986). Glucose readily enters the brain and, thus, can directly influence brain glucoreceptors (Oomura et al., 1988). The finding that intracerebroventricular injections of glucose produce dose- and time-dependent enhancement of memory consolidation clearly suggests that peripherally administered glucose may affect memory by directly altering brain functioning (Lee et al., 1988). However, the finding that memory is also influenced by peripherally administered fructose, a sugar that has little influence on the brain, suggests that this sugar, as well as glucose, may also act, at least in part, at peripheral sites in influencing memory (Messier and White, 1987). In support of this view, Talley et al. (2002) showed that vagotomy blocks the memory-enhancing effects of peripherally administered L-glucose, an enantiomer of glucose that does not cross the blood–brain barrier.

3.26.3.2 Glucocorticoids

There is also extensive evidence that adrenocortical hormones are involved in modulating memory consolidation (for reviews, see de Kloet, 1991; Bohus, 1994; McEwen and Sapolsky, 1995; Lupien and McEwen, 1997; Roozendaal, 2000). As with epinephrine, posttraining injections of glucocorticoids produce dose- and time-dependent enhancement of memory (Cottrell and Nakajima, 1977; Sandi and Rose, 1994; Roozendaal and McGaugh, 1996a; Zorawski and Killcross, 2002; Okuda et al., 2004). However, in contrast to epinephrine, glucocorticoids are highly lipophylic and, thus, readily enter the brain and bind directly to mineralocorticoid receptors (MRs) and glucocorticoid receptors (GRs) (McEwen et al., 1968; de Kloet, 1991). These two receptor types differ in their affinity for corticosterone and synthetic ligands. MRs have a high affinity for the natural steroids corticosterone and aldosterone, whereas GRs have a high affinity for synthetic ligands such as dexamethasone and the GR agonist RU 28362 (Reul and de Kloet, 1985; Sutanto and de Kloet, 1987; Reul et al., 1990). As a consequence, MRs are mostly saturated during basal levels of corticosterone, whereas GRs become occupied by higher levels of corticosterone induced by stressful stimulation.

The memory-modulating effects of glucocorticoids released following arousing stimulation appear to involve the selective activation of the low-affinity GRs (Oitzl and de Kloet, 1992; Roozendaal et al., 1996b; Lupien and McEwen, 1997), as blockade of GRs, but not MRs, shortly before or immediately after training impairs long-term memory. Such findings provide strong support for the hypothesis that endogenously released glucocorticoids enhance memory consolidation. Glucocorticoids are known to act through intracellular and intranuclear receptors and can affect gene transcription either by direct binding of receptor homodimers to DNA (Beato et al., 1995; Datson et al., 2001) or via protein–protein interactions with other transcription factors such as Jun or Fos (Heck et al., 1994). However, as discussed later, glucocorticoids may also act more rapidly by interacting with membrane receptors and/or potentiating the efficacy of the norepinephrine signal cascade via an interaction with G-protein-mediated actions (Roozendaal et al., 2002b).

3.26.3.3 Adrenergic-Glucocorticoid Interactions

Evidence from several kinds of studies indicates that catecholamines and glucocorticoids released from the adrenal glands interact in influencing memory consolidation. Glucocorticoids alter the sensitivity of epinephrine in influencing memory consolidation

in adrenalectomized rats (Borrell et al., 1983, 1984). Further, in adrenally intact rats, administration of meytrapone, a corticosterone-synthesis inhibitor that reduces the elevation of circulating corticosterone induced by aversive stimulation, attenuates the memory-enhancing effects of epinephrine administered posttraining (Roozendaal et al., 1996a). Such findings suggest that synergistic actions of epinephrine and corticosterone may be essential in mediating stress effects on memory enhancement.

The studies cited above used emotionally arousing footshock training, conditions that induce the release of both corticosterone and epinephrine. Studies using an object recognition task investigated whether adrenergic activation induced by emotional arousal is essential in enabling corticosterone effects on memory consolidation (Okuda et al., 2004). Rats were given either extensive habituation to an apparatus or no prior habituation and were then allowed to explore objects in the apparatus. Placing rats in a novel testing apparatus evokes novelty-induced arousal, and habituation of rats to the apparatus is known to reduce this arousal response (de Boer et al., 1990). Corticosterone administered immediately posttraining to nonhabituated (i.e., emotionally aroused) rats enhanced their 24-h retention performance. In contrast, posttraining corticosterone did not enhance retention of object recognition in habituated rats (Okuda et al., 2004), providing evidence that training-associated emotional arousal may be essential for enabling glucocorticoid effects on memory consolidation. Other findings indicated that training-induced adrenergic activation is a critical component of emotional arousal in enabling glucocorticoid effects on memory consolidation. As is shown in **Figure 2**, the β-adrenoceptor antagonist propranolol, coadministered with the corticosterone immediately after the object recognition training, blocked the corticosterone-induced memory enhancement (Roozendaal et al., 2006b). To investigate whether a pharmacologically induced increase in adrenergic activity enables glucocorticoid effects on memory consolidation, a low dose of the α_2-adrenoceptor antagonist yohimbine was administered to well-habituated (i.e., nonaroused) rats immediately after object recognition training. Corticosterone administered together with yohimbine induced dose-dependent enhancement of memory consolidation (Roozendaal et al., 2006b). Posttraining injections of corticosterone and yohimbine separated by a 4-h delay did not enhance memory consolidation. These findings are thus consistent with the hypothesis that adrenergic activation is essential in enabling glucocorticoid enhancement of memory consolidation. The nature of this interaction is discussed in more detail later.

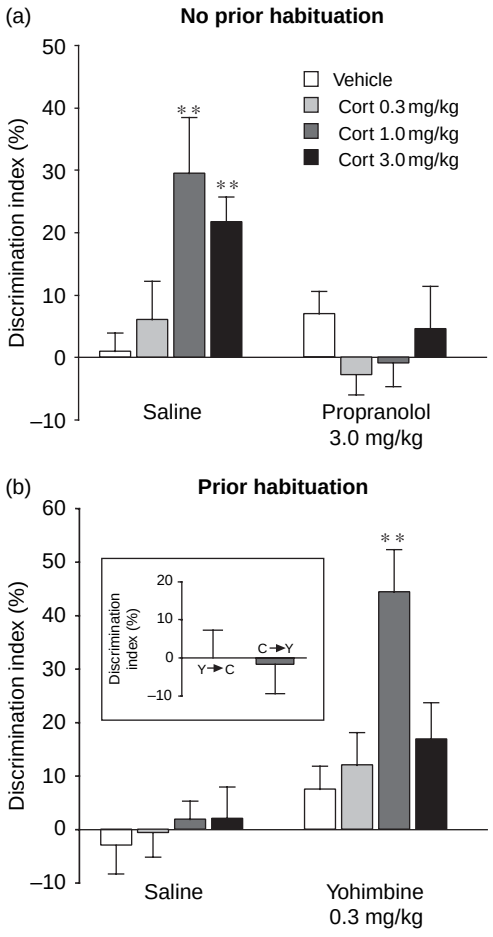

Figure 2 Glucocorticoid effects on memory consolidation for object recognition training require adrenergic activation. (a) Immediate posttraining administration of the β-adrenoceptor antagonist propranolol (3.0 mg/kg, sc) blocked the corticosterone-induced enhancement of object recognition memory in naïve rats. (b) The α_2-adrenoceptor antagonist yohimbine (0.3 mg/kg, sc) enabled a corticosterone effect on object recognition memory in habituated rats. Inset: Posttraining injections of yohimbine (0.3 mg/kg, sc) and corticosterone (1.0 mg/kg, sc) separated by a 4-h delay did not induce memory enhancement. Y → C; Yohimbine administered immediately after training and corticosterone 4 h later; C → Y; corticosterone administered immediately after training and yohimbine 4 h later. Results represent discrimination index (mean ± SEM) in percentage on a 24-h retention trial. **, $p < .01$, as compared with the corresponding vehicle group. From Roozendaal B, Okuda S, Van der Zee EA, and McGaugh JL (2006b) Glucocorticoid enhancement of memory requires arousal-induced noradrenergic activation in the basolateral amygdala. *Proc. Natl. Acad. Sci. USA* 103: 6741–6746.

3.26.3.4 Other Neuromodulatory Systems

As discussed earlier in this chapter, drugs affecting many other neuromodulatory and transmitter systems also influence memory consolidation. The dose- and time-dependent enhancement of memory induced by the stimulant drugs known to act via GABA (picrotoxin, bicuculline) and catecholamines (amphetamine, clenbuterol) has also been obtained in studies investigating the effects of opiate receptor antagonists (Messing et al., 1979; Introini and Baratti, 1984) and muscarinic cholinergic receptor agonists (Stratton and Petrinovich, 1963; Flood et al., 1981; Baratti et al., 1984; Introini-Collison and McGaugh, 1988; Power et al., 2003b), as well as drugs and hormones affecting several other systems, including corticotropin-releasing hormone (Roozendaal et al., 2002a), adrenocorticotropin (Gold and van Buskirk, 1976), vasopressin (de Wied, 1984), oxytocin (Bohus, 1980), substance P (Huston and Staubli, 1981; Schlesinger et al., 1986), histamine (Passani et al., 2001; da Silva et al., 2006), and cholecystokinin (Flood et al., 1987). Additionally, many studies have investigated interactions of these systems in modulating memory consolidation (McGaugh, 1989; McGaugh and Gold, 1989).

As is discussed below, the effects of many neuromodulatory systems are mediated by interactions with noradrenergic and muscarinic cholinergic systems within the amygdala. The initial research investigating such interactions investigated the effects of peripherally administered drugs and hormones (McGaugh and Cahill, 1997). Considerable evidence indicates that opiate and GABAergic influences on memory consolidation are mediated via adrenergic influences. The finding that the β-adrenoceptor antagonist propranolol blocks the memory-enhancing effects of the opiate receptor antagonist naloxone (Izquierdo and Graudenz, 1980) is consistent with evidence that opiates regulate the release of norepinephrine in the brain (Arbilla and Langer, 1978; Nakamura et al., 1982). Further, the β-adrenoceptor agonist clenbuterol blocks the memory impairment induced by the GABAergic agonist muscimol (Introini-Collison et al., 1994). As discussed below, such findings are consistent with the hypothesis that opioids and GABA impair memory by decreasing norepinephrine release in the brain (Quirarte et al., 1998; Hatfield et al., 1999). Thus, noradrenergic activation appears to be critical for opioid peptidergic and GABAergic influences on memory consolidation.

In contrast to the effects of opioid peptidergic and GABAergic drugs, cholinergic effects do not appear to be mediated by adrenergic activation. However, there is extensive evidence that muscarinic activity is a requirement for norepinephrine-induced memory enhancement. Systemic injections of the muscarinic cholinergic receptor antagonist atropine attenuate the memory-enhancing effects of the β-adrenoceptor agonist clenbuterol as well as that of epinephrine (Introini-Collison and McGaugh, 1988; Introini-Collison and Baratti, 1992). Thus, cholinergic activation appears to provide modulatory influences on memory consolidation that are downstream from adrenergic activation.

3.26.4 Involvement of the Amygdala in Modulating Memory Consolidation

Goddard's (1964) finding that electrical stimulation of the amygdala administered shortly after rats were trained on an aversively motivated task impaired their memory of the training was the first to suggest that the amygdala plays a role in influencing memory consolidation. The conclusion that the amygdala stimulation disrupted the consolidation of the memory of the training was confirmed by many subsequent findings from other laboratories (Kesner and Wilburn, 1974; McGaugh and Gold, 1976). One possible interpretation of these findings is that the stimulation disrupted the consolidation of memory processes occurring within the amygdala. However, many subsequent findings have indicated that amygdala stimulation modulates memory consolidation via influences mediated by amygdala efferent projections to other brain regions. The finding that posttraining electrical stimulation of the amygdala can either enhance or impair memory, depending on the stimulation intensity and the training conditions (Gold et al., 1975), clearly indicates that the effects are modulatory and not simply memory impairing. Further, the evidence that lesions of the stria terminalis (a major amygdala pathway) block the memory-impairing effects of posttraining electrical stimulation (Liang and McGaugh, 1983) strongly suggested that the modulation involves amygdala projections to other brain regions (see following).

3.26.4.1 Noradrenergic Influences in the BLA

Experiments by Kesner and Ellis (Ellis and Kesner, 1981; Kesner and Ellis, 1983) and Gallagher et al.

(1981) were the first to use posttraining drug infusions to investigate the involvement of neuromodulatory systems in the amygdala in memory consolidation. ß-Adrenoceptor antagonists infused into the amygdala impaired rats' retention of inhibitory avoidance, and concurrent infusion of norepinephrine blocked the memory impairment (Gallagher et al., 1981). These investigators also found that, as is found with systemic administration (Messing et al., 1979; Izquierdo and Graudenz, 1980), posttraining intraamygdala infusions of opioid peptidergic agonists and antagonists impaired and enhanced memory, respectively. The findings of more recent studies indicate that the BLA is selectively involved in such amygdala memory-modulatory influences. The adjacent central nucleus does not appear to play a significant role, if any, in modulating memory consolidation (Tomaz et al., 1992; Parent and McGaugh, 1994; Roozendaal and McGaugh, 1996a, 1997a; DaCunha et al., 1999; McGaugh et al., 2000). Thus, the effects of relatively large intraamygdala drug infusion volumes typically used in most early studies as well as many recent studies are likely the result of selective influences on BLA activity. Moreover, findings of more recent studies indicating that posttraining intraamygdala infusions of drugs influence retention performance tested 24 h or longer after the training but do not affect performance tested within a few hours after training, provide strong evidence that the treatments selectively affect the consolidation of long-term memory (Bianchin et al., 1999; Schafe and LeDoux, 2000; Barros et al., 2002).

Other early findings also implicated the amygdala in adrenergic influences on memory consolidation. Adrenal demedullation or posttraining administration of epinephrine alter the memory-modulating effects of electrical stimulation of the amygdala (Liang et al., 1985), and lesions of either the amygdala or the stria terminalis block epinephrine effects on memory consolidation (Cahill and McGaugh, 1991; Liang and McGaugh, 1983). Although earlier studies reported evidence suggesting that epinephrine induces the release of norepinephrine in the brain (Gold and van Buskirk, 1978), the finding that posttraining intraamygdala infusions of the β-adrenoceptor antagonist propranolol block epinephrine effects on memory consolidation (Liang et al., 1986) provided the first evidence suggesting that epinephrine effects on memory are mediated by noradrenergic activation within the amygdala. In support of this implication, many subsequent studies reported that posttraining infusions of norepinephrine or the β-adrenoceptor agonist clenbuterol into the amygdala (or selectively into the BLA) produce dose-dependent enhancement of memory consolidation (Liang et al., 1986, 1990, 1995; Introini-Collison et al., 1991, 1996; Izquierdo et al., 1992; Bianchin et al., 1999; Ferry and McGaugh, 1999; Hatfield and McGaugh, 1999; LaLumiere et al., 2003, 2005; Huff et al., 2005). Furthermore, posttraining intraamygdala infusions of β-adrenoceptor antagonists impair retention and block the memory-enhancing effects of norepinephrine coadministered (Liang et al., 1986, 1995; Salinas and McGaugh, 1995).

In addition to β-adrenoceptor influences, α-adrenoceptor activation in the BLA also modulates memory consolidation. Intra-BLA infusions of the α_1-adrenoceptor antagonist prazosin impair inhibitory avoidance memory, whereas infusions of the nonselective α-adrenoceptor agonist phenylephrine, administered together with yohimbine, an α_2-adrenoceptor antagonist, enhance retention (Ferry et al., 1999a). The α_1-adrenoceptor-induced memory enhancement most likely involves an interaction with ß-adrenoceptors, as posttraining intra-BLA infusions of the β-adrenoceptor antagonist atenolol block the memory enhancement produced by activation of α_1-adrenoceptors. The finding that posttraining intraamygdala infusions of the synthetic cyclic adenosine monophosphate (cAMP) analog 8-bromo-cAMP enhance retention (Liang et al., 1995) is consistent with the hypothesis that activation of ß-adrenoceptors modulates memory via a direct coupling to adenylate cyclase. Thus, the finding that intra-BLA infusions of the α_1-adrenoceptor antagonist prazosin do not prevent the memory enhancement induced by concurrently infused 8-bromo-cAMP suggests that the memory-enhancing effects of α_1-adrenoceptor activation are mediated by an interaction with ß-adrenoceptors upstream from cAMP, probably at the G-protein level (Ferry et al., 1999b).

There is extensive evidence indicating that noradrenergic activity within the BLA also plays an important role in mediating the modulatory effects of other hormones and neurotransmitters on memory consolidation (Roozendaal, 2007). Many studies have reported that, as with peripherally administered drugs, intra-BLA infusions of the GABAergic receptor antagonists bicuculline and picrotoxin enhance memory consolidation and that GABAergic receptor agonists impair memory (e.g., Brioni et al., 1989; Izquierdo et al., 1992; Bianchin et al., 1999; Wilensky et al., 2000; Huff et al., 2005). Similarly, the opioid peptidergic antagonist naloxone enhances memory

when infused into the amygdala posttraining, whereas opioid peptidergic agonists impair memory consolidation (McGaugh et al., 1988; Introini-Collison et al., 1989). Consistent with the evidence from studies using peripheral drug administration, β-adrenoceptor antagonists infused into the amygdala block the memory-enhancing effects of bicuculline or naloxone infused concurrently (McGaugh et al., 1988, 1990; Introini-Collison et al., 1989). In contrast, intraamygdala injections of α_1- or α_2-adrenoceptor antagonists do not block naloxone effects on memory consolidation (McGaugh et al., 1988). Thus, as was found with peripherally administered drugs, GABAergic and opioid peptidergic influences within the BLA appear to modulate memory consolidation by influencing β-adrenoceptor activation via influences on the release of norepinephrine. Ragozino and Gold (1994) reported that posttraining intraamygdala infusions of glucose block the memory impairment induced by the opiate drug morphine. However, such glucose infusions do not attenuate the memory impairment induced by propranolol (Lennartz et al., 1996; McNay and Gold, 1998). Thus, glucose effects do not appear to act via adrenergic activation within the amygdala.

Other recent studies reported that β-adrenoceptor activation within the BLA is also required for mediating the memory-modulatory effects of corticotropin-releasing hormone (CRH) and orphanin FQ/nociceptin (OFQ/N), a recently discovered opioid-like peptide. Retention is enhanced by posttraining intra-BLA infusions of CRH (Liang and Lee, 1988) and impaired by a CRH receptor antagonist (Roozendaal et al., 2002a). Unlike CRH, posttraining intra-BLA infusions of OFQ/N impair retention, and an OFQ/N receptor antagonist enhances retention (Roozendaal et al., 2007). Atenolol infused into the BLA blocks the memory-enhancing effect of CRH and the OFQ/N antagonist, whereas it potentiates the memory-impairing effect of OFQ/N administered concurrently (Roozendaal et al., 2007). These findings thus indicate that, as with many other neuromodulatory systems, endogenously released CRH and OFQ/N interact with noradrenergic activity within the BLA in modulating memory consolidation. Similar findings were obtained in studies of the effects of dopamine. Posttraining intra-BLA infusions of dopamine induce dose-dependent memory enhancement that is blocked by coinfusion of a β-adrenoceptor antagonist as well as D1 or D2 receptor antagonists (LaLumiere et al., 2004). However, noradrenergic activation within the BLA affecting memory also appears to require concurrent interaction with dopamine receptors, as dopamine receptor antagonists block the memory-enhancing effects of posttraining intra-BLA infusions of clenbuterol (LaLumiere et al., 2004).

The extensive evidence indicating that adrenoceptor activation within the amygdala is critical for the modulation of memory consolidation suggests that emotionally arousing learning experiences should induce the release of norepinephrine within the amygdala and that drugs and hormones that enhance memory consolidation should increase the release. Findings of studies using *in vivo* microdialysis and high-performance liquid chromatography to measure ongoing changes in norepinephrine levels in the amygdala strongly support these implications. As is shown in **Table 1**, footshock comparable to that typically used in inhibitory avoidance training significantly increases amygdala norepinephrine levels (Galvez et al., 1996; Quirarte et al., 1998). Moreover, drugs and hormones that enhance memory consolidation (e.g., epinephrine, picrotoxin, and naloxone) potentiate footshock-induced increases in norepinephrine levels in the

Table 1 Treatment effects on memory and amygdala norepinephrine levels

amygdala, and drugs that impair consolidation (e.g., muscimol, β-endorphin, and OFQ/N) decrease amygdala norepinephrine levels (Quirarte et al., 1998; Williams et al., 1998; Hatfield et al. 1999; Kawahara et al., 2004). Additionally, stimulation of the vagus nerve or the NTS increases norepinephrine levels in the amygdala and enhances memory consolidation (Clayton and Williams, 2000; Hassert et al., 2004). McIntyre et al. (2002) investigated norepinephrine levels in the amygdala induced by inhibitory avoidance training. Consistent with findings of previous studies using footshock (Galvez et al., 1996; Quirarte et al., 1998; Hatfield et al., 1999), norepinephrine levels increased following the training. However, the duration of the increased norepinephrine levels seen after training was greater than that previously found with footshock stimulation alone (i.e., without training). Additionally, and importantly, the increase in norepinephrine levels assessed in individual animals over an interval of 90 min after training correlated highly with their subsequent retention performance, tested the following day (**Figure 3**).

3.26.4.2 Glucocorticoid Influences in the BLA

There is extensive evidence that glucocorticoids affect memory consolidation through influences involving the BLA. The findings of studies of the effects of glucocorticoids on memory for inhibitory avoidance training are similar to those of studies of the effects of epinephrine. Lesions of the BLA or stria terminalis block the memory-enhancing effects of posttraining systemic injections of the synthetic glucocorticoid dexamethasone (Roozendaal and McGaugh, 1996a,b). Furthermore, memory is modulated by either systemic or intra-BLA infusions of glucocorticoids (Roozendaal and McGaugh, 1996a, 1997a), and like the effects of epinephrine, such modulation requires noradrenergic activation within the amygdala. Intra-BLA infusions of a ß-adrenoceptor antagonist block the memory-enhancing effects of systemic injections of dexamethasone or corticosterone, as well as the effects of the GR agonist RU 28362 infused into the BLA concurrently (Quirarte et al., 1997; Roozendaal et al., 2002b, 2006a,b).

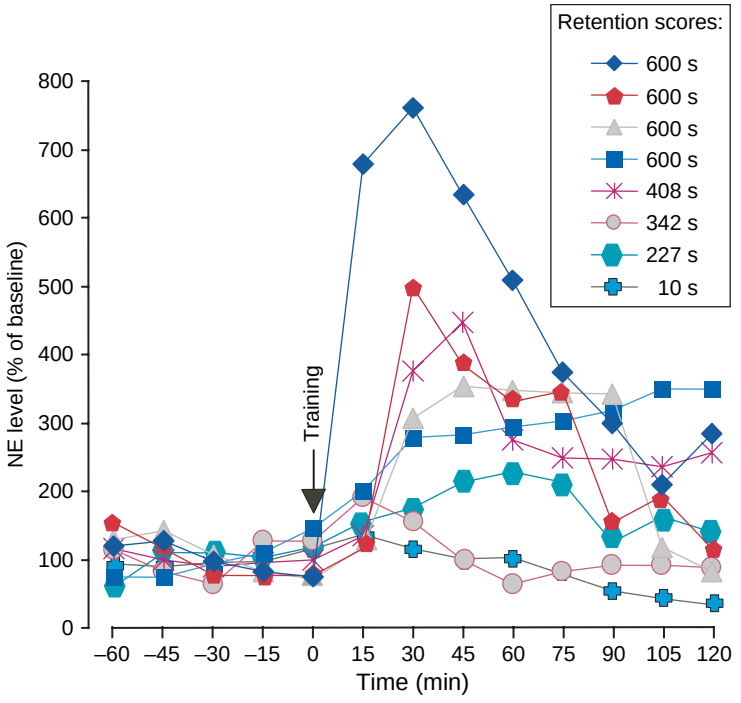

Figure 3 Norepinephrine levels in the amygdala in individual animals following inhibitory avoidance training. Percent of baseline norepinephrine following inhibitory avoidance training is graphed for each individual rat. The key notes retention score on the following day. Amygdala norepinephrine levels correlate with 24-h retention performance. Correlation values for the first five posttraining samples varied from +0.75 to +0.92. From McIntyre CK, Hatfield T, and McGaugh JL (2002) Amygdala norepinephrine levels after training predict inhibitory avoidance retention performance in rats. *Eur. J. Neurosci.* 16: 1223–1226.

As discussed above, studies investigating the effects of glucocorticoids administered systemically after object recognition training found that, in naïve (i.e., emotionally aroused) rats, propranolol blocked the memory enhancement induced by corticosterone and that, in habituated (i.e., emotionally less aroused) rats, corticosterone enhanced memory only when norepinephrine release was stimulated by yohimbine (Roozendaal et al., 2006b). A subsequent experiment (Roozendaal et al., 2006b) found that, in naive rats, intra-BLA infusions of a β-adrenoceptor antagonist blocked the effects of systemically administered corticosterone on object recognition memory. Further, in habituated rats, corticosterone activated BLA neurons, as assessed by phosphorylated cAMP response-element binding (pCREB) immunoreactivity levels, only in animals also given yohimbine. Considered together, these findings provide strong evidence that the BLA is a critical locus of the synergistic actions of glucocorticoids and emotional arousal-induced noradrenergic activation in influencing memory consolidation.

Findings of studies investigating the mechanism of glucocorticoid interactions with the noradrenergic system suggest that activation of GRs in the BLA may facilitate memory consolidation by potentiating the norepinephrine signaling cascade through an interaction with G-protein-mediated effects. The enhancement of memory for inhibitory avoidance training induced by posttraining intra-BLA infusions of the GR agonist RU 28362 is blocked by concurrent infusion of Rp-cAMPS, a drug that inhibits protein kinase A activity and thus blocks the norepinephrine signaling cascade (Roozendaal et al., 2002b). Moreover, intra-BLA infusions of the GR antagonist RU 38486 attenuate the memory-enhancing effects of the ß-adrenoceptor agonist clenbuterol infused concurrently such that a much higher dose of clenbuterol (100 ng vs. 1 ng) is required to induce memory enhancement (Roozendaal et al., 2002b).

As was found with epinephrine, glucocorticoid effects on memory consolidation also appear to involve brain stem nuclei, including the NTS, that send noradrenergic projections to the BLA. A GR antagonist infused into the NTS attenuates the memory-enhancing effects of systemically administered dexamethasone (Roozendaal et al., 1999b). Moreover, the finding that posttraining infusions of RU 28362 into the NTS enhance inhibitory avoidance retention and that intra-BLA infusions of a ß-adrenoceptor antagonist block the enhancement (Roozendaal et al., 1999b) provides additional evidence that the NTS influence on memory consolidation involves noradrenergic activation of the BLA (Williams et al., 1998, 2000; Clayton and Williams, 2000; Miyashita and Williams 2002).

3.26.4.3 Cholinergic Influences in the BLA

The finding that stria terminalis lesions block the memory-enhancing effect of systemically administered cholinergic drugs (Introini-Collison et al., 1989) provided the first evidence suggesting that muscarinic cholinergic influences within the amygdala may be involved in regulating memory consolidation. Subsequent studies have provided extensive evidence that posttraining intraamygdala infusions of muscarinic cholinergic receptor agonists and antagonists enhance and impair, respectively, memory for many kinds of training, including inhibitory avoidance, Pavlovian fear conditioning, conditioned place preference, and change in reward magnitude (Introini-Collison et al., 1996; Vazdarjanova and McGaugh, 1999; Salinas et al., 1997; Passani et al., 2001; Power and McGaugh, 2002; Schroeder and Packard, 2002; Power et al., 2003a,b; LaLumiere et al., 2004). Results of experiments using posttraining infusions of the muscarinic cholinergic receptor agonist oxotremorine administered together with selective antagonists indicate that both M1 and M2 muscarinic cholinergic receptor types are involved in the memory-enhancing effects of cholinergic activation (Power et al., 2003a). The finding that lesions of the nucleus basalis, the major source of cholinergic innervation of the BLA, impair inhibitory avoidance retention and that posttraining intra-BLA infusions of either oxotremorine or the acetylcholinesterase inhibitor physostigmine attenuate the memory impairment provided additional evidence that cholinergic activation within the BLA regulates memory consolidation (Power and McGaugh, 2002).

As noted above, in contrast to the effects of GABAergic and opioid peptidergic drugs, cholinergic effects on memory consolidation do not require concurrent noradrenergic activation. A ß-adrenoceptor antagonist does not block the memory-enhancing effect of intraamygdala infusions of oxotremorine. However, a low and otherwise ineffective dose of the muscarinic cholinergic receptor antagonist atropine blocks the memory enhancement induced by intraamygdala infusions of clenbuterol (Dalmaz et al., 1993; Salinas et al., 1997). Thus, cholinergic activation in the BLA appears to act downstream

from adrenergic activation in modulating memory consolidation. Other findings indicate that cholinergic activation within the BLA is critical for enabling glucocorticoid as well as dopamine enhancement of memory consolidation. Atropine infused into the BLA blocks the memory-enhancing effects of RU 28362 or dopamine infused concurrently as well as the effects of systemically administered dexamethasone (Power et al., 2000; LaLumiere et al., 2004). Conversely, cholinergic activation within the BLA affecting memory also appears to require concurrent interaction with dopamine, as dopamine receptor antagonists block the memory-enhancing effects of posttraining intra-BLA infusions of oxotremorine (LaLumiere et al., 2004).

Studies of the effects of histamine receptor antagonists and agonists infused into the BLA provide additional evidence of a role of acetylcholine in the BLA in modulating consolidation (Passini et al., 2001). H_3 receptor antagonists (ciproxifan, clobenprobit, or thioperamide) infused into the BLA decrease acetylcholine release, as assessed by *in vivo* microdialysis, and concurrent infusions of the H_2 receptor agonist cimetidine block the decreased acetylcholine release. Moreover, posttraining intra-BLA infusions of H_3 receptor antagonists, administered in doses found to decrease acetylcholine release, impair memory for contextual fear conditioning (Passani et al., 2001). As other studies have reported that posttraining systemically administered H_3 receptor antagonists enhance memory and block memory impairment induced by a muscarinic cholinergic antagonist (Bernaerts et al., 2004), it seems likely that the central and peripheral actions of H_3 receptor antagonists involve different actions. There is also evidence that acetylcholine is released within the amygdala during training. Studies using *in vivo* microdialysis have shown that acetylcholine levels in the amygdala increase while rats perform a spontaneous alternation task and that the increase is correlated with performance on the task (Gold, 2003; McIntyre et al., 2003). As this task is known to involve hippocampal functioning, these findings are consistent with other evidence, discussed below, suggesting that the amygdala influences memory processing that involves the hippocampus. **Figure 4** summarizes some of the neuromodulatory interactions within the BLA involved in regulating memory consolidation.

3.26.4.4 Other Neuromodulatory Influences in the BLA

The BLA is also involved in mediating the modulatory effects of other hormones and neurotransmitters on memory consolidation. For example, a recent study reported not only that the reproductive hormone relaxin binds to specific receptors in hypothalamic regions to regulate reproductive behaviors but also that posttraining intra-BLA infusions of relaxin also induce dose-dependent impairment of inhibitory avoidance memory (Ma et al., 2005). Other recent studies implicated the amygdala in the memory-modulatory effects of bombesin (gastrin-releasing peptide). Posttraining intra-BLA infusions of the bombesin receptor antagonist RC-3095 impair memory of inhibitory avoidance (Roesler et al., 2004b), whereas temporary inactivation of the BLA blocked the memory-modulatory effects of systemically administered bombesin or its antagonist (Rashidy-Pour and Razvani, 1998; Roesler et al., 2004b). Furthermore, the finding that bombesin infused into the NTS also modulates memory consolidation (Williams and McGaugh, 1994) and that inactivation of the NTS blocks the effects of peripherally administered bombesin (Rashidy-Pour and Razvani, 1998) suggests that noradrenergic activity may be essential in mediating the effects of bombesin on memory consolidation. This suggestion is supported by the evidence that the bombesin receptor antagonist selectively impaired memory consolidation of aversively motivated inhibitory avoidance training and not that of emotionally less arousing object recognition training (Roesler et al., 2004a), which, as discussed above, induces less noradrenergic activation of the BLA.

3.26.5 Involvement of the Amygdala in Modulating Memory Extinction

Several studies have investigated whether extinction learning (i.e., learning that cues that previously predicted aversive or appetitive consequences no longer predict such consequences) is regulated by the same neuromodulatory systems that regulated the original learning. An early study found that posttraining peripheral administration of picrotoxin enhances the extinction of cued fear conditioning (McGaugh et al., 1990). Experiments using intra-BLA infusions have found that the GABAergic antagonist bicuculline and norepinephrine administered posttraining enhance extinction of contextual fear conditioning (Berlau and McGaugh, 2006). If such extinction involves the same processes engaged by fear conditioning, the effects of bicuculline would be expected to require β-adrenoceptor activation. Consistent with

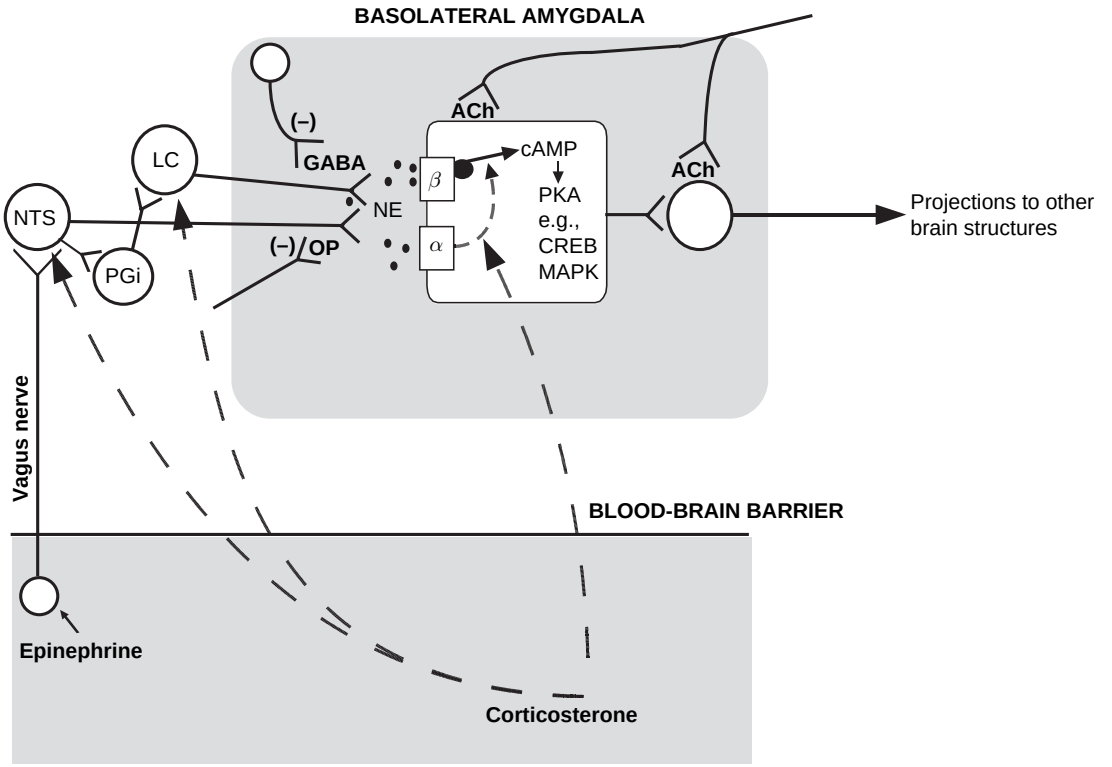

Figure 4 Schematic summarizing the role of the noradrenergic system of the basolateral amygdala in memory consolidation. Norepinephrine (NE) is released in the basolateral amygdala following training in aversively motivated tasks and binds to both β-adrenoceptors and α_1-adrenoceptors at postsynaptic sites. The β-adrenoceptor is coupled directly to adenylate cyclase to stimulate cAMP formation. The α_1-adrenoceptor modulates the response induced by β-adrenoceptor stimulation. Intracellular cAMP can initiate a cascade of molecular events in the basolateral amygdala. The memory-modulatory effects of several other neuromodulatory influences, including that of epinephrine, glucocorticoid, opioid peptidergic, and GABAergic systems, are mediated by converging influences on the noradrenergic system of the basolateral amygdala. Drug interactions with the noradrenergic system can occur at both presynaptic and postsynaptic loci. These noradrenergic effects in the basolateral amygdala are required for regulating memory consolidation in other brain regions. α, α_1-adrenoceptor; ACh, acetylcholine; β, β-adrenoceptor; cAMP, adenosine 3′,5′-cyclic monophosphate; CREB, cAMP-response element-binding protein; GABA, gamma-aminobutyric acid; LC, locus coeruleus; MAPK, mitogen-activated protein kinase, NTS, nucleus of the solitary tract; OP, opioid peptide; Pgi, nucleus paragigantocellularis; PKA, protein kinase A. From McGaugh JL (2000) Memory: A century of consolidation. *Science* 287: 248–251, and Roozendaal B (2000) Glucocorticoids and the regulation of memory consolidation. *Psychoneuroendocrinology* 25: 213–238.

that implication, posttraining infusions of bicuculline did not enhance extinction memory consolidation when infused into the BLA together with a low and otherwise ineffective dose of propranolol. Additionally, the GABAergic agonist muscimol coinfused into the BLA with norepinephrine posttraining did not block the memory enhancement induced by norepinephrine. These findings are consistent with the evidence discussed above indicating that norepinephrine effects in the BLA act downstream from GABAergic influences (Introini-Collison et al., 1994; McGaugh and Cahill, 1997). Other studies have reported that extinction of fear conditioning is enhanced by pre- or postextinction infusions of the *N*-methyl-D-aspartate (NMDA) partial agonist d-cycloserine (Walker et al., 2002; Ledgerwood et al., 2003, 2005). Furthermore, intra-BLA infusions of d-cycloserine block the impairing effects of concurrent administration of the GABAergic agonist muscimol on the consolidation of extinction memory (Akirav, 2007). Consistent with extensive evidence of glucococorticoid enhancement of consolidation of memory of fear-based training, dexamethasone administered systemically after extinction training or intra-amygdally prior to extinction also enhanced extinction of fear-potentiated startle (Yang et al., 2006). Furthermore, corticosterone given systemically immediately after retention testing on a

contextual fear conditioning task facilitated extinction of this memory (Cai et al., 2006). Other studies have reported that the BLA modulates the extinction of conditioned place preference. Glucose or oxotremorine infused into the BLA immediately after extinction training enhanced the extinction of amphetamine-induced place preference (Schroeder and Packard, 2003, 2004).

3.26.6 Amygdala Interactions with Other Brain Systems in Modulating Memory

Although many of the experiments investigating BLA involvement in memory consolidation have used inhibitory avoidance training and testing (Parent and McGaugh, 1994; Izquierdo et al., 1997; McGaugh et al., 2000; McGaugh and Izquierdo, 2000; Wilensky et al., 2000), comparable effects of posttraining amygdala treatments have been obtained in experiments using many different kinds of training tasks, including contextual fear conditioning (Sacchetti et al., 1999; Vazdarjanova and McGaugh, 1999; LaLumiere et al., 2003), cued fear conditioning (Sacchetti et al., 1999; Schafe and LeDoux, 2000; Roozendaal et al., 2006a), Y-maze discrimination training (McGaugh et al., 1988), change in reward magnitude (Salinas et al., 1997), conditioned place preference (Hsu et al., 2002; Schroeder and Packard, 2003, 2004), radial-arm maze appetitive training (Packard and Chen, 1999), water-maze spatial and cued training (Packard et al., 1994; Packard and Teather, 1998), conditioned taste aversion (Miranda et al., 2003), olfactory training (Kilpatrick and Cahill, 2003a), object recognition (Roozendaal et al., 2006b), extinction of contextual fear conditioning (Berlau and McGaugh, 2006), and extinction of conditioned reward (Schroeder and Packard, 2003). Thus, although there is abundant evidence that the BLA is involved in modulating memory of aversively motivated training, such as footshock training used in inhibitory avoidance and Pavlovian fear conditioning, the evidence also clearly indicates that the BLA modulates the consolidation of memory for many different kinds of training experiences (McGaugh, 2002; Packard and Cahill, 2001), and as these different training experiences are known to engage different brain systems both during training and during the consolidation occurring after training (Quillfeldt et al., 1996; Zanatta et al., 1996; Izquierdo et al., 1997; Packard and Knowlton, 2002; Gold, 2004), the BLA-induced modulation no doubt involves influences on processing occurring in these other brain regions.

As discussed above, there is considerable evidence that neuromodulatory interactions occurring within the amygdala influence memory consolidation. Such influences may be, at least in part, a result of influences on neuroplasticity within the amygdala. However, several kinds of evidence suggest that alterations in amygdala functioning affect memory consolidation through amygdala influences on other brain regions involved in memory consolidation. The BLA sends projections to many other brain regions, some via the stria terminalis (Young, 1993; Pitkänen, 2000; Petrovich et al., 2001; Price, 2003; Sah et al., 2003). The evidence, discussed above, that stria terminalis lesions block the memory-modulating effects of electrical stimulation and intraamygdala drug infusions strongly suggests that modulation within the amygdala is not sufficient to affect memory: efferent projections seem required. The evidence that posttraining BLA treatments affect memory for many kinds of training clearly suggests that processing in different brain regions is required. This implication is supported by the finding that training known to involve the amygdala (e.g., Pavlovian fear conditioning) induces the expression of several transcriptionally regulated genes implicated in synaptic plasticity in many brain areas, including the hippocampus, striatum, and cortex, as well as the amygdala (Ressler et al., 2002). These effects appear to be involved in memory consolidation and not simply a result of nonspecific effects of stress or arousal, as they were found only when the stimuli used in the training induced learning. The findings of the many types of studies discussed later provide compelling evidence that the amygdala interacts with other brain regions in modulating the consolidation of memory for different kinds of training.

3.26.6.1 BLA Interactions with the Caudate Nucleus, Hippocampus, and Nucleus Accumbens

The amygdala projects directly to the caudate nucleus (via the stria terminalis) and both directly and indirectly to the hippocampus (Pitkänen, 2000; Petrovich et al., 2001). The evidence that stria terminalis lesions block the memory-enhancing effects of oxotremorine that was infused posttraining into the caudate nucleus suggests that efferents from the amygdala influence memory processing involving

the caudate nucleus (Packard et al., 1996). There is considerable evidence that the caudate nucleus and hippocampus are involved in different kinds of learning (e.g., Packard and McGaugh, 1992, 1996; McDonald and White, 1993; Packard and Cahill, 2001). In studies of rats given water-maze training, Packard and colleagues (Packard et al., 1994; Packard and Teather, 1998) found that amphetamine that was infused posttraining into the caudate nucleus selectively enhanced memory of visually cued training, whereas infusions administered into the dorsal hippocampus selectively enhanced memory of spatial training. In contrast, amphetamine infused into the amygdala posttraining enhanced memory for both types of training. Additionally, inactivation of the hippocampus (with lidocaine) prior to testing blocked retention of the spatial training, and inactivation of the caudate nucleus blocked retention of the visually cued training. But importantly, inactivation of the amygdala prior to retention testing did not block memory of either kind of training. Thus, although the amygdala modulates the consolidation of both caudate nucleus-dependent and hippocampus-dependent tasks, such findings suggest that it is not a locus of memory for either type of training. Additionally, in rats trained in a radial-arm maze spatial task, lidocaine infused into the amygdala blocked the memory enhancement induced by posttraining intrahippocampal infusions of glutamate (Packard and Chen, 1999). Such findings are consistent with extensive evidence that the hippocampus is involved in the learning of contextual information (Hirsh, 1974; Rudy and Sutherland, 1989; Phillips and LeDoux, 1992; Eichenbaum et al., 1996; McNish et al., 1997; Matus-Amat et al., 2004).

In fear conditioning tasks, including inhibitory avoidance, that are typically used in memory modulation studies, the rats learn that footshock occurs in a specific context. Further, that information can be learned if rats are first exposed to the context and then, on a subsequent day, given a brief footshock. As is shown in **Figure 5**, infusions of oxotremorine administered into the hippocampus after context exposure enhanced the subsequent conditioning, but infusions administered after the footshock training were ineffective (Malin and McGaugh, 2006). In contrast, oxotremorine infused into the rostral anterior cingulate cortex selectively enhanced memory when administered after the footshock. Oxotremorine infused into the BLA enhanced retention when administered after either the context or footshock training, consistent with extensive evidence that BLA activity modulates memory for many different kinds of experiences. Other findings of studies of the effects of posttraining intraamygdala infusions of a GR agonist provide additional evidence of BLA–hippocampus interactions in memory consolidation. As is shown in **Figure 6**, unilateral posttraining intrahippocampal infusions of the specific GR agonist RU 28362 enhanced rats' retention of inhibitory avoidance training, and the retention enhancement was blocked selectively by ipsilateral infusions of a ß-adrenoceptor antagonist into the BLA (Roozendaal et al., 1999a). The memory enhancement induced by GR activation in the hippocampus is also blocked by lesions of the BLA, stria terminalis, or nucleus accumbens (Roozendaal and McGaugh, 1997b; Roozendaal et al., 2001).

The BLA projects to the nucleus accumbens primarily via the stria terminalis (Kelley et al., 1982; Wright et al., 1996). The possible involvement of the BLA–stria terminalis–nucleus accumbens pathway in modulating memory consolidation was suggested by the finding that lesions of the nucleus accumbens, like lesions of the BLA, block the memory-enhancing effects of systemically administered dexamethasone (Roozendaal and McGaugh, 1996a; Setlow et al., 2000). Furthermore, the finding that unilateral lesions of the BLA combined with contralateral (unilateral) lesions of the nucleus accumbens also blocked the dexamethasone effect strongly indicates that these two structures interact via the stria terminalis in influencing memory consolidation (Setlow et al., 2000). Further evidence of BLA–nucleus accumbens interactions in modulating memory consolidation is provided by the finding (LaLumiere et al., 2005) that memory enhancement induced by intra-BLA infusions of dopamine is blocked by infusions of a dopamine receptor antagonist into the nucleus accumbens shell (but not the core). Conversely, a dopamine receptor antagonist infused into the BLA blocks the memory enhancement induced by infusions of dopamine infused into the nucleus accumbens shell posttraining (**Figure 7**).

As the hippocampus is known to project to the nucleus accumbens, that region may be a critical locus of converging BLA and hippocampal modulatory influences on memory consolidation (Mulder et al., 1998). The finding that inactivation of the nucleus accumbens with infusions of bupivacaine prior to training blocks the acquisition of contextual fear conditioning provides evidence consistent with this hypothesis (Haralambous and Westbrook, 1999). It is not known whether the BLA–nucleus accumbens

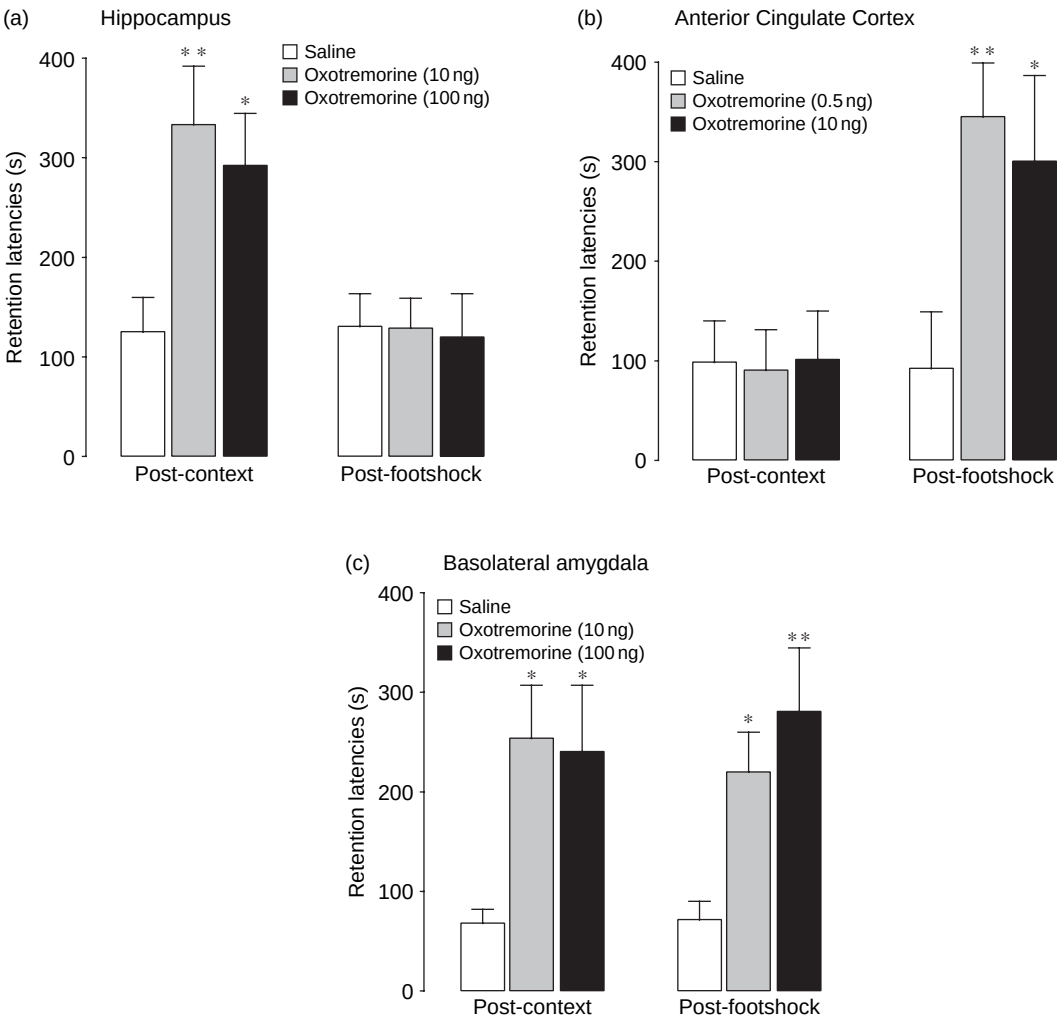

Figure 5 Differential involvement of the hippocampus, anterior cingulate cortex, and basolateral amygdala in memory for context and footshock. (a) Posttraining infusions of the muscarinic cholinergic receptor agonist oxotremorine (10 or 100 ng in 0.5 μl) into the dorsal hippocampus enhanced 48-h inhibitory avoidance retention latencies when administered after context exposure but not after the shock exposure given 24 h later. (b) Posttraining infusions of oxotremorine (0.5 or 10 ng in 0.5 μl) into the anterior cingulate cortex selectively enhanced 48-h inhibitory avoidance retention latencies when administered after the shock experience but not after the context exposure. (c) Posttraining infusions of oxotremorine (10 or 100 ng in 0.2 μl) into the basolateral amygdala enhanced 48-h inhibitory avoidance retention latencies when administered after either the context exposure or the shock experience. Results represent retention latencies (mean + SEM) in seconds. $*$, $p < .05$; $**$, $p < .01$ compared with the corresponding saline group. USA* 103: 1959–1963.

and hippocampus–nucleus accumbens pathways are also involved in mediating other BLA neuromodulatory influences on memory consolidation.

Other findings indicate that noradrenergic stimulation of the BLA that enhances memory consolidation also increases dorsal hippocampal levels of activity-regulated cytoskeletal protein (Arc) (McIntyre et al., 2005), an immediate-early gene implicated in hippocampal synaptic plasticity and memory consolidation processes (Guzowski et al., 2000). Additionally, inactivation of the BLA with infusions of lidocaine impairs memory consolidation and decreases Arc protein levels in the dorsal hippocampus (McIntyre et al., 2005). Further, the finding that intra-BLA infusions of muscimol attenuate the increase in Arc mRNA induced by contextual fear conditioning provides

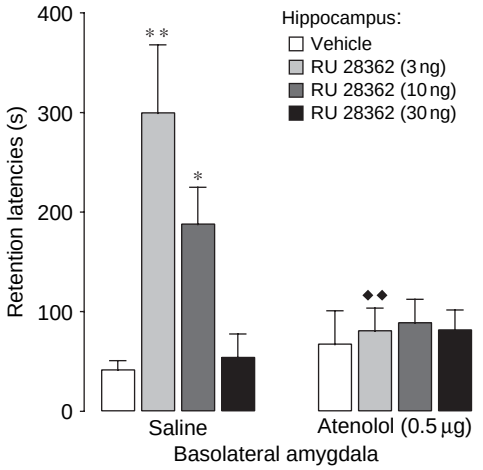

Figure 6 Glucocorticoid effects in the hippocampus on memory consolidation require noradrenergic activity of the basolateral amygdala. Immediate posttraining unilateral infusions of the glucocorticoid receptor agonist RU 28362 (3, 10, or 30 ng in 0.5 µl) induced dose-dependent enhancement of 48-h inhibitory avoidance retention latencies in rats given saline infusions into the basolateral amygdala concurrently. Ipsilateral infusions of the β-adrenoceptor antagonist atenolol (0.5 µg in 0.2 µl) into the basolateral blocked the memory enhancement induced by the glucocorticoid receptor agonist. Results represent retention latencies (mean + SEM) in seconds. *, $p < .05$; **, $p < .01$ compared with the corresponding vehicle group. ◆◆, $p < .01$ compared with the corresponding saline group. From Roozendaal B, Nguyen BT, Power A, and McGaugh JL (1999a) Basolateral amygdala noradrenergic influence enables enhancement of memory consolidation induced by hippocampal glucocorticoid receptor activation. *Proc. Natl. Acad. Sci. USA* 96: 11642–11647.

further evidence that the BLA modulates memory consolidation via regulation of Arc expression in the hippocampus (Huff et al., 2006).

Studies of BLA influences on hippocampal neuroplasticity provide additional important evidence of amygdala–hippocampal interactions (Abe, 2001). Electrical stimulation of the BLA enhances the induction of long-term potentiation (LTP) in the dentate gyrus of the hippocampus (Ikegaya et al., 1995b; Akirav and Richter-Levin, 1999; Frey et al., 2001; Almaguer-Melian et al., 2003). Also, selective lesions of the BLA or infusions of a ß-adrenoceptor antagonist into the BLA block the induction of LTP in the dentate gyrus (Ikegaya et al., 1994, 1995a, 1997). Consistent with the findings of BLA modulation of memory, norepinephrine and corticosterone both influence the effects of BLA stimulation on dentate gyrus LTP (Akirav and Richter-Levin, 2002). Recent findings indicate that electrical stimulation of the BLA also enhances LTP at cortical synapses onto striatal neurons (Popescu et al., 2007). Such findings fit well with the evidence that posttraining amygdala activation enhances consolidation of striatal-dependent memory (Packard et al., 1994; Packard and Teather, 1998).

The recent findings that Pavlovian fear conditioning induces an increase in synchronization of theta-frequency activity in the lateral amygdala and CA1 region of the hippocampus strongly suggest that activation of an amygdala–hippocampus circuit is involved in fear-based learning (Pape et al., 2005). More generally, studies of synchronized oscillatory activity occurring within the BLA suggest that such activity may facilitate the temporal lobe as well as neocortical processes involved in consolidating explicit or declarative memory (Paré, 2003; Pelletier and Paré, 2004). Importantly, there is also evidence that the firing of cells in the BLA of cats is increased greatly by a single footshock and that the increased firing lasts for at least 2 h (Pelletier et al., 2005). Such increased firing may serve to modulate memory processing in efferent brain regions, including the entorhinal cortex and hippocampus (Paré et al., 2002; Pelletier and Paré, 2004; McGaugh, 2005). This view is supported by additional physiological evidence that, in cats, during the early stages of reward-based learning, training-induced BLA activity increases the impulse transmission from perirhinal to entorhinal cortical regions (Paz et al., 2006).

3.26.6.2 BLA–Cortical Interactions in Memory Consolidation

It is now well established that posttraining infusions of drugs into various cortical regions can impair or enhance the consolidation of memory for several kinds of training (Ardenghi et al., 1997; Izquierdo et al., 1997; Baldi et al., 1999; Sacchetti et al., 1999; Malin and McGaugh, 2006). The findings of several recent studies indicate that the BLA modulates cortical functioning involved in memory consolidation. Neurons within the BLA project directly to the entorhinal cortex (Paré et al., 1995; Paré and Gaudreau, 1996; Pikkarainen et al., 1999; Petrovich et al., 2001). The memory enhancement induced by posttraining drug infusions administered into the entorhinal cortex (Izquierdo and Medina, 1997) requires a functioning BLA, as lesions of the BLA prevent the memory enhancement induced by 8-bromo-cAMP infused posttraining into the

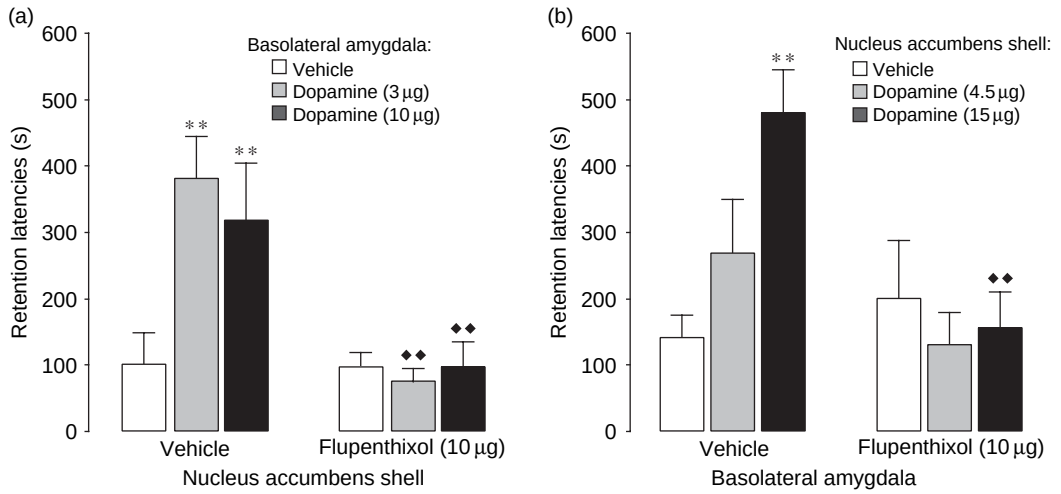

Figure 7 Modulation of memory consolidation by the basolateral amygdala or nucleus accumbens shell requires concurrent dopamine receptor activation in both brain regions. (a) Intrabasolateral amygdala infusions of dopamine (3 or 10 μg in 0.2 μl) immediately after inhibitory avoidance training produced enhancement of 48-h retention performance in rats receiving vehicle into the nucleus accumbens shell. Infusion of the general dopamine receptor antagonist *cis*-flupenthixol (10 μg in 0.3 μl) into the nucleus accumbens shell blocked the memory enhancement induced by dopamine infusions into the basolateral amygdala. (b) Intranucleus accumbens shell infusions of dopamine (4.5 or 15 μg in 0.3 μl) also induced memory enhancement, and this effect was blocked by concurrent infusions of *cis*-flupenthixol (10 μg in 0.2 μl) into the basolateral amygdala. Results represent retention latencies (mean + SEM) in seconds. **, $p < .01$ compared with the vehicle group; ◆◆, $p < .01$ compared with the corresponding vehicle group. From LaLumiere RT, Nawar EM, and McGaugh JL (2005) Modulation of memory consolidation by the basolateral amygdala or nucleus accumbens shell requires concurrent dopamine receptor activation in both brain regions. *Learn. Mem.* 12: 296–301.

entorhinal cortex (Roesler et al., 2002). Other recent studies have reported that BLA lesions or blocking of β-adrenoceptors in the BLA also block the memory-enhancing effects of 8-bromo-cAMP infused post-training into the insular cortex (Miranda and McGaugh, 2004) and of oxotremorine infused into the rostral anterior cingulate cortex (Malin et al., 2007). Additionally, the finding that lesions of the rostral anterior cingular cortex block the memory-enhancing effects of oxotremorine infused posttraining into the BLA indicates that cortical functioning is essential for BLA memory-modulatory effects (Malin et al., 2007). However, other evidence indicates that the rostral anterior cingulate cortex and the BLA serve quite different functions in memory. As discussed earlier, the anterior cingulate cortex appears to play a somewhat selective role in memory for nociceptive information, whereas extensive evidence indicates that the BLA is not dedicated to the modulation of any specific kinds of information (Packard et al., 1994; Malin and McGaugh, 2006). The BLA appears to be promiscuous in its modulation of emotionally influenced memory consolidation (McGaugh, 2002).

Other recent studies reported evidence indicating interactions between the BLA and the medial prefrontal cortex in regulating memory consolidation. Inactivation of the medial prefrontal cortex with the AMPA-receptor antagonist CNQX impairs consolidation of inhibitory avoidance memory (Liang et al., 1996). In contrast, activation of noradrenergic and dopaminergic mechanisms in the medial prefrontal cortex enhances consolidation of inhibitory avoidance and trace fear conditioning (Liang, 2001; Runyan and Dash, 2004). A GR agonist infused into the medial prefrontal cortex induces similar memory enhancement. However, and importantly, lesions of the BLA block this GR agonist–induced memory enhancement. Furthermore, consistent with the evidence of reciprocal inhibitory influences between both brain regions (McDonald, 1991; Perez-Jaranay and Vives, 1991; Rosenkranz and Grace, 2002), infusions of RU 28362 into the medial prefrontal cortex after inhibitory avoidance training increases BLA activity, as assessed with phosphorylation of extracellular-regulated kinase (ERK), a member of the mitogen-activated protein kinase family (Roozendaal et al., unpublished findings). Further,

blockade of this increase in phosphorylated ERK levels in the BLA with the MEK inhibitor PD98059 blocks the memory enhancement induced by medial prefrontal cortex GR agonist infusions. Interestingly, infusions of a GR agonist into the BLA induce a similar increase in phosphorylated ERK activity in the medial prefrontal cortex, suggesting mutual interactions between both brain regions in regulating memory consolidation.

It is likely that the BLA also influences cortical functioning, at least in part, via its projection through the stria terminalis (Price, 1981) to the nucleus basalis, which provides cholinergic activation of the cortex. Studies have reported findings suggesting that the nucleus basalis–cortical projections may be essential for learning-induced cortical plasticity (Miasnikov et al., 2001, 2006; Weinberger, 2003). Stimulation of the BLA activates the cortex, as indicated by EEG desynchronization, and potentiates nucleus basalis influences on cortical activation. Moreover, inactivation of the nucleus basalis with lidocaine blocks the BLA effects on cortical activation (Dringenberg and Vanderwolf, 1996; Dringenberg et al., 2001). Thus, the BLA may influence cortical functioning in memory consolidation, at least in part, through its effects on the nucleus basalis and consequent cholinergic activation of the cortex. In support of this suggestion, Power et al. (2002) reported that selective lesions of cortical nucleus basalis corticopetal cholinergic projections induced by 192-IgG saporin blocked the dose-dependent enhancement of inhibitory avoidance induced by posttraining intra-BLA infusions of norepinephrine (**Figure 8**). Thus, it is clear that cortical cholinergic activity is required for BLA influences on memory consolidation. **Figure 9** summarizes the interaction of the BLA with other systems in regulating memory consolidation.

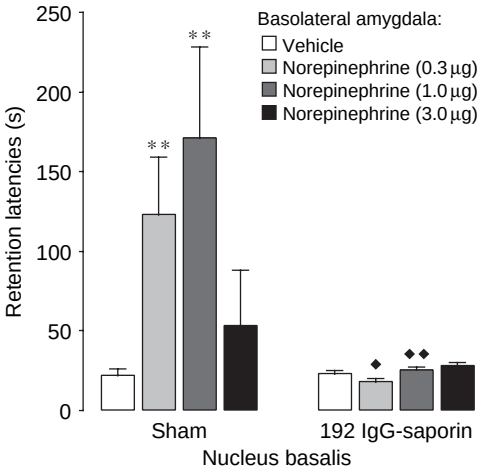

Figure 8 Lesions of nucleus basalis cholinergic neurons with 192 IgG-saporin block the memory enhancement induced by posttraining infusions of norepinephrine into the basolateral amygdala. Intrabasolateral amygdala infusions of norepinephrine (0.3, 1.0, or 3.0 ng in 0.2 µl) immediately after inhibitory avoidance training produced a dose-dependent enhancement of 48-h retention performance in sham-operated rats. Rats with 192 IgG-saporin lesions did not show memory enhancement with norepinephrine infusions. Results represent retention latencies (mean + SEM) in seconds. **, $p < .01$ compared with the saline group; ◆, $p < .05$; ◆◆, $p < .01$ compared with the corresponding sham lesion group. From Power AE, Thal LJ, and McGaugh JL (2002) Lesions of the nucleus basalis magnocellularis induced by 192 IgG-saporin block memory enhancement with posttraining norepinephrine in the basolateral amygdala. *Proc. Natl. Acad. Sci. USA* 99: 2315–2319.

3.26.7 Amygdala Activity and Modulation of Human Memory Consolidation

As discussed above, the findings of animal experiments very clearly provide extensive evidence that stress hormones released by emotional experiences influence memory consolidation and that the influence is mediated by activation of the BLA. The findings of many human studies of effects of emotional arousal, stress hormones, and amygdala activation on memory are consistent with those of animal studies (Cahill and McGaugh, 1998, 2000; Cahill, 2000; Dolan, 2000; Buchanan and Adolphs, 2004; LaBar and Cabeza, 2006). Cortisol administered to subjects prior to presentations of words or pictures enhanced subsequent recall (Buchanan and Lovallo, 2001; Abercrombie et al., 2003, 2006; Kuhlmann and Wolf, 2006). Amphetamine administered to human subjects, either before or after they learned lists of words, also enhanced long-term memory (Soetens et al., 1993, 1995). Administration of propranolol to subjects prior to their viewing an emotionally arousing slide presentation blocked the enhancing effects of emotional arousal on long-term memory (Cahill et al., 1994). Propranolol also blocks the memory enhancement produced by stress-released epinephrine (Nielson and Jensen, 1994). Further, epinephrine or cold pressor stress (which stimulates the release of adrenal stress hormones) administered to subjects after they viewed emotionally arousing slides enhanced the subjects' long-term memory of the slides (Cahill and Alkire, 2003; Cahill et al., 2003). Similar effects were produced by administration of the α_2-adrenoceptor

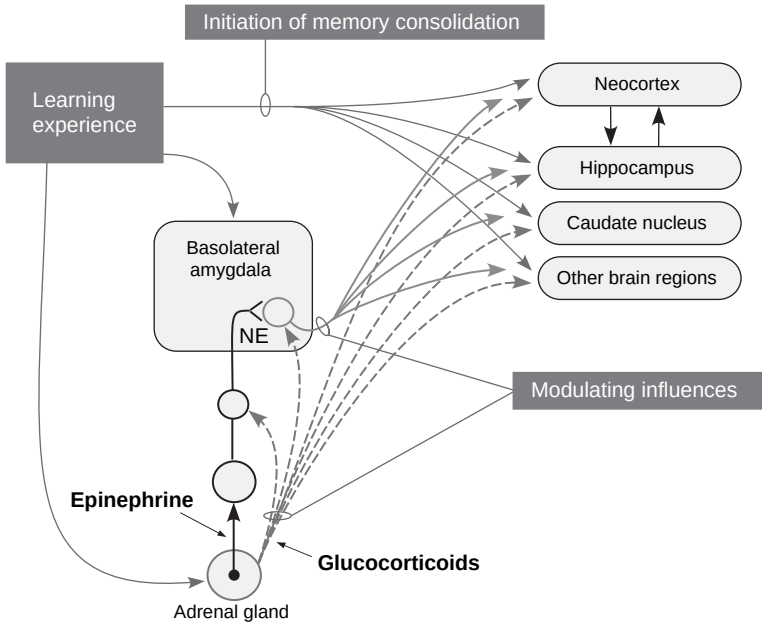

Figure 9 Schematic summarizing interactions of the basolateral amygdala with other brain regions in mediating emotional arousal–induced modulation of memory consolidation. Experiences initiate memory consolidation in many brain regions involved in the forms of memory represented. Emotionally arousing experiences also release adrenal epinephrine and glucocorticoids and activate the release of norepinephrine in the basolateral amygdala. The basolateral amygdala modulates memory consolidation by influencing neuroplasticity in other brain regions. From McGaugh JL (2000) Memory: A century of consolidation. *Science* 287: 248–251.

antagonist yohimbine, which stimulates norepinephrine release (O'Carroll et al., 1999; Southwick et al., 2002). These findings of studies of memory in human subjects are, thus, consistent with those of the animal experiments discussed above in providing evidence of the central roles of emotional activation and stress hormones in modulating memory consolidation (*See* Chapter 3.24).

Recent human studies have also provided extensive evidence that amygdala activation is involved in enabling the enhanced memory induced by emotional arousal. Memory for emotionally arousing material is not enhanced in human subjects with selective bilateral lesions of the amygdala, as it is in normal subjects (Cahill et al., 1995; Adolphs et al., 1997). Studies using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) brain imaging have provided additional evidence that the influence of emotional arousal on human memory involves amygdala activation. In the first study of the relationship between amygdala activity during encoding and subsequent memory, Cahill et al. (1996) reported that amygdala activity assessed by PET imaging as subjects viewed emotionally arousing films correlated highly (+0.93) with the subjects' recall of the films assessed in a surprise memory test 3 weeks later. Importantly, the degree of emotional arousal rather than the valence of the emotionally arousing material appears to be critical in influencing memory. In a subsequent study using PET imaging, Hamann et al. (1999, 2002) reported that amygdala activity induced by viewing either pleasant or unpleasant slides correlated highly with memory for the slides assessed 1 month later. Studies using fMRI have obtained highly similar findings. Canli et al. (2000) found that subjects' memory for a series of scenes tested 3 weeks after brain scanning correlated highly with amygdala activity induced by viewing the scenes. Furthermore, and importantly, the relationship between amygdala activity during encoding and subsequent memory was greatest for the scenes that the subjects had rated as being the most emotionally intense.

Human memory studies have provided additional evidence of the importance of noradrenergic acti vation of the amygdala. When assessed during encoding, PET imaging of amygdala activity that is assessed over many minutes of arousal as well as event-related fMRI of amygdala activity induced by single items both predict long-term memory of the

arousing stimuli (Cahill et al., 1996; Canli et al., 2000). And, importantly, β-adrenoceptor antagonists (e.g., propranolol) block the increase in amygdala activity and enhanced retention induced by emotional stimuli obtained in fMRI studies (Strange and Dolan, 2004; van Stegeren et al., 2005). Thus, β-adrenergic activation of the amygdala appears to be essential for the short-latency modulation induced by brief and mild emotional arousal used in fMRI studies as well as the effects found in human and animal studies, with longer intervals of time between learning and stress hormone activation or administration.

An additional finding of human brain imaging studies of memory studies is that, with both PET and fMRI experiments, activity of the right amygdala is related to enhanced memory in men, whereas activity of the left amygdala is correlated with enhanced memory in women (Cahill et al., 2001, 2004; Canli et al., 2001). Understanding the bases of such sex differences may provide further insights into mechanisms of emotional arousal underlying influences on memory consolidation.

Other findings based on an analysis of PET and fMRI scans provide evidence, consistent with that from many animal studies, indicating that amygdala activation influences memory processing in other brain regions. The activity of the amygdala and hippocampal/parahippocampal regions are correlated during emotional arousal (Hamann et al., 1999), and such activation is correlated with subsequent retention (Dolcos et al., 2004). The results of a 'path analysis' (structural equation modeling) study (Kilpatrick and Cahill, 2003b) of amygdala activity scanned, using PET, while subjects viewed neutral or emotionally arousing films (Cahill et al., 1996) suggest that emotional arousal increased amygdala influences on activity of the ipsilateral parahippocampal gyrus and ventrolateral prefrontal cortex. Such findings provide additional evidence that amygdala influences on activity of other brain regions are critical in creating lasting memories.

3.26.8 Involvement of the Amygdala in Modulating Memory Retrieval and Working Memory

Most studies investigating neuromodulatory influences on memory have focused on the neurobiological mechanisms underlying the consolidation of recent experiences. However, there is also much evidence that neuromodulatory systems influence memory retrieval and working memory. Most of such studies have investigated the effects of either peripherally administered hormones and neurotransmitters or the effects of direct infusions of a variety of drugs into the hippocampus and medial prefrontal cortex, brain regions that are critically involved in regulating memory retrieval and working memory. However, consistent with its role in memory consolidation, recent findings indicate that the BLA, via its projections to these brain regions, also plays an important modulatory role in regulating drug effects on these memory functions.

3.26.8.1 Memory Retrieval

Several studies investigated the effects of peripherally administered hormones and drugs on memory retrieval in rats. Stress exposure or the glucocorticoid corticosterone administered systemically shortly before testing for memory of training on inhibitory avoidance or water-maze spatial tasks (24 h earlier) produces temporary impairment of retention performance (Bohus, 1973; de Quervain et al., 1998; Yang et al., 2003; Roozendaal et al., 2004a; Pakdel and Rashidy-Pour, 2006; Sajadi et al., 2006). As the same treatments administered shortly before training do not affect either acquisition or retention performance assessed immediately after acquisition, such findings indicate that glucocorticoids impair retention by influencing memory retrieval. These findings are consistent with those indicating that stress exposure or glucocorticoids administered immediately after a learning session also impair retention performance tested 30–60 min after the session, that is, at a time when the memory trace has not yet been consolidated into long-term memory (Diamond et al., 1999; Woodson et al., 2003; Okuda et al., 2004). Similarly, as is found with memory consolidation, glucocorticoid effects on memory retrieval depend on concurrent activation of noradrenergic mechanisms. The β-adrenoceptor antagonist propranolol administered systemically 30 min before inhibitory avoidance retention testing blocks the memory retrieval impairment induced by concurrent injections of corticosterone (Roozendaal et al., 2004a). As stimulation of β_1-adrenoceptors with systemic injections of the selective agonist xamoterol induces a memory retrieval impairment comparable to that seen after corticosterone administration (Roozendaal et al., 2004b), the findings suggest that glucocorticoid effects on memory retrieval impairment involve activation of noradrenergic mechanisms. Norepinephrine

effects on memory retrieval are most likely dose dependent, as other studies reported that under other conditions, norepinephrine or noradrenergic stimulation can also enhance memory retrieval (Sara and Devauges, 1989; Devauges and Sara, 1991; Barros et al., 2001; Murchison et al., 2004). Peripheral administration of the opioid peptidergic antagonist naloxone or D2, but not D1, dopamine receptor antagonists also block the impairing effect of concurrently administered corticosterone or dexamethasone on memory retrieval (Rashidy-Pour et al., 2004; Pakdel and Rashidy-Pour, 2006). Other studies have reported that memory retrieval is also influenced by systemic administration of drugs affecting several other modulatory systems, including epinephrine, adrenocorticotropin, β-endorphin, vasopressin, acetylcholine, and serotonin (e.g., Altman et al., 1987; Izquierdo et al., 2002; Sato et al., 2004). In investigating drug effects on learning and memory, including memory retrieval, it is critically important to distinguish the effects of the drugs on memory retrieval from those on other processes that may affect the behavior used to assess memory. Not all of the studies cited above adequately controlled for such performance effects.

Many studies have reported evidence indicating that the hippocampus is involved in memory retrieval (Hirsch, 1974; Squire et al., 2001). Inactivation of the hippocampus with local infusions of the glutamatergic AMPA/kainate receptor antagonist LY326325 or the GABAergic agonist muscimol impairs memory retrieval of water-maze spatial and contextual fear conditioning tasks (Holt and Maren, 1999; Riedel et al., 1999). As the GR agonist RU 28362 administered into the hippocampus shortly before retention testing also impairs retrieval of spatial memory (Roozendaal et al., 2003, 2004b), such findings indicate that glucocorticoid-induced memory retrieval impairment depends, in part, on GR activation in the hippocampus. Consistent with the findings of experiments of peripherally administered drugs, a β-adrenoceptor antagonist infused into the hippocampus prevents the retrieval-impairing effect of a GR agonist administered concurrently (Roozendaal et al., 2004b). Other studies have shown that the effect of novelty stress on memory retrieval is blocked by intrahippocampal infusions of the AMPA receptor antagonist CNQX and the metabotropic glutamate receptor antagonist MCPG, as well as the cAMP blocker Rp-cAMPs (Izquierdo et al., 2000). In contrast, infusions of the protein synthesis inhibitor anisomycin do not block corticosterone effects on memory retrieval (Sajadi et al., 2006), suggesting that stress and corticosterone may influence memory retrieval through a rapid, protein synthesis–independent mechanism.

Retrieval of memory of emotionally arousing information also induces activation of the BLA (Hall et al., 2001; Boujabit et al., 2003). Furthermore, intra-BLA infusions of norepinephrine or CNQX affect memory retrieval of inhibitory avoidance training (Liang et al., 1996; Barros et al., 2001). In contrast, intra-BLA infusions of a GR agonist do not appear to affect memory retrieval (Roozendaal et al., 2003). However, the BLA interacts with the hippocampus in mediating glucocorticoid effects on memory retrieval. Lesions of the BLA or infusions of a β-adrenoceptor antagonist into the BLA block the impairing effect of a GR agonist infused into the hippocampus on memory retrieval (Roozendaal et al., 2003, 2004b). These findings are thus consistent with those described earlier on memory consolidation (e.g., Roozendaal and McGaugh, 1997b; Roozendaal et al., 1999a) and indicate that the BLA regulates memory retrieval via interactions with other brain regions.

The findings of studies examining stress hormone effects on memory retrieval in humans are consistent with those of animal experiments and indicate that glucocorticoids impair memory retrieval via an interaction with noradrenergic mechanisms. Stress-level cortisol or cortisone administration to human subjects impairs delayed, but not immediate, recall on episodic tasks (de Quervain et al., 2000; Wolf et al., 2001; Buchanan and Adolphs, 2004; Buss et al., 2004; Het et al., 2005; Kuhlmann et al., 2005a,b, 2006), and the β-adrenoceptor antagonist propranolol given orally blocks the impairing effect of glucocorticoids on memory retrieval (de Quervain et al., 2007). Recent findings from an $H_2^{15}O$-PET study indicate that glucocorticoid effects on memory retrieval in human subjects are also mediated, at least in part, by actions in the hippocampus (de Quervain et al., 2003). However, other findings of human imaging studies indicate that the amygdala is also activated during the retrieval of previously learned emotionally arousing material and that the effect is independent of the valence of the emotional material (Dolan, 2000). Further, recent findings of human brain imaging studies are consistent with findings of animal studies in indicating that the amygdala and hippocampus interact during the retrieval of emotionally arousing information (Dolcos et al., 2005; Greenberg et al., 2005; Smith et al., 2006).

3.26.8.2 Working Memory

Evidence from lesion, pharmacological, imaging, and clinical studies indicates that working memory, a dynamic process whereby information is updated continuously, depends on the integrity of the medial prefrontal cortex (Brito et al., 1982; Fuster, 1991; Taylor et al., 1999; Rowe et al., 2000; Levy and Fallow, 2001; Stern et al., 2001; Lee and Kesner, 2003). Decrements in prefrontal cortical function are induced by local depletion of norepinephrine and dopamine, suggesting that these monoamines regulate prefrontal cortical function (Brozoski et al., 1979; Bubser and Schmidt, 1990; Cai et al., 1993). The importance of endogenous norepinephrine and dopamine stimulation in the medial prefrontal cortex is indicated by studies in which local infusion of either noradrenergic α_2 (Li et al., 1999) or dopaminergic D1 antagonists (Sawaguchi and Goldman-Rakic, 1991; Seamans et al., 1998) administered into the medial prefrontal cortex impairs performance on working memory tasks. In contrast, activation of α_2-adrenoceptors with guanfacine improves working memory functions in rats and monkeys. Together, these data suggest that norepinephrine and dopamine are necessary for optimal medial prefrontal cortical function.

Excessive levels of norepinephrine or dopamine, however, impair working memory. The impairing effects of high doses of norepinephrine are mediated by activation of the α_1- and β-adrenoceptor (Arnsten and Jentsch, 1997; Arnsten et al., 1999; Birnbaum et al., 1999; Ramos et al., 2005). In contrast, α_2-adrenoceptor activation enhances working memory (Taylor et al., 1999). Electrophysiological studies have shown increased medial prefrontal cortical activity in the delay period during which the information needs to be retained (Fuster, 1991). Adrenergic agents that enhance working memory increase this neuronal activity during the delay period, whereas adrenergic drugs that impair working memory decrease such neuronal activity (Li et al., 1999). Dopaminergic D1 receptor agonists influence working memory following an inverted-U-shaped dose–response relationship. Too little or too much D1 receptor stimulation impairs prefrontal cortical activity and working memory in mice, rats, and monkeys (Cai and Arnsten, 1997; Zahrt et al., 1997; Li et al., 1999; Lidow et al., 2003).

Working memory deficits are also observed following exposure to stress (Arnsten and Goldman-Rakic, 1998). Mild uncontrollable stress impairs performance on a delayed alternation task but does not impair performance on nonmnemonic control tasks that have similar motivational and motor demands (Murphy et al., 1996). Mild stress, such as noise or exposure to the predator odor TMT, increases norepinephrine and dopamine turnover in the medial prefrontal cortex (Finlay et al., 1995; Morrow et al., 2000). The medial prefrontal cortex response to stress is blocked by anxiolytic benzodiazepine drugs and mimicked by the anxiogenic benzodiazepine inverse agonist FG7142 (Tam and Roth, 1985; Murphy et al., 1996; Birnbaum et al., 1999). Also, like stress, glucocorticoid administration impairs working memory. Basal levels of endogenous glucocorticoids are required to maintain prefrontal cortical function (Mizoguchi et al., 2004), but systemic injections of stress doses of corticosterone or intramedial prefrontal cortical administration of the GR agonist RU 28362 impair working memory, as assessed by delayed alternation performance, in rats (Roozendaal et al., 2004c). Additionally, stress-level cortisol treatment impairs prefrontal cortex–dependent inhibitory control of behaviors in squirrel monkeys (Lyons et al., 2000), as well as working memory performance in human subjects (Lupien et al., 1999; Young et al., 1999; Wolf et al., 2001). Glucocorticoids appear to interact with noradrenergic mechanisms in inducing working memory impairment, as systemic administration of the β-adrenoceptor antagonist propranolol blocks the working memory impairment of corticosterone administered concurrently (Roozendaal et al., 2004c). Such findings suggest that corticosterone effects on working memory impairment may involve a facilitation of noradrenergic mechanisms in the medial prefrontal cortex. This hypothesis is supported by findings of an *in vivo* microdialysis study indicating that systemic administration of corticosterone increases levels of norepinephrine in the medial prefrontal cortex (Thomas et al., 1994).

Glucocorticoid-induced working memory impairment also depends on interactions of the medial prefrontal cortex with the BLA. As discussed earlier, the BLA both sends projections to and receives projections from the medial prefrontal cortex (McDonald, 1991; Perez-Jaranay and Vives, 1991; Rosenkranz and Grace, 2002). The BLA itself does not appear to play a significant role in working memory (Wan et al., 1994; Bianchin et al., 1999; Roozendaal et al., 2004c), but lesions of the BLA block the impairment induced by either systemic administration of corticosterone or infusions of a GR agonist into the medial prefrontal cortex (Roozendaal et al., 2004c) (**Figure 10**). These findings thus indicate that the BLA interacts with the medial prefrontal cortex in regulating stress hormone effects on working memory.

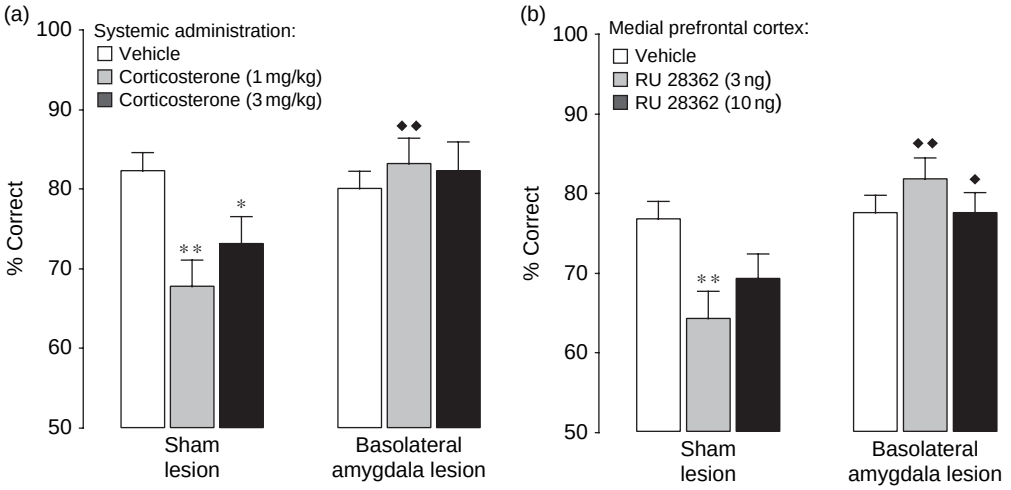

Figure 10 The basolateral amygdala interacts with the medial prefrontal cortex in mediating glucocorticoid effects on working memory. Systemic injections of corticosterone (1.0 or 3.0 mg/kg, ip) (a) or infusions of the specific glucocorticoid receptor agonist RU 28362 (3.0 or 10.0 ng in 0.5 μl) into the medial prefrontal cortex (b) impaired delayed alternation performance in sham-lesioned rats. Lesions of the basolateral amygdala blocked working memory impairment induced by either corticosterone or RU 28362. Results represent percent correct choices (mean + SEM). *, $p < .05$; **, $p < .01$ compared with the corresponding vehicle group; ◆, $p < .05$; ◆◆, $p < .01$ compared with the corresponding sham-lesion group. Neurosci.* 24: 1385–1392.

3.26.9 Concluding Comments

Research investigating memory modulation evolved from many sources. Key, of course, was Müller and Pilzecker's (1900) perseveration–consolidation hypothesis proposed over a century ago. The subsequent findings that treatments such as electroconvulsive shock administered after training induces retrograde amnesia (Duncan, 1949; McGaugh and Herz, 1972) provided critical evidence supporting that hypothesis. Those findings also suggested the possibility that posttraining treatments that stimulate brain activity might enhance memory consolidation. This implication was confirmed by evidence that posttraining administration of stimulant drugs enhances long-term memory (Breen and McGaugh, 1961; McGaugh, 1966, 1973). Livingston's (1967) hypothesis that activation of the limbic system might promote the storage of recently activated brain events, as well as Kety's (1972) proposal that adrenergic catecholamines released by emotional states may serve to influence consolidation, suggested physiological processes that might mediate the posttraining modulation of memory consolidation induced by stimulant drugs. Although the findings obtained in studies of memory modulation fit perhaps in a general way with these early ideas, there are many more parts to this memory modulatory system, and they interact in complex ways that were not anticipated. The early studies of adrenal stress hormone influences on memory consolidation (e.g., Gold and van Buskirk, 1975, 1976; McGaugh, 1989; McGaugh and Gold, 1989; Roozendaal, 2007) provided compelling evidence that peripheral hormones released by emotional arousals play an important role. The findings (e.g., Liang et al., 1986) suggesting that stress hormones as well as drugs affect memory by noradrenergic activation of the amygdala (i.e., the BLA) provided strong evidence suggesting that the BLA is an essential part of a memory-modulatory system. This suggestion has now been confirmed by the extensive findings that the BLA interacts with many other brain regions in modulating memory consolidation (McGaugh, 2000, 2002, 2004). The findings indicating that stress hormones modulate memory retrieval and working memory via noradrenergic influences and the BLA provide yet other chapter to the story of memory modulation (Roozendaal, 2002; Roozendaal et al., 2003, 2004a). Of course, our understanding of memory-modulatory systems is incomplete. Much more needs to be discovered about how the BLA interacts with other brain systems and how it acts to influence neuroplasticity in other brain regions involved in consolidating newly acquired information of many different kinds. But in the past several decades, research on memory modulation has made significant

progress in understanding how emotional arousal influences the consolidation and retrieval of significant experiences. Research findings have revealed at least some understanding of why it is, as William James (1890) noted, that emotional experiences may leave scars on the cerebral tissue.

3.27 Memory-Enhancing Drugs

P. E. Gold, University of Illinois at Urbana-Champaign, Champaign, IL, USA

3.27.1 Background

3.27.1.1 Introduction

The formation of new memories can be impaired in many ways, from lesioning brain regions to blocking neurotransmitter actions to interfering with activation of transcription factors. Thus, the ability to interfere with memory processing is readily demonstrated. Remarkably, there are also treatments that can enhance memory processing. Like studies that impair memory, evidence for enhancement of memory offers insights into possible mechanisms responsible for forming new memories. Development of drugs that enhance memory – cognitive enhancers, 'smart pills,' anti-aging drugs – also address a more romantic vision of ways to make us smarter and to keep us that way as we age. Descriptions of tests of drug enhancement of memory during aging will be included in the discussions of some of the drugs; a more complete and recent discussion of drug enhancement in aging and Alzheimer's disease can be found in Disterhoft and Oh (2006). The ability to enhance memory and other cognitive functions raises a host of ethical issues about whether and when we should use these treatments; these issues are also covered elsewhere (cf. Rose, 2002; Farah et al., 2004).

3.27.1.2 Early Studies of Drug Enhancement of Learning and Memory

Pharmacological treatments that produce amnesia receive much of the attention as tools with which to investigate the neurobiological bases of learning and memory. Many of these treatments impair memory when administered near the time of training. In particular, the findings that some treatments impair memory when given after training (i.e., the treatments produce retrograde amnesia) provide much of the evidence for memory consolidation, the view that memory formation takes time to reach completion.

There is also a significant literature showing that some drugs can enhance memory. What is perhaps the first demonstration that a drug could improve memory was provided about 90 years ago by Karl

Lashley (Lashley, 1917), who showed that injections of low doses of strychnine increased the rate of food-motivated maze learning. The current era of tests of drug enhancement of memory can be traced to McGaugh and Petrinovich (1959), who extended Lashley's findings and reported enhanced maze learning in rats that received strychnine 10 min prior to training on each of 5 days. Subsequent experiments showed that strychnine, and also pentylenetetrazol, enhanced memory in rats, mice, rabbits, and cats. Enhanced memory was evident for a wide range of tasks in addition to food-motivated mazes, including discrimination learning, avoidance learning, and classical conditioning (Kelemen and Bovet, 1961; McGaugh and Thomson, 1962; Hunt and Krivanek, 1966; Benevento and Kandel, 1967; Cholewiak et al., 1968).

3.27.1.3 The Posttraining Design

These early findings were very encouraging, but the designs of the experiments left open many interpretations of the effects beyond specific actions on learning and memory processing. For example, strychnine might alter exploration in a manner that fostered better learning (Whishaw and Cooper, 1970). This is just one of many performance variables – others include sensory acuity, motivation to find food, attention, and retrieval mechanisms – that could lead to more rapid learning by mechanisms other than effects on memory. Considerations such as these led to the use of an experimental design shared with studies of retrograde amnesia. These are demonstrations that treatments administered after training can retroactively impair or enhance memory (Duncan, 1949; McGaugh, 1966).

Retrograde effects on memory provide much of the support for studies of memory consolidation (McGaugh, 1966, 2000; Gold and McGaugh, 1975; Gold, 2006). In addition to addressing issues regarding memory consolidation, the use of the posttraining design is very important for distinguishing between drug enhancement of memory formation and modification of performance variables (Gold and McGaugh, 1978; Gold, 1986; McGaugh, 1989). With a posttraining design, all subjects – control and experimental alike – are trained in the absence of drug treatment. Because the drug is administered after training, there can be no differences in performance variables such as motivation or locomotor activity during training that can explain later improvements on tests of memory. The tests of memory are generally administered 24 h or more after training and drug treatment, at a time when the direct effects of the drug have dissipated. The additional demonstration of a retrograde enhancement gradient, in which the enhancement of memory decreases as the time between training and treatment increases, is an important procedure to ensure that the drug administered after training is not having residual effects on memory tests given later, typically 1 or more days after the training-treatment procedure. For example, consider findings that a drug enhances memory at 24 h after training if the drug is administered within a few minutes of training but not if administered 4 h later. Restated, the findings show that the drug-induced enhancement of memory is evident when the drug is administered 24 h before testing but not 20 h before testing. Findings such as these do not support interpretations of the enhanced memory as the result of lingering effects of the drug, but instead convincingly demonstrate the absence of a proactive effect on memory processing during testing.

3.27.1.4 Posttraining Drug Enhancement of Memory

The posttraining design has been used to great benefit in the era of drug enhancement of memory that began in the 1960s and continues now. McGaugh and colleagues led the studies that examined the efficacy of a wide range of drugs in enhancing memory for learning in many tasks in rodents (McGaugh, 1966, 1989, 2000). In most of these experiments, rats were trained daily and received the drug treatment at variable delays after training. The major overall findings were that (1) posttraining administration of any of several drugs could enhance memory, (2) the dose-response was an inverted-U or more complex function, and (3) the effects on memory decreased with time between training and testing. Most of the drugs found to enhance memory were stimulants, including strychnine, pentylenetetrazol, caffeine, and amphetamine, among others. There were also differences reported in the dose-response functions across rat and mouse strains, across ages, and across tasks. Some of these variables will be discussed again later in considering hormonal enhancement of memory. Of interest, memory enhancement was evident not only for appetitive and aversive tasks, but also for latent memory, for example, learning about a spatial maze on 'pretraining' trials administered without reward or punishment (McGaugh, 1989). In addition, the posttraining design has been used effectively in

demonstrating enhancement of memory in humans with drugs and other treatments (Parker et al., 1980; Manning et al., 1992; Soetens et al., 1993; Nielson et al., 1996; Bruce et al., 1999; Scholey and Fowles, 2002; Cahill and Alkire, 2003).

3.27.1.5 Memory Consolidation versus Memory Modulation

One of the striking features that came from studies of enhancement of memory with drugs, as well as impairments of memory with many treatments, was that the time courses of retrograde enhancement and retrograde amnesia were very different in different experimental conditions (Gold and McGaugh, 1975; Gold, 2006). Across amnestic treatments, retrograde amnesia and enhancement gradients might be as short as 500 ms or as long as weeks. The variability in the time windows during which memory is susceptible to modification has important implications for the goals of studies of memory consolidation, whether using treatments that enhance or impair memory. One of the key goals of memory consolidation experiments has been the identification of the time needed to form new memories, a time often based on the temporal properties obtained in retrograde amnesia or enhancement studies. One set of temporal properties comes from retrograde amnesia and enhancement gradients. Because these are highly variable, it is difficult to use any one temporal gradient to discuss the time needed for memory formation. A second set of temporal properties is often identified through amnesia studies that test the time after training to the onset of amnesia. These studies also yield a wide range of time parameters, from minutes to many hours (cf. Gold, 2006). Thus, it seems very difficult to fit these times, with poor temporal constraints, into a framework of memory consolidation, a practice nonetheless prevalent even today in investigations into cellular and molecular mechanisms of memory.

If memory consolidation studies do not yield a time constant for the formation of memory, then the issue is why do memories remain susceptible to modification during the time soon after training? It was thinking such as this that led to the development of an alternative way to think about drugs that enhance memory. Perhaps if retrograde amnesia and enhancement gradients do not reflect the time needed for memory formation, the gradients reflect the ability of some endogenous responses to experience to modulate later memory for that experience. Simply put, events that lead to high arousal, and particularly the neurochemical and hormonal consequences of the arousal, will modulate later memory (Gold and McGaugh, 1975; Gold, 1987; Cahill and McGaugh, 1998). And it is clear in many contexts that experiences with high arousal and affect are those best remembered.

The special role of postexperiential modulation of memory is well illustrated for learning about events that are unexpected and rather quick. Two examples are experiencing a near-accident while driving through an intersection or receiving a footshock when entering a dark compartment. In both instances, the neuroendocrine responses to the incidents largely come after, not before, the experience. The idea of modulation of memory is that the formation of new memories retains the capacity to be regulated by the ensuing neurobiological components of emotion and arousal. In general terms, the implication is that organismic responses that evolved to respond physiologically to potentially dangerous situations, including both endocrine and brain responses, were adopted by brain processes involved in the formation of memory as mechanisms through which to select from all experiences those that should be best remembered.

A major implication of this view is that memory for a mild experience will be made stronger by administration of treatments that activate some of the biological responses associated with emotion and arousal. In particular, this thinking predicts that treatments that activate or mimic hormonal and neurochemical functions related to emotion and arousal will enhance memory. As described next, these are precisely the results obtained in more recent studies that examine drugs aimed at hormones and neuromodulators.

3.27.2 Peripheral Factors

3.27.2.1 Epinephrine

Epinephrine is perhaps the hormone best studied and best understood as an enhancer of memory formation processes. In early experiments (Gold and van Buskirk, 1975), rats were trained in a one-trial inhibitory avoidance task using a footshock of low intensity. Soon after training, the rats received an injection of epinephrine. When tested for memory 24 h later, those rats that received the epinephrine had higher avoidance latencies (**Figure 1**, left graph). The effects were time-dependent; enhancement of memory decreased as the time after training increased. In addition, the

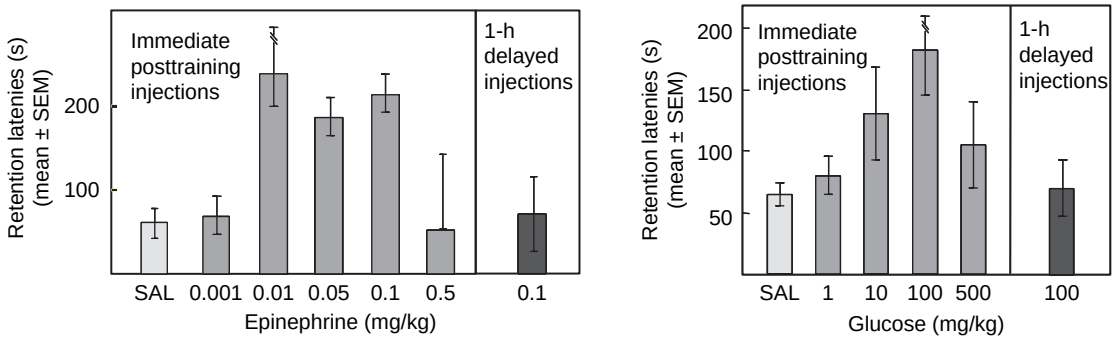

Figure 1 Dose-response function for epinephrine and glucose effects on memory in rats. Rats were trained in a one-trial inhibitory avoidance task; received injections of saline (SAL), epinephrine, or glucose immediately after training; and were tested 24 h later. Note the inverted-U dose-response curve for enhancement of memory seen on the test trial. Note also that injections of epinephrine or glucose 1 h after training did not significantly enhance memory on tests 24 h later. Left from Gold PE and van Buskirk RB (1975) Facilitation of time dependent memory processes with posttrial epinephrine injections. *Behav. Biol.* 13: 145–15; used with permission; right from Gold PE (1986) Glucose modulation of memory storage processing. *Behav. Neural Biol.* 45: 342–349; used with permission.

effects were dose-dependent, following an inverted-U dose-response curve. When circulating levels of epinephrine were measured after training and epinephrine injections, the findings indicated that the epinephrine dose optimal for enhancing memory resulted in peak circulating levels comparable to those seen after training with more intense footshock (Gold and McCarty, 1981; McCarty and Gold, 1981). Thus, epinephrine apparently mimicked an endogenous response to training, and the mimicry promoted the formation of new memory much as would a higher footshock level.

Later experiments showed that epinephrine, like strychnine and analeptics studied earlier, enhanced memory for a wide range of tasks, including not only avoidance tasks but also food- and water-motivated mazes, unrewarded spontaneous alternation measures of spatial working memory, and habituation and extinction (Gold, 1995). In humans, epinephrine enhances verbal memory for emotional information (Cahill and Alkire, 2003).

The proximal mechanisms by which epinephrine enhances memory have received considerable attention. Circulating epinephrine is largely excluded from the brain (Axelrod et al., 1959), indicating that it is likely that the hormone acts directly on peripheral targets in a manner that leads to regulation of brain functions. There are two main positions, which are not mutually exclusive, regarding the nature of the peripheral target. One position is that epinephrine acts on β-adrenergic receptors on the vagus nerve, with vagal afferents carrying to the brain information about the epinephrine signal (Williams and Clayton, 2003). The principal evidence for this view is that epinephrine effects on memory are blocked by inactivation of the vagus terminal field in the nucleus tractus solitarius (Clayton and Williams, 2000). Furthermore, posttraining vagal stimulation enhances memory in both rats and humans (Clark et al., 1998, 1999) and results in release of norepinephrine in the amygdala (Hassert et al., 2004). Together, the findings suggest that epinephrine may regulate brain memory processes via actions on vagal afferents. More direct tests (e.g., blockade of the effects of epinephrine on memory in vagotomized rats, neurophysiological measures of vagal activity, and neurochemical measures in the vagal terminal field, the nucleus tractus solitarius) have not yet been performed.

The effects of epinephrine on memory are also blocked by inactivation of the locus coeruleus or amygdala, as well as by blockade of β-adrenergic receptors in the amygdala, the latter presumably blocking central norepinephrine actions and not direct actions in the amygdala of circulating epinephrine. In addition, epinephrine injections result in release of central norepinephrine throughout the brain, including the amygdala (Gold and van Buskirk, 1978a,b; Williams et al., 1998). A second proximal mechanism proposed to mediate epinephrine enhancement of memory is based on a classic physiological response to epinephrine release from the adrenal medulla, an increase in blood glucose levels mediated in large part by liberation of hepatic glucose stores (McNay and Gold, 2002). These findings comprise the next section.

3.27.2.2 Glucose

Posttraining injections of glucose enhance memory in time- and dose-dependent manner similar to that of epinephrine (**Figure 1**, right graph). The dose-response function has an inverted-U form, with maximal enhancement of memory obtained at doses that lead to blood glucose levels similar to those attained after epinephrine doses that enhance memory (Gold, 1986; Hall and Gold, 1986). In addition, although enhancement of memory with epinephrine is blocked by peripheral coadministration of adrenergic receptor antagonists (Gold and van Buskirk, 1978b), enhancement of memory by glucose remains intact in the presence of adrenergic antagonists (Gold, 1986). In addition, modest food restriction, to deplete hepatic glucose stores, reduces the efficacy with which epinephrine but not glucose enhances memory (Talley et al., 2000); enhancement of memory with glucose is also intact after vagotomy (Talley et al., 2002) These findings suggest that increases in blood glucose levels subsequent to epinephrine release contribute importantly to the effects of the hormone on memory.

Like epinephrine, glucose enhances memory after training on a wide range of aversive tasks, including inhibitory avoidance (Gold, 1986; Kopf et al., 2001; Rashidy-Pour, 2001), conditioned emotional response (Messier and White, 1984), and swim (Oomura et al., 1993; Li et al., 1998) tasks. Although tests of glucose, like those of epinephrine, grew from considerations of stress and arousal responses and therefore initially involved aversive tasks, glucose also enhances memory for nonaversive tasks, including spatial memory in a radial arm maze and nonmatching to sample task (Winocur and Gagnon, 1998), spatial working memory in spontaneous alternation tasks (Ragozzino et al., 1996; McNay and Gold, 2002), operant bar pressing (Messier et al., 1990), and habituation of exploratory behavior (Kopf and Baratti, 1996). Moreover, glucose also enhances verbal memory in humans, including in healthy young adult and aged populations, as well as in individuals with Down syndrome and Alzheimer's disease (Manning et al., 1993; for reviews, see Korol, 2002; McNay and Gold, 2002; Messier, 2004; Gold, 2005). In individuals with Alzheimer's disease, the effects of glucose were particularly pronounced both in terms of percent improvement and breadth of cognitive domains (**Figure 2**). Of interest, the dose of glucose that enhances memory in humans results in increases in circulating levels comparable to those related to glucose and epinephrine enhancement of memory in rodents. The pervasive enhancement of memory by glucose across multiple classes of memory and species suggests that glucose may play a key role in regulating neural plasticities involved in the formation of memory in multiple neural systems. Because of this, the mechanisms by which glucose mediates its effects on memory are important for understanding basic properties of memory formation. In addition, development of drugs targeting these mechanisms has the potential to enhance memory in human populations, particularly those with cognitive dysfunctions.

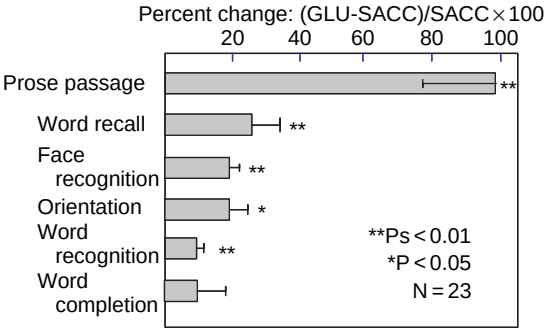

Figure 2 Glucose enhancement of cognitive functions in individuals with Alzheimer's disease. The patients were each tested on two occasions, once soon after ingesting a fruit drink sweetened with saccharin (SACC, control) and once after ingesting a fruit drink sweetened with glucose (GLU). On the glucose treatment day compared to the saccharin treatment day, the patients performed better when tested for memory of new information, on a narrative prose passage and word recall tests, as well as retrieval of old information included in the face recognition and orientation tests. From Manning CA, Ragozzino M, and Gold PE (1993) Glucose enhancement of memory in patients with Alzheimer's disease. *Neurobiol. Aging* 14: 523–528; used with permission.

In contrast to circulating epinephrine, which is excluded from the brain, glucose has ready access to brain targets via a facilitated transport system (Choeiri et al., 2005; McNay and Gold, 2002). The direct access to the brain opens the possibility that glucose effects on memory are a result of direct brain actions. Consistent with this possibility, microinjections of glucose into the lateral ventricles (Lee et al., 1988) or into any of several neural sites also enhance memory. For example, glucose injections into the medial septum (Ragozzino et al., 1995; Stefani and Gold, 1998; Talley et al, 1999), hippocampus (Ragozzino et al., 1998; Krebs and Parent, 2005), and amygdala (Ragozzino et al., 1994; Lennartz et al., 1996; McNay and Gold, 1998) all enhance memory for some tasks, presumably by upregulating the contributions of these systems to memory.

During the past decade, it has become clear that different brain systems are especially important for processing different attributes of memory (cf. White and McDonald, 2002; Poldrack and Packard, 2003; Gold, 2004; Korol, 2004). Consistent with this view, microinjections of glucose into different brain regions are generally effective at enhancing memory in those tasks typically associated with each memory system. The roles of multiple memory systems are, however, more complex than just separation of functions. In many instances, damage to or inactivation of one system can enhance learning associated with a different system. These demonstrations are taken as evidence that memory systems at times compete for control over learning and memory functions. If damage of a brain region can enhance learning and memory for a task best associated with another neural system, then enhancement of processing in one brain area might impair learning and memory for a noncanonical task. Like hippocampal damage or inactivation, glucose injections into the striatum impaired learning of a spatial task, suggesting that glucose upregulated striatal processing in a manner that interfered with hippocampal functions (Pych et al., 2006). Related to these issues, glucose injections into the hippocampus or striatum alter the preference for selection of place and response strategies (Canal et al., 2005) in a T-maze that can be solved using either strategy (Tolman et al., 1946; Packard and McGaugh, 1996).

These findings raise significant issues important for developing drugs to enhance learning and memory. If multiple memory systems compete with each other for control over learning, systemically administered drugs might enhance the memory processing of brain systems that are positively and negatively associated with learning the task. Yet, the findings suggest otherwise. As noted earlier, most drugs that enhance memory do so for a wide range of tasks. Assessments of fluxes in extracellular glucose levels during learning as well as measures of glucose effects on neurotransmitter functions offer clues that might reconcile this apparent paradox. Glucose levels in the brain appear to respond to training in a region specific manner. Specifically, extracellular glucose levels are depleted in the hippocampus but not the striatum when rats are engaged in a spatial working memory task (McNay et al., 2001). Systemic injections of glucose block that depletion but, in the absence of depletion, do not appear to increase extracellular glucose levels. Thus, there may be regional specificity that links delivery of glucose to those brain areas that are engaged by the task.

Similar relationships appear in examinations of release of acetylcholine in the hippocampus while rats are tested on a spatial working memory task and receive glucose to enhance memory. In this experiment (Ragozzino et al., 1996), glucose augmented the testing-related increase in release of acetylcholine in the hippocampus. Importantly, however, glucose did not lead to an increase in acetylcholine release in control animals resting in a holding cage. Thus, the neurochemical effects of glucose were restricted to conditions under which the brain area was activated. In showing that glucose delivery and neurochemical consequences were sensitive to cognitive functions, the findings suggest that other systemic drug treatments might similarly be amenable to functional targeting of action. This possibility has important implications for development of memory-enhancing drug treatments and needs more experimental investigation.

At a mechanistic level, one promising candidate for glucose effects on memory is that glucose may act by modulating the conductance of central adenosine triphosphate-sensitive potassium (K-ATP) channels. These channels are best characterized for their significant contribution to the resting baseline membrane potential of pancreatic β-cells and thereby regulate of insulin secretion (Ashcroft, 2005; Hansen, 2006). When blood glucose levels rise, intracellular ATP levels increase. The high ATP levels inhibit the K-ATP channels and depolarize the cells, activating voltage-sensitive Ca^{++} channels with an influx of Ca^{++} triggering release of insulin. Because of the significance of these channels to regulation of blood glucose levels, including in patients with diabetes, there is a relatively large repertoire of drugs aimed at these channels, particularly including drugs that act at a sulfonylurea regulatory subunit of the K-ATP channels to open and close the channels. K-ATP channel conductance is decreased by increases in intracellular ATP levels and by sulfonylurea-class drugs such as glibenclamide and is increased by decreases in intracellular ATP concentration and by drugs such as lemakalim.

Of potential interest to understanding glucose effects on brain function, K-ATP channels exist in the brain and are widely distributed (cf. Liss and Roeper, 2001). In the ventromedial hypothalamus, the channels appear to be important in regulating food intake, apparently sensing extracellular glucose levels in manner much like that seen in pancreatic β-cells. The wide brain distribution of the channels points to other functions as

well, in particular linking cellular excitability and metabolic states. With findings showing dynamic changes in extracellular glucose levels in the context of memory tests, fluctuations in extracellular glucose may modulate cell excitability. According to this view, decreases in K-ATP channel conductance would increase cellular sensitivity to depolarizing stimuli and increase the likelihood of stimulus-evoked neurotransmitter release, a possibility for which there is a good deal of evidence (e.g., Amoroso et al., 1990; Fellows et al., 1993; Panten et al., 1996). Additionally, there may be significant contributions of K-ATP channels to regulation of excessive glutamate release and subsequent excitotoxity after hypoxia and other brain insults, as well as involvement in neurodegenerative conditions like Alzheimer's disease and Parkinson's disease (Haddad and Jiang, 1994; Dirnagl et al., 1999; Yamada et al., 2001; cf. Liss and Roeper, 2001).

With respect to learning and memory, injections of glibenclamide, a drug that closes K-ATP channels, attenuated impairments of inhibitory (passive) avoidance memory produced by intraventricular injections of various K-ATP channel openers (Ghelardini et al., 1998). Several experiments have examined the effects on memory of direct brain injections of drugs that act at the K-ATP channel. The findings support the view that glucose may modulate learning and memory processes by acting on central K-ATP channels. Injections of glibenclamide into either the medial septum or the hippocampus result in enhanced memory (Stefani and Gold, 1998, 2001; Stefani et al., 1999). Conversely, injections of lemakalim or galanin, drugs that open the K-ATP channel, impair alternation performance; these impairments can be reversed by concomitant glucose administration (**Figure 3**). With systemic injections as well, drugs that open and close K-ATP channels block and potentiate, respectively, glucose enhancement of memory (Rashidy-Pour, 2001). Moreover, a recent paper suggests that the K-ATP channel blocker, glibenclamide, can override central nervous system deficits observed in humans under experimental hypoglycemia (Bingham et al., 2003). Subjects made hypoglycemic via glucose/insulin clamps exhibited impaired performance on a four-choice reaction time test. The impairments were reversed by pretreatment with glibenclamide. These findings add to the evidence that K-ATP channels may be a step subsequent to glucose actions in regulating brain and cognitive functions.

An elegant approach to understanding the mechanism by which glucose enhances memory is found in a recent paper that examined possible molecular pathways that might be regulated by glucose (Dash et al., 2006). The experiments examined possible glucose activation of the tuberous sclerosis complex-mammalian target of rapamycin (TSC-mTOR) pathway. The selection for investigation of the TSC-mTOR cascade was based on a convergence of signaling pathways important for mediating the effects of growth factors in promoting protein synthesis important for memory formation with the pathways involved in nutrient-mediated growth processes. Rats were weakly trained on the hidden platform version of the swim task. The rats received posttraining injections of glucose or of treatments that impair the TSC-mTOR pathway. The findings indicate that glucose activated the pathway and enhanced memory, whereas treatments that interfered with the pathway impaired memory (**Figure 4**). Moreover, glucose was unable to enhance memory in the presence of inhibition of the TSC-mTOR pathway. In addition to supporting a specific molecular basis for glucose enhancement of memory, this experiment also opens a new avenue of investigation in which drugs long known to enhance memory can be used to identify the molecular bases of memory formation. Moreover, the findings open the possibility of future drug development targeting, from a multitude of potential actions of glucose, to those cellular and molecular responses specifically related to memory formation.

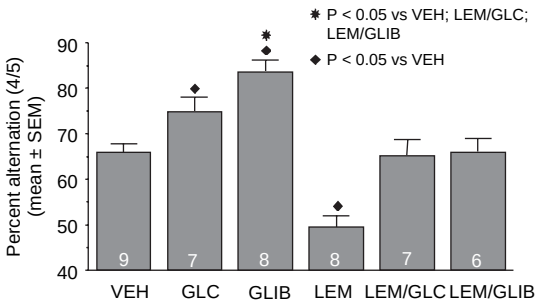

Figure 3 Effects of K^+-ATP channel modulators on memory in young rats. Drugs were injected into the hippocampus prior to spontaneous alternation testing on a 4-arm plus-shaped maze. Like glucose (GLC), the channel opening drug glibenclamide (GLIB) enhanced alternation scores, while the channel closing drug lemakalim (LEM) impaired alternation scores. Combination treatments were additive. VEH, vehicle. From Stefani MR and Gold PE (2001) Intra-hippocampal infusions of K-ATP channel modulators influence spontaneous alternation performance: Relationships to acetylcholine release in the hippocampus. *J. Neurosci.* 21: 609–614; used with permission.

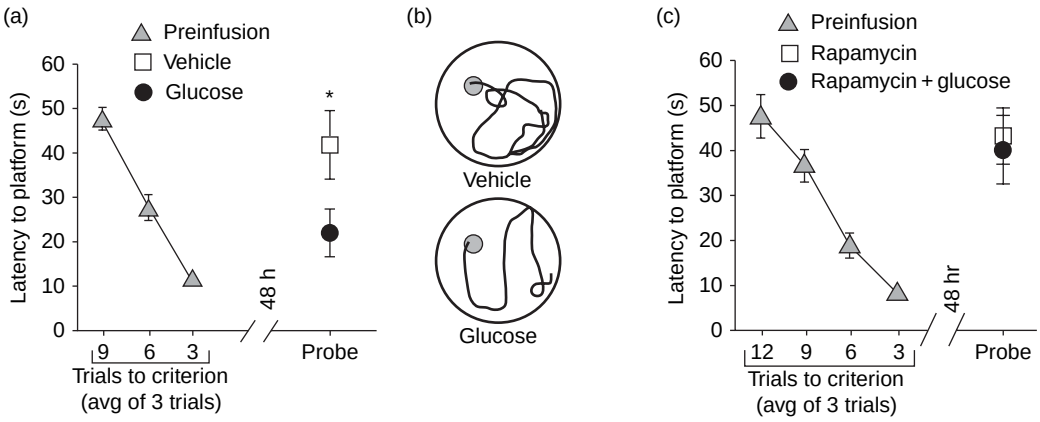

Figure 4 (a) Posttraining infusion of glucose augments long-term spatial memory. Animals were trained in the hidden platform version of the Morris water maze by using a soft criterion and then were infused with either vehicle ($n = 9$) or 20 μg/hippocampus glucose ($n = 10$). Training and probe trial performance (latency) are shown. (b) Representative probe trial traces of a vehicle-infused and a glucose-infused animal showing the path taken before the first platform crossing. Glucose-infused animals had a reduced mean distance traveled and an increased number of platform crossings when compared with vehicle-infused rats (not shown) (c) Posttraining administration of glucose did not enhance memory in the presence of the mTOR inhibitor rapamycin. Animals were infused with either 0.9 ng of rapamycin/hippocampus or 0.9 ng of rapamycin plus 20 μg of glucose/hippocampus. Error bars indicate SEM. From Dash PK, Orsi SA, and Moore AN (2006) Spatial memory formation and memory-enhancing effect of glucose involves activation of the tuberous sclerosis complex–mammalian target of rapamycin pathway. *J. Neurosci.* 26: 8048–8056; used with permission.

Pharmacological enhancement of memory by epinephrine and glucose has yielded interesting relationships with age-related impairments of memory (Gold, 2004, 2006). Aged rats and mice exhibit rapid forgetting across tasks, including inhibitory avoidance tasks. A hypothesis that decreases in release of epinephrine from the adrenals into blood during training might be diminished in aged rats was incorrect. Contrary to the hypothesis, epinephrine release after simple handling or after footshock was substantially greater in aged (2-year-old) rats than in young adult rats (Mabry et al., 1995a,c). Under conditions of greater stress such as immersion in cold water as in the swim task, aged rats produced extraordinarily high circulating levels of epinephrine as compared to young rats (Mabry et al., 1995b).

An explanation for the surprising result that aging was accompanied by increased rather than decreased release of a key memory-enhancing hormone comes from studies of differences in increases in blood glucose in young and old rats after stress. Aged rats exhibit increases in glucose levels that are absent at low levels of stress or doses of injected epinephrine and diminished at high levels of stress or epinephrine dose (Mabry et al., 1995a). Thus, the findings open the possibility that there is an impairment of the mechanisms by which epinephrine leads to glucose liberation from hepatic stores. Related to this view is evidence that glucose enhances memory in aged rats (McNay and Gold, 2001). Moreover, when engaged in a spatial working memory task sensitive to manipulations of the hippocampus, extracellular levels decline in both young and aged rats, but do so to much greater magnitude and duration in aged rats. Injections of glucose that enhance memory in aged rats block this considerable depletion of extracellular glucose levels in the hippocampus. Whether these endocrine, neurochemical, and behavior results are related to glucose effects on neurotransmitters like acetylcholine or are based on other actions of glucose requires additional attention.

3.27.2.3 ACTH and Glucocorticoids

In addition to enhancement of memory by epinephrine and glucose, there is extensive evidence showing that other humoral factors also enhance memory. A spate of papers in the 1970s and 1980s examined the effects of adrenocorticotropic hormone (ACTH) on memory (cf. de Wied, 1990). As with other drugs that enhance memory, ACTH did so with an inverted-U dose-response curve and in a retrograde time-dependent manner (Gold and van Buskirk, 1976). One of the most intriguing aspects of

that work was the identification of the site on the ACTH molecule most important for enhancing memory (de Wied, 1999). The 39 amino acids that comprise ACTH are cleaved from the precursor protein proopiomelanocortin. Most of the memory-enhancing properties were retained with the small peptide $ACTH_{4-9}$. Importantly, although the small peptides had effects on memory formation, they did not lead to the release of corticosterone from the adrenal cortex. Thus, the peptides had actions on memory that did not depend on the classic hormonal response to ACTH. Perhaps because of limitations on the analytical and pharmacological methods of the time, these studies were not continued in parallel with those of epinephrine and glucose.

Of more intense current interest is the contribution of glucocorticoids to memory formation. Although not necessary for the effects on memory of the small ACTH-based peptides, corticosterone itself also enhances memory for many tasks, with characteristics again including inverted-U dose-response curves and retrograde temporal gradients (cf., McEwen, 2001; Luine, 2002; Roozendaal, 2002; Wolf, 2003; Diamond et al., 2004; Sandi, 2004; Korol and Gold, 2007). The inverted-U dose-response curve may result from differential binding at low and high concentrations to mineralocorticoid and glucocorticoid receptors (Oitzl and de Kloet, 1992; Pavlides et al., 1996; Ahmed et al., 2006).

As is true for many modulators, the amygdala appears to be important for mediating the effects of corticosterone on memory (Roozendaal, 2002, 2003). Lesions of the stria terminalis or injections of β-adrenergic antagonists into the amygdala block the memory enhancement produced by systemic corticosterone administration.

Glucocorticoid enhancement of memory may be accomplished by interactions with norepinephrine modulation of memory. In particular, enhancement of memory after intra-amygdala injections of a glucocorticoid agonist was blocked by coadministration of either a β-adrenergic receptor antagonist or a protein kinase A inhibitor (Roozendaal et al., 2002). In the converse experiment, a glucocorticoid antagonist attenuated memory enhancement produced by a β-adrenergic receptor agonist, but not by an analog of adenosine 3′,5′-cyclic monophosphate (cAMP), a presumed downstream product of norepinephrine actions important for the enhancement of memory. Thus, the interaction of glucocorticoids and norepinephrine to enhance memory may come at a cell locus between norepinephrine activation of postsynaptic β-receptors and the initiation of a molecular cascade through cAMP. A schematic of possible interactions of glucocorticoids with neurotransmitters and cAMP is shown in **Figure 5**.

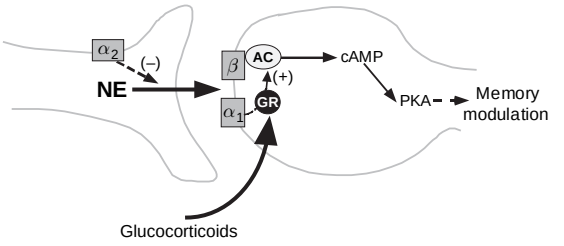

Figure 5 Schematic summarizing glucocorticoid effects on the β-adrenoceptor-AMP/protein kinase A (PKA) signaling pathway in the basolateral nucleus of the amygdala in influencing memory consolidation. Norepinephrine (NE) is released following training in aversively motivated tasks and binds to both β-adrenoceptors and α_1-adrenoceptors at postsynaptic sites. The β-adrenoceptor is coupled directly to adenylate cyclase to stimulate cAMP formation. The α_1-adrenoceptor modulates the response induced by β-adrenoceptor stimulation. Glucocorticoids may facilitate the β-adrenoceptor-cAMP system via a coupling with α_1-adrenoceptors. Other studies have demonstrated that cAMP may initiate a cascade of intracellular events involving activation of cAMP-dependent protein kinase (PKA). Our findings suggest that these effects in the basolateral amygdala are required for regulating memory consolidation in other brain regions. Abbreviations: α_1, α_1-adrenoceptor; α_2, α_2-adrenoceptor; AC, adenylate cyclase; β, β-adrenoceptor; GR, glucocorticoid receptor; cAMP, adenosine 3′,5′-cyclic monophosphate. From Roozendaal B, Quirarte GL, and McGaugh JL (2002) Glucocorticoids interact with the basolateral amygdala b-adrenoreceptor-cAMP/PKA system in influencing memory consolidation. *Eur. J. Neurosci*. 15: 553–560; used with permission.

3.27.2.4 Estrogen

Estrogen appears to act both to enhance memory and to regulate the cognitive strategy used to solve learning tasks (cf. Dohanich, 2002; Korol, 2004; Korol and Gold, 2007). Posttraining injections of estrogen enhance memory in rodents trained in the swim task (Packard and Teather, 1997a,b; Gresack and Frick, 2006), inhibitory and active avoidance tasks (Farr et al., 2000; Rhodes and Frye, 2006), and object recognition task (Gresack and Frick, 2006). Estrogen regulation of acetylcholine release at the time of training may contribute to the effects on memory (Marriott and Korol, 2003; Gibbs et al., 2004).

In contrast to other drugs noted earlier, estrogen appears to enhance learning and memory for some tasks and to impair learning and memory for others (Korol, 2004). The differences might be mediated by differential actions of estrogen on multiple memory systems (White and McDonald, 2002; Gold, 2004; Kesner and Rogers, 2004; White, 2004). Direct comparisons of estrogen effects across different versions of a food-motivated maze reveal that estrogen, administered for 2 days prior to training, enhances memory for hippocampus-sensitive place learning but impairs memory for striatum-sensitive response learning (**Figure 6**; Korol and Kolo, 2002). Estrogen status is also related to whether rats select place or response solutions to a T-maze that can be solved equally well using either strategy. Naturally cycling female rats preferentially exhibit place response at high estrogen and response strategies at low estrogen phases of their estrus cycle (Korol et al., 2004). Also, ovariectomized rats given estrogen choose place strategies, whereas those not given estrogen show response strategies. These findings suggest that estrogen can be viewed at once as a memory-enhancing and a memory-impairing treatment, depending on the specific task attributes. These differential effects seem likely to have their bases in actions of estrogen on different memory systems. Consistent with this view, estrogen administered directly to the hippocampus or striatum reveals enhanced memory for spatial tasks and for response tasks, respectively (Zurkovsky et al., 2007).

One aspect of the interest in estrogen and memory is that decreases in estrogen levels might lead to cognitive changes at the time of menopause. In addition to findings obtained in rodents, as earlier, support for this view came from several experiments that examined the effects of hormone replacement therapies on women, finding evidence for enhancement of memory in several experimental settings (for reviews see: Sherwin, 2006; Maki, 2006). In contrast, the findings of the large randomized controlled trials in the Women's Health Initiative Memory (WHIM) study failed to support the idea that hormone replacement therapy protected against cognitive decline in postmenopausal women (Espeland et al.,

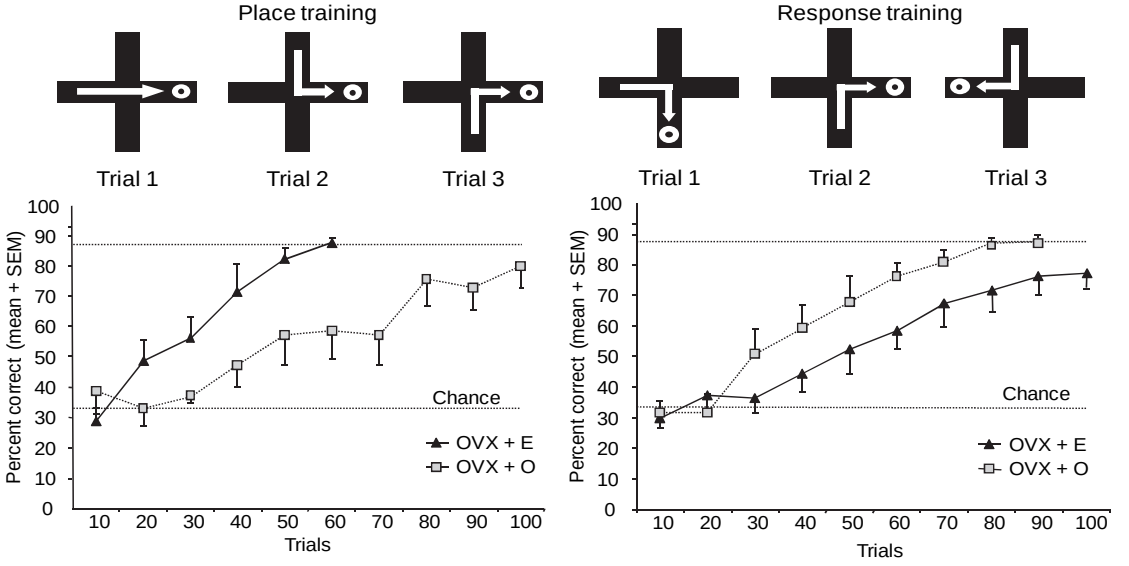

Figure 6 Effects of estrogen on maze learning in ovariectomized rats. Top figures show graphical representation of training protocols for place and response tasks in a plus-shaped maze. Place training required rats to locate food reward in an arm that maintained its position relative to the room cues throughout training. Start arms were randomly assigned across the other three arms. Response training required rats to locate food by making a right or left (not shown) turn. The goal arm was varied across training but maintained its position relative to the start arm with respect to the correct turn. Bottom graphs show learning curves, with trials groups into 10-trial blocks, in place and response versions of the maze for ovariectomized rats trained after treatment with oil (O) or estradiol (E). For place training, E-treated rats had steeper learning curves than did O-treated rats, suggesting faster learning. For response learning, E-treated rats were slower to acquire the task than were O-treated rats. Note that data reflect training until all rats reached criterion. OVX, ovariectomy. From Korol DL and Kolo LL (2002) Estrogen-induced changes in place and response learning in young adult female rats. *Behav. Neurosci.* 116: 411–420; used with permission.

2004; Shumaker et al., 2004). Of several variables, it appears that time since menopause before the start of a hormone regimen may be especially important. In the WHIM experiments, hormone therapy began in women at approximately 72 years of age, whereas those in smaller prior studies had tested women at or close to the time of menopause. This difference has led to suggestions that there is a time window after decline in ovarian function during which the hormones are most effective at enhancing cognition (Gibbs and Gabor, 2003; Maki, 2006; Sherwin, 2006). The time window has direct support in studies of both rodents and nonhuman primates (e.g., Lacreuse et al., 2002; Daniel et al., 2006). There is also evidence that fitness and exercise may interact with hormone treatments in postmenopausal women, augmenting the positive effects and blunting negative effects of the hormones on both brain and cognitive measures (Erickson et al., 2007).

3.27.3 Neurotransmitters

3.27.3.1 Overview

Drugs targeting many neurotransmitters can enhance memory. For most neurotransmitters, or at least for specific receptors, the effects on memory of agonists and antagonists oppose each other. For example, systemic and central administration of norepinephrine and glutamate receptor agonists enhances memory, whereas administration of their antagonists impairs memory; gamma-aminobutyric acid (GABA) and opioid agonists impair memory, and antagonists enhance memory. With central injections, intrahippocampal injections of many drugs with these targets of action similarly enhance and impair memory (Izquierdo et al., 1992; Packard, 1999; Farr et al., 2000; Roesler et al., 2003). Particularly when injected systemically, these effects are often additive (Gold, 1995). Combined subthreshold doses of two memory-enhancing drugs often enhance memory, and coadministration of a memory-enhancing and -impairing drug often cancels their respective effects on memory.

However, injections into specific brain regions are not always additive across drugs, suggesting hierarchical arrangements that cannot always be explained by simple interactions across neurochemical systems and instead suggesting serial processing, at least in part, of neurotransmitter functions in modulation of memory. Additivity might explain findings that intra-amygdala injections of clenbuterol (β-noradrenergic agonist) enhance memory and that the enhancement is blocked by atropine (muscarinic antagonist) (Introini-Collison et al., 1996); injections of cholinergic antagonists can themselves impair memory (Izquierdo et al., 1993). However, memory enhancement with the cholinergic muscarinic receptor agonist, oxotremorine, injected into the amygdala is not blocked by propranolol (Introini-Collison et al., 1996). Studies examining the interactions between neurotransmitter-related drugs have provided insights into the organization of neurochemical substrates of memory modulation (McGaugh et al., 1993; Gold, 1995; McIntyre et al., 2003b; Power et al., 2003), although the full nature of these interactions awaits further clarification.

Nonetheless, the general pharmacological picture seems quite clear, especially for systemically administered drugs. When administered near the time of training on many tasks, drugs that activate or mimic norepinephrine, acetylcholine, or glutamate enhance memory, and drugs that activate or mimic GABA or opioids impair memory. The converse examples exist for drugs that interfere with the functions of the respective neurochemical systems.

The roles of many of these neurotransmitter systems are often characterized in different manners. The roles of acetylcholine and norepinephrine are described in terms of modulating memory formation (Gold, 2003; Power et al., 2003; McIntyre et al., 2003b). In contrast, the role ascribed to glutamate is generally one of being intrinsic to memory formation, a direct component of the processes that make memories rather than of processes that regulate or modulate memory formation (Riedle et al., 2003). Drugs that act at the *N*-methyl-D-aspartate (NMDA) receptor for glutamate are thought to be permissive in enabling permanent changes in synaptic efficacy, as seen in several forms of long-term potentiation. However, some of these functions are modulatory in nature (i.e., amplifying the main tetanus- or experience-induced changes in synaptic efficacy). The designations of modulator and mediator become quite murky as the pharmacological evidence grows.

3.27.3.2 Acetylcholine

Research in the early 1980s provided evidence that postmortem examinations of the brains of individuals with Alzheimer's disease revealed dramatic loss of forebrain cholinergic markers (Bartus et al., 1982; Whitehouse et al., 1982; Coyle et al., 1983; Winkler

et al., 1998). These findings led to successful experiments in rats and mice revealing enhancement of memory and attention in young and aged rats and mice, as well as in rodent models of Alzheimer's disease, using drugs that augment cholinergic functions (Dutar et al., 1995; Everitt and Robbins, 1997; Iversen, 1998; Woolf, 1998; Disterhoft et al., 1999; Hasselmo, 1999; Sarter et al., 1999; van der Zee and Luiten, 1999; Sarter and Bruno, 2000). The promise of these agents led directly to the development of cholinesterase inhibitors that block the breakdown of acetylcholine to treat cognitive decline in Alzheimer's disease. Currently prescribed drugs include tacrine (Cognex), donepizil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl) (cf. Disterhoft and Oh, 2006).

The drugs most often tested include agents that augment cholinergic functions indirectly or by direct receptor actions. Many studies examine the effects of acetylcholinesterase inhibitors, such as physostigmine, on memory in rodents. By inhibiting the degradation of acetylcholine after it is released from terminals, physostigmine increases the local concentration and the duration of the neurochemical actions of acetylcholine. Acetylcholinesterase inhibitors enhance learning and memory in rodents for tasks including inhibitory avoidance (Riekkinen et al., 1991), place and object recognition (Lamirault et al., 2003), and discrimination training (Marighetto et al., 2000). Acetylcholinesterase inhibitors are also very effective at reversing the impairing effects on memory of many drugs and brain lesions that impair memory (cf. Iversen, 1998; Gold and Stone, 1988). Drugs acting at either muscarinic or nicotinic cholinergic receptors also enhance learning, memory, and neural plasticity in rats and mice in many contexts and support the view that the neurotransmitter has important functions in regulating memory processing (e.g., Power et al., 2003; Gold, 2004; Hasselmo, 2006; Levin et al., 2006).

Acetylcholine appears to have many functions relevant to enhancement of memory. Release of acetylcholine may contribute to the memory-enhancing effects of glucose (**Figure 7**). Although neither peripheral nor intrahippocampal injections of glucose themselves increase the release of acetylcholine in the hippocampus, the injections augment acetylcholine release in the hippocampus while rats are engaged in a hippocampus-sensitive task (Ragozzino et al., 1996, 1998). In general, the magnitude of the increase in release is associated with enhancement of memory by glucose.

Another function of acetylcholine may be to balance the relative contributions of different memory systems to memory (Gold, 2003), perhaps regulating

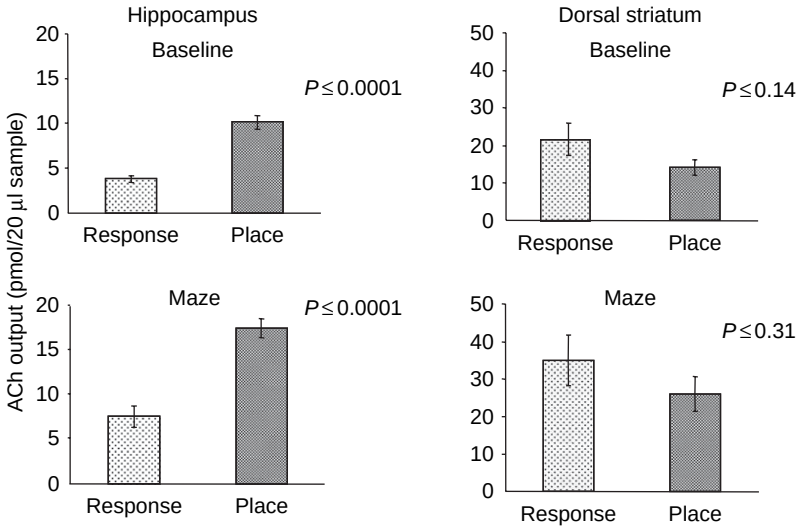

Figure 7 Acetylcholine (ACh) content in microdialysis samples collected concurrently from the hippocampus and dorsal striatum. Note the difference in *y*-axes for the two brain areas. Extracellular concentrations of ACh were greater in the striatum than in the hippocampus. Within the hippocampus, ACh release was significantly greater in rats that used a spatial strategy than in rats that used a response strategy. This was evident both prior to and during training. Although the scores were not significantly different at baseline or during training, the relationship between ACh release in the striatum of rats in the two groups was in the direction opposite that seen in the hippocampus. From McIntyre CK, Marriott LK, and Gold PE (2003a) Patterns of brain acetylcholine release predict individual differences in preferred learning strategies in rats. *Neurobiol. Learn. Mem.* 79: 177–183; used with permission.

the content of memory by modulating the level of activation of multiple memory systems. In one example, rats trained on a dual-solution T-maze solved equally well using either place (hippocampus-sensitive) or response (striatum-sensitive) solutions. The ratio of release of acetylcholine in the hippocampus versus dorsolateral striatum, measured just before training, predicted whether individual rats would show a preference for learning using a place or response solution (McIntyre et al., 2003a). These shifts may be related to evidence showing that acetylcholine shifts the cognitive function from attention at low levels of release to memory consolidation at higher levels of release (Hasselmo and McGaughy, 2004). These findings fit a broader context of evidence that acetylcholine regulates signal-to-noise ratios at the time of learning, regulates theta rhythms in the hippocampus, and modulates neuronal excitability (cf. Gold, 2003). More generally, the results suggest that acetylcholine enhances memory processing in multiple memory systems. By upregulating some systems more than others, the consequence would be that acetylcholine may alter the quality of memories as well as the strength of memories.

Acetylcholine also promotes neural plasticity assessed anatomically in the brains of honeybees (**Figure 8**; Ismail et al., 2006). New foragers exhibit substantial growth in the size of the mushroom body neuropil after extensive foraging experience. However, less experience is needed before neuropil growth is evident if a bee's foraging experience is coupled with administration of pilocarpine, a muscarinic agonist. Acetylcholine appears to promote neuroplasticity in somatosensory cortex (Dykes, 1997) and permit neurophysiological plasticity in auditory cortex during classical conditioning to tones (Weinberger, 2003, 2004).

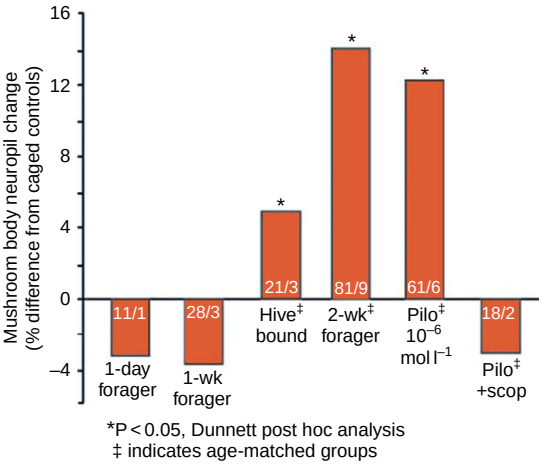

Figure 8 Effects of foraging experience with and without muscarinic agonist on the mushroom bodies. Estimates of the volume of the mushroom body neuropil were made for a total of 309 individuals, across nine experiments, conducted over three field seasons. To facilitate comparisons across all treatments, the % difference in neuropil volume relative to the caged control group in each experiment was calculated. Statistical analysis of these data used a mixed analysis of variance model ($F = 39.00$; $P < 0.0001$) and Dunnett *post hoc* tests (groups showing significant differences from the caged control group are indicated with the % difference). Key experimental groups are shown with the % difference indicated. Sample sizes are given in each bar (number of brains/number of trials). From Ismail N, Robinson GE, and Fahrbach SE (2006) Stimulation of muscarinic receptors mimics experience-dependent plasticity in the honey bee brain. *Proc. Natl. Acad. Sci. USA* 103: 207–211; used with permission.

3.27.3.3 Norepinephrine

Considerable evidence indicates that release of norepinephrine, particularly in the amygdala, may be a key brain component mediating enhancement of memory by a wide range of drugs (McIntyre et al., 2003; McGaugh, 2004). To some extent, interest in the role of norepinephrine in memory grew from the apparent involvement of the neurotransmitter in mediating the effects of epinephrine on memory. Indirect measures of norepinephrine release after epinephrine injections under conditions that enhance memory revealed release of norepinephrine throughout the brain (Gold and van Buskirk, 1978a,b); intermediate and high levels of release were associated with memory enhancement and impairment, respectively. More recent experiments, using *in vivo* microdialysis to study more directly release of norepinephrine, have found that peripheral epinephrine injections result in release of epinephrine within the amygdala (Williams et al., 1998). In addition, the magnitude of posttraining release of norepinephrine in the amygdala is positively correlated with later memory after inhibitory avoidance training. Posttraining injections of norepinephrine or β-adrenergic agonists directly into the amygdala enhance memory in an inverted-U dose-response manner (Liang et al., 1990; Hatfield and McGaugh, 1999).

The amygdala, and particularly the basolateral nucleus of the amygdala, may be a central mediator of many memory-enhancing treatments. For example, interference with noradrenergic functions in the amygdala, by lesions or by injections of β-adrenergic

antagonists such as propranolol, block enhancement of memory by epinephrine, corticosterone, and GABA and opioid antagonists (McGaugh et al., 1988; Introini-Collison et al., 1989; Roozendaal et al., 1999). Moreover, there are considerable interactions between norepinephrine and acetylcholine within the amygdala. Often, the effects of cholinergic drugs on memory are not blocked by interference with β-noradrenergic receptors, in contrast to interactions of the β-noradrenergic receptors with other memory-enhancing treatments, results suggesting convergence of cholinergic and noradrenergic mechanisms within the amygdala to enhance memory (cf. McIntyre et al., 2003b).

Thus, neurochemical mechanisms in the amygdala may be a core mechanism common to the enhancement of memory with a wide range of treatments. Identifying the neurochemical bases of these effects may offer a plan for rational development of therapeutic agents targeted directly at mechanisms underlying memory enhancement by many treatments.

3.27.3.4 Glutamate

As the major excitatory neurotransmitter in the brain, it is not surprising that drugs that interfere with glutamate functions impair memory formation (cf. Riedel et al., 2003, for comprehensive review). A focus on memory-enhancing glutamatergic drugs yields far fewer examples, although there is clear evidence that glutamate itself enhances memory when injected directly into memory systems important for the learning task. Glutamate injections directly into the amygdala, administered immediately after presentation of a weak taste as the conditioned stimulus, enhance acquisition of a conditioned taste aversion to that taste (Miranda et al., 2002). In the same experiment, the investigators found that presentation of an unconditioned stimulus, lithium chloride, resulted in large increases in glutamate release measured with *in vivo* microdialysis. Other examples of glutamate enhancement of memory include enhancement of inhibitory avoidance training with posttraining injections of glutamate into the locus coeruleus (Clayton and Williams, 2000). Because the locus coeruleus is the site of cell bodies of neurons that distribute norepinephrine to the forebrain, the enhancement may be mediated by norepinephrine release at sites distal to the site of injection. Glutamate may also enhance memory processing at sites proximal to the injection. Using a dual-solution maze in which a rat could find food reward using either place or response solutions, glutamate infusions into the hippocampus or striatum differentially enhance place and response learning assessed on later probe trials (Packard, 1999).

Glutamate acts at several receptors with quite different functions, including both ligand-gated ion channels (ionotropic receptors) and G-protein-coupled (metabotropic) receptors. One receptor that has received attention is the metabotropic glutamate receptor subtype 5 (Simonyi et al., 2005). Posttraining injections of a drug, 3,3′-difluorobenzaldezine, that enhances these receptors facilitate later memory for spatial memory (Balschun et al., 2006). There is also evidence that ampakines, drugs that enhance alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptors, enhance learning and long-term potentiation (Lynch, 2006). AMPA receptors are responsible for fast excitatory neurotransmission mediated by glutamate, and the receptor modulation may reflect general increases in neural excitability as a mechanism of action. Enhancement of memory in a delayed matching to sample task has been seen in sleep-deprived monkeys (Porrino et al., 2005), although studies using post-training designs and unimpaired versus impaired memory have not been assessed. Of interest, parallel brain imaging studies show that the ampakines led to normalization of changes in metabolic activity in those brain areas where alterations were seen after sleep deprivation and not in other areas. These findings are reminiscent of the effects, described earlier, of glucose on acetylcholine release in the hippocampus when rats were engaged in training but not when rats were at rest (Ragozzino et al., 1996). The situational selectivity of such drug effects deserves considerable attention in developing drugs effective in enhancing multiple forms of memory.

3.27.4 Intracellular Factors

3.27.4.1 Calcium Channel Blockers

Considerable evidence suggests that dysfunctions of calcium regulation can impair memory and that such dysfunctions might contribute to those impairments during aging (cf. Disterhoft et al., 1996, 2004; Foster and Kumar, 2002; Foster, 2006). Disterhoft and colleagues have provided extensive evidence suggesting that drugs that attenuate age-related increases in

calcium during activation of hippocampal (CA1) pyramidal neurons can enhance learning and memory in aged rabbits and rats. The task involves following the presentation of a tone with an air puff to the cornea, after a short delay, to establish an eyeblink classical conditioning response. Acquisition of this learned response is slowed or absent in aged rabbits and rats. Neurophysiological recordings from CA1 neurons reveal that there are age-related increases in the afterhyperpolarization (AHP) evident after a burst of action potentials. The AHP is characterized by an outward potassium current mediated by an influx of calcium that occurs with the action potential and serves to limit additional action potentials during its occurrence.

Of particular relevance to aging and memory, the AHPs are greatly enhanced in hippocampal pyramidal neurons of aged versus young animals, suggesting that the pyramidal neurons are less excitable and, perhaps, less able to participate in or to initiate mechanisms of learning and memory. Administration of nimodipine, an L-type calcium channel antagonist, reversed the age-related impairments in conditioning and in the AHPs (Deyo, et al., 1989; Disterhoft et al., 1996; cf. Disterhoft et al., 2004). Of additional interest, drugs that augment cholinergic functions, including cholinesterase inhibitors and muscarinic receptor agonists, also enhanced learning and memory in this system and attenuated the AHP in aged animals (cf. Disterhoft and Oh, 2006). Findings such as these offer an excellent opportunity to address the mechanisms in common across treatment domains.

3.27.4.2 Intracellular Molecular Targets

As discussed earlier, considerable evidence quite consistently identifies classes of drugs, particularly those acting on specific neurotransmitters and receptors, that enhance memory. However, the cellular mechanisms by which the drugs act are less clear. Also unclear is whether deeper understanding of the most effective drugs to enhance memory will come from more specific identification of neurotransmitter receptors that mediate enhancement of memory, from examinations of combination drug protocols that act on multiple receptors (e.g., memory enhancing drug cocktails) or from drugs that act on putative intracellular mechanisms that might mediate memory enhancement by one or several neurotransmitters.

Of possible intracellular mechanisms that might contribute to enhancement of memory, cAMP response element-binding protein (CREB) has received considerable attention as an important regulator of memory formation (Silva et al., 1998; Izquierdo et al., 2002; Barco et al., 2003; Tully et al., 2003; Carlezon et al., 2005; Josselyn and Nguyen, 2005). In particular, CREB is often thought to facilitate the conversion of early to late stages of memory. Phosphorylation of CREB is correlated with memory formation (Izquierdo et al., 2002), and interference with CREB functions impairs memory formation (Guzowski and McGaugh, 1997). Although there have been significant attempts to identify pharmacological agents that might enhance CREB functions and thereby enhance memory (Barco et al., 2003; Tully et al., 2003), explicit tests of such drugs are not yet readily found. Also missing, for CREB as well as for many other putative components of the molecular biology of memory formation, are tests of whether these factors are the mediators of enhancement of memory by neurotransmitter actions or whether the factors elicit changes in neurotransmission related to modulation of memory. It seems unlikely that CREB is essential for memory. Epinephrine enhances memory in CREB-knockout mice (Frankland et al., 2004), and memory seems normalized by spaced versus massed training trials (Kogan et al., 1997). These findings suggest that activation of CREB is not necessary for memory formation or for modulation of memory, though it may be a step that precedes or interacts with the mechanisms by which systemic epinephrine injections modulate memory.

The absence of more information examining interrelationships between intracellular molecules implicated in memory processing and memory-enhancing treatments appears to be based on two elements. First, molecular cascades important to memory have primarily been identified with drugs that block specific components of these cascades. Complementary drugs that activate these cascades often do not exist or have not received sufficient attention in this regard. Second, the paucity of studies examining molecular cascades in memory enhancement may reflect the presumption in such studies that investigations are examining the mechanisms of memory formation rather than the mechanisms that modulate memory formation. At this point, either modulation or mechanism of memory formation seems to provide a plausible explanation of the findings obtained with studies of molecular cascades of memory, though the view that

the molecules make new memories is dominant in research efforts.

A recent study explicitly related memory enhancement to an intracellular molecular target (McIntyre et al., 2005). Memory-enhancing injections of clenbuterol, a β-adrenergic agonist, were administered immediately after inhibitory avoidance training. Consistent with past findings, the treatment enhanced later memory. This treatment also resulted in increased expression of Arc protein. Arc is localized to dendritic regions near points of synaptic stimulation and appears to be associated with synaptic plasticity and memory (Guzowski et al., 2005). This is an early study in what promises to be a very useful approach of coupling memory-enhancing treatments to gene and protein responses important for the enhancement of memory.

3.27.5 Conclusions

Even over 50 years after the main demonstrations that drugs can enhance memory, the findings still seem quite remarkable in several respects. Although it is rather easy to imagine that interference with neural activity can impair memory, it is more surprising, at least to this writer, that drug perturbation of neural activity can also improve memory formation. Many of the drugs that enhance memory are related to neurotransmitters. For example, amphetamine augments catecholamine functions by blocking reuptake mechanisms. β-adrenergic, nicotinic, and glutamatergic receptor agonists act largely on postsynaptic receptors to mimic the action of the neurotransmitters norepinephrine, acetylcholine and glutamate, respectively. Although these neurotransmitters all appear to have a positive role in memory formation, the drugs that mimic them do not match the temporal and spatial patterning that appears to be a key element of neural processing generally, and in the formation of memory in particular. The apparent illogic may be addressed by findings that many neurotransmitters, notably including norepinephrine, acetylcholine, glutamate, and others, may have important extrasynaptic functions with release sites for neurotransmitters that are not always associated with close postsynaptic appositions (Descarries and Mechawar, 2000; Bach-y-rita, 2001; Descarries et al., 2004; Carmignoto and Fellin, 2006; Vizi and Mike, 2006). Findings such as these suggest that the temporal and spatial properties of neural activity may not apply to all neurotransmitters in all brain areas and may instead function much like local hormones, changing the functional state of the areas they bathe. One of those functional states may be readiness to alter connectivity in response to information flow, a function consistent with the idea of modulation of memory. Another explanation is based on the neurophysiological responses to some neurotransmitters involved in enhancement of memory. An example here is that the iontophoretic application of low levels of norepinephrine, serotonin, or acetylcholine can enhance both the postsynaptic excitation and inhibition produced by glutamate and GABA, respectively. In this way, the neuromodulators may enhance the impact of information flowing through traditional synapses, augmenting the signal-to-noise ratio and thereby enhancing memory formation.

It is also possible to move beyond these system-level views of how memory-enhancing drugs might work to the cellular and molecular bases by which they work. Mechanisms at this level might be the consequence of receptor binding leading to biochemical cascades important to memory or might be, similarly but less directly, the consequence of amplification of signals handled by other neurotransmitters, as discussed earlier. In contrast to the investigations of drugs that impair memory, far less attention has been given to the cellular and molecular bases by which well-studied drugs enhance memory. This is a research area ripe for future investigations.

3.28 Episodic Memory Decline and Healthy Aging

S. Daselaar and R. Cabeza, Duke University, Durham, NC, USA

Aging is accompanied by continuing degradation of the anatomy and function of our brain. While our brain shrinks and its functions decline, cognitive processes also slow down and begin to falter. Among the most prevalent cognitive problems in older adults are deficits in memory function. Difficulties in learning and memory can be found to a certain degree in all older adults. Understanding age-associated memory decline is important for two reasons. First, in view of the mounting number of older adults in today's society, cognitive aging is increasingly becoming a problem in our health care system, and therapeutic intervention methods can only be developed on the basis of knowledge obtained through basic research. Second, there is a subgroup of elderly whose memory impairments are more severe, preventing normal functioning in their environment. In these persons, such impairments can be the earliest manifestation of pathological age-related conditions, such as Alzheimer's disease (AD). Particularly in the early stages of this disease, the differentiation from normal age-related memory impairments is very difficult. Thus, it is important to delineate which memory impairments can be regarded as correlates of normal aging and which impairments are associated with age-related pathology.

One type of memory that is particularly affected by the aging process is our memory for personally experienced past events, or episodic memory (EM) (Tulving, 1983; Gabrieli, 1998). Clinical studies have shown that EM is primarily dependent on the integrity of the medial temporal lobe (MTL) memory system

(Milner, 1972; Squire et al., 2001). However, the prefrontal cortex (PFC) also plays an important role in EM (Stuss and Alexander, 2000; Fletcher and Henson, 2001; Maril et al., 2003). As a result of increased accessibility of brain imaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), aging research has now started to focus on the relationship between age-related changes in memory performance and changes in brain function. Functional neuroimaging (PET and fMRI) provides an ideal method to study patterns of neurocognitive decline, because changes in brain activity can be directly related to the effects of aging on behavioral measures, providing a link between cerebral aging and cognitive aging. One popular neurocognitive view is that the decline in EM associated with healthy aging results from a selective deterioration of PFC regions, whereas degradation of other brain regions, such as the MTL, is a hallmark of pathological age-related conditions (West, 1996; Buckner, 2004; Hedden and Gabrieli, 2004). However, there is now substantial evidence that MTL decline contributes to EM deficits in healthy older adults, and hence, it is no longer possible to attribute these deficits exclusively to PFC decline. In this chapter, we review recent PET and fMRI studies of healthy aging and EM with a focus on age-related changes in PFC and MTL regions.

In relation to these findings, we address two major factors thought to underlie age-related memory decline and strongly linked to PFC and MTL function, namely, deficits in executive function and deficits in binding processes. The term 'executive function' describes a set of cognitive abilities that control and regulate other abilities and behaviors. With respect to EM, executive functions are necessary to keep information available online so that it can be encoded in, or retrieved from, EM. The PFC is generally thought to be the key brain region underlying executive functions (Miller and Cohen, 2001). Binding refers to our capacity to bind into one coherent representation the individual elements that together make up an episode in memory, such as sensory inputs, thoughts, and emotions. According to relational memory theory, different subregions of MTL are differentially involved in memory for relations between items and memory for individual items (Cohen and Eichenbaum, 1993; Eichenbaum et al., 1994). In particular, the hippocampal formation is more involved in binding or relational memory operations, whereas the surrounding parahippocampal cortex is more involved in individual item memory.

This chapter has four main sections. In the first section, we begin with a brief overview of behavioral evidence indicating how EM performance changes as we age. In the second section, we discuss the anatomical and physiological changes in MTL and PFC that accompany the aging process. In the third section, we focus on functional neuroimaging studies of EM that reveal age-related changes in MTL and/or PFC regions. In the final section, we discuss different interpretations of age-related memory decline that have emerged from these findings, and how they relate to deficits in executive function and binding capacity.

3.28.1 Effects of Aging on Memory Performance: Executive Functions Versus Binding Deficits

Age-related deficits in EM may reflect difficulties during the formation of new episodic memory traces (encoding) and/or during the recovery of stored memory traces (retrieval). Two main theories of cognitive aging have been put forward to account for age-related deficits in EM encoding and retrieval. According to the resource deficit hypothesis (Craik, 1986), age-related cognitive impairments, including EM deficits, are the result of a general reduction in attentional resources. As a result, older adults have greater difficulties with cognitive tasks that provide less environmental support and, hence, require greater self-initiated processing. According to the binding deficit hypothesis (Johnson et al., 1993; Naveh-Benjamin, 2000), older adults are impaired in forming and remembering associations between individual items and between items and their context. As a result, age-related EM impairments are more pronounced on tasks that require binding between study items. In separate sections below, we discuss some examples of behavioral studies of encoding, retrieval, and aging in relation to these two theories of cognitive aging. Within each of these sections, we group studies according to whether they manipulated factors affecting mainly encoding or retrieval. However, it is important to keep in mind that behavioral studies cannot make a clear distinction between these two phases of episodic memory.

3.28.1.1 Resource Deficit Hypothesis

3.28.1.1.1 Encoding

In terms of encoding, the resource deficit hypothesis is supported by evidence that age-related deficits are

most pronounced when there is little environmental support to help encoding. For instance, age-related differences tend to be larger when young and older adults intentionally try to encode a list of study items than when a deep semantic processing task is used to guide encoding (Craik and Simon, 1980; Burke and Light, 1981). As an example, in a recent study (Troyer et al., 2006), older adults showed significantly impaired recognition memory performance following intentional encoding of a list of proper names, but they performed equally well as young adults when encoding was incidental and involved making semantic associations to the names.

Likewise, age differences in encoding can be reduced by providing additional semantic context with the study items. For example, in one study (Craik et al., 1987), young and older adults encoded a list of words either with or without a short descriptive phrase. Age-related deficits were much smaller when the encoded words were accompanied by the descriptive phrases. Also, age-related deficits in encoding become greater when there is no apparent link between the elements. Smith et al. (1998) found that older adults' difficulties in recalling associations between two pictures were attenuated when the two pictures were linked by preexistent relationships. The authors interpreted these findings in terms of age-related differences in self-initiated processing.

3.28.1.1.2 Retrieval

Similar to encoding, retrieval studies of aging have shown that age-related deficits in retrieval become larger on tasks that put a greater demand on executive function. Older adults experience more difficulties on recall and context memory tasks, which are more dependent on self-initiated search processes, than on recognition tasks, in which candidate targets are provided by the experimenter and the participant only needs to decide whether or not they were part of the study list (Rabinowitz, 1984; Rabinowitz and Craik, 1986; Craik and McDowd, 1987). For example, in a study by Craik and McDowd, young and older adults performed cued recall and recognition tasks, both of which also included a secondary reaction time task. As expected, older adults performed less well than the young adults on the recall task, but not on the recognition task (see **Figure 1**). Moreover, relative to recognition, older adults were much more impaired during recall on the secondary task than were the young adults. These findings are in line with the idea that recall requires more resources than

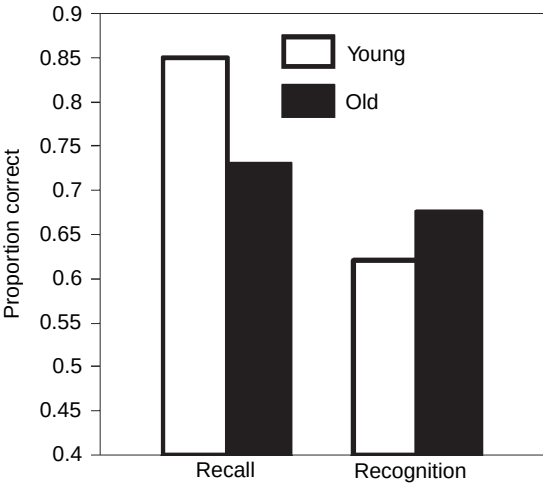

Figure 1 Reduced memory performance in older adults compared with young adults during cued recall, but not during recognition. Adapted from Craik FIM and McDowd JM (1987) Age differences in recall and recognition. *J. Exp. Psychol. Learn. Mem. Cogn.* 13: 474–479.

recognition and that these resources are reduced in older adults.

One explanation for the greater age-related decline in recall than in recognition is that older adults do not spontaneously produce retrieval cues to guide the search process. In line with this idea, several studies have found that age-related deficits are reduced when cues are provided (Park and Shaw, 1992; Naveh-Benjamin and Craik, 1995). For example, age differences in EM become smaller when the encoding context is reinstated during retrieval. In a study by Naveh-Benjamin and Craik, young and older adults encoded words that were either shown in one of two different fonts or spoken by a female or a male voice. Age differences in recognition performance were much smaller when the font or voice was reinstated during recognition. In other words, older adults benefit when provided with environmental support at retrieval.

3.28.1.2 Binding Deficit Hypothesis

3.28.1.2.1 Encoding

In addition to deficits in self-initiated processing, several studies have shown that older adults consistently exhibit age-related deficits in encoding tasks that require binding different pieces of information together, even when memory for individual features is intact (Schacter et al., 1994; Chalfonte and Johnson, 1996; Mitchell et al., 2000b; Naveh-Benjamin, 2000). Chalfonte and Johnson (1996) tested age-related differences in encoding of

both color and item information across three experiments. While no effect of age was found for individual features, older adults exhibited significant deficits in recognition for combined features compared with younger adults. Furthermore, age-related differences in memory for bound features persisted across various encoding instructions. Similar results were reported by Mitchell et al. (2000b), who also interpreted results as an age-related deficit in binding features in memory.

Recent studies have indicated that this associative deficit is not limited to arbitrary associations (e.g., word–color, item–location) but is also found in more ecologically valid pairings (Naveh-Benjamin, 2000; Naveh-Benjamin et al., 2004). For instance, in a study by Naveh-Benjamin and colleagues (2004), young and older adults studied a list of face–name pairs. Memory for individual faces and names was tested using forced-choice recognition tests in which the faces and names were paired with other names and faces not seen at study. Associative memory for the face–name pairs was tested in a separate test that included only studied faces and names. Participants paired a face or name with the corresponding name or face shown at study by choosing from two alternatives. Although older adults performed similarly to the young adults on individual face and name recognition, they were considerably impaired on the associative recognition test. These age-related differences persisted even when the young adults encoded information under divided attention (see **Figure 2**). These results indicate that binding deficits in older adults cannot be explained solely by a reduction in attentional resources. Thus, available evidence suggests that, even though older adults show deficits in general memory performance, this deficit is greater for associative tasks.

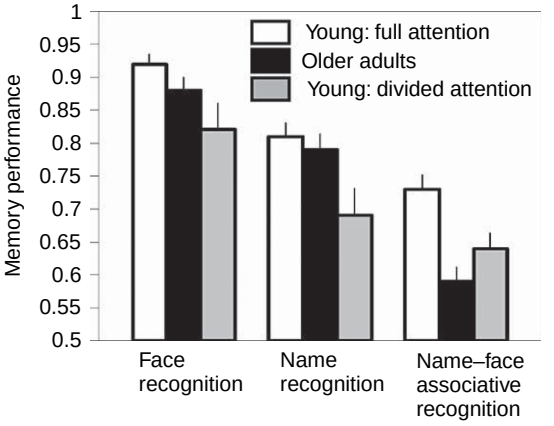

Figure 2 Reduced memory performance in older adults compared with young adults during associative recognition, but not during recognition of single faces and names; binding deficits in older adults cannot be explained solely by a reduction in attentional resources. Adapted from Naveh-Benjamin M, Guez J, and Shulman S (2004) Older adults' associative deficit in episodic memory: Assessing the role of decline in attentional resources. *Psychon. Bull. Rev.* 11: 1067–1073.

3.28.1.2.2 Retrieval

Age-related associative deficits are present during retrieval as well. According to dual-process models, recognition memory can be based on the recovery of specific contextual details (recollection) or on the mere feeling that an event is old or new in the absence of confirmatory contextual information (familiarity). Older adults are more impaired in recollection than in familiarity, which has been demonstrated using the Remember/Know (R/K) paradigm (Parkin and Walter, 1992; Mantyla, 1993; Java, 1996; Davidson and Glisky, 2002; Bastin and Van der Linden, 2003), ROC curves (Howard et al., 2006), and the process-dissociation procedure (Jennings and Jacoby, 1993). For example, Parkin and Walter (1992) used the R/K paradigm in which participants indicate whether their recognition judgment was based on recollection (R) or familiarity (K). They found that older adults made fewer R responses and more K responses than younger adults. Given that recollection involves the retrieval of associations between core and contextual elements of an episode, this evidence is consistent with the view that binding deficits are an important factor in age-related EM decline (Naveh-Benjamin, 2000).

In line with the aforementioned deficits in recollection, older adults are also less accurate in recalling information associated with the context in which an item was encoded, including the color, case, or font of words (Park and Puglisi, 1985); modality of presentation (e.g., auditory or visual) (Light et al., 1992); and speaker gender (Kausler and Puckett, 1981). For example, when given a list of made-up facts (e.g., Bob Hope's father was a fireman) and tested on them 1 week later, both younger and older adults could successfully recall the items, but older adults were impaired at knowing where they had first learned the information (McIntyre and Craik, 1987). Similarly, older adults are impaired at knowing where on a computer screen an item was presented, though they have little problem in recognition of items themselves (Parkin et al., 1995). Thus, impaired memory for context appears to exceed memory impairments for individual items. A prevailing

theory accounting for these recollection and context memory deficits involves the binding deficit hypothesis.

3.28.1.3 Summary

To summarize, behavioral evidence of EM encoding and retrieval has provided support for both resource and binding deficit hypotheses. In support of the resource deficit hypothesis, age-related deficits in encoding and retrieval are greater on EM tasks with little environmental support, which require more self-initiated processing. The resource deficit hypothesis is in line with the idea that a general reduction in executive function plays an important role in age-related memory decline. In support of the binding deficit hypothesis, age deficits are more pronounced when encoding and retrieval tasks require the formation or recollection of item–item or item–context associations. The binding deficit hypothesis supports the idea that a decline in relational memory functions plays an important role in age-related EM deficits.

3.28.1.4 Assumptions Regarding Brain Regions Underlying Resource and Binding Deficits

Adding brain assumptions to the resource and binding deficit hypotheses is straightforward, because different neural substrates have been proposed for executive and binding operations. As noted in the introduction, the PFC is considered the key brain region underlying executive functions and the managing of attentional resources (Miller and Cohen, 2001). Based on this generally accepted idea, Craik (1983) proposed that older adults' deficits in executive processing are related to a reduction in the efficiency of PFC functioning.

The strong relation between PFC function and executive processes is exemplified by patient, animal, and functional neuroimaging studies using the well-known Wisconsin Card Sorting Test (WCST) – a task that draws heavily on top-down attentional and executive processes (Miller and Cohen, 2001). In this task, participants sort a set of cards according to number, color, and symbol without being told the correct sorting rule, and this rule changes periodically. The experimenter only indicates whether a response was correct or not. Thus, any given card can be associated with several possible actions, and the correct one is determined by whichever rule is currently in effect. Several researchers have found that humans with PFC damage show clear deficits in the WCST. They are able to acquire the initial rule but are unable to adapt their behavior when the rule changes (Milner, 1963). Similar findings have been reported in animal studies. For instance, Dias et al. found that monkeys with experimental lesions to the PFC show very similar deficits in analog task of the WCST (Dias et al., 1996b, 1997). Finally, functional neuroimaging studies have also indicated the importance of PFC in the WCST. For example, a recent fMRI study found that different PFC subregions mediate different types of executive operations during WCST performance. Whereas ventrolateral PFC activity in the WCST was related to simple working memory operations, dorsolateral PFC activity was associated with more complex/manipulative working memory operations (Lie et al., 2006).

Similar to the strong relation between PFC and executive function, there is substantial evidence that the MTL is critical for binding. Recent evidence indicates that within MTL, binding is specifically associated with the function of the hippocampus, whereas the surrounding cortical regions (e.g., perirhinal cortex) are more involved in individual item memory (Brown and Aggleton, 2001; Eichenbaum, 2006).

The selective role of the hippocampus in binding operations can be exemplified with patient, animal, and functional neuroimaging studies that capitalized on the distinction between recollection-based (item–context binding) and familiarity-based (individual item memory) EM retrieval. Regarding patient data, using several different measures including ROC curves, Yonelinas and colleagues (2002) found that hypoxic patients, who typically have greater hippocampal than parahippocampal damage, showed a decline in recollection measures but normal familiarity. This was also reflected in their ROC curves, which were less asymmetrical (recollection) and more curvilinear (familiarity). These findings suggest that an intact hippocampus is necessary for recollection but not for familiarity. Regarding animal data, Fortin et al. (2004) also examined the contribution of recollection and familiarity processes using ROC curves in an odor recognition memory test designed for rodents. Normal rats showed ROC curves that had asymmetrical and curvilinear components, indicating the existence of both recollection and familiarity. However, following selective damage to the hippocampus, the ROC curve was not asymmetrical

(recollection) but completely curvilinear (familiarity), supporting the view that the hippocampus specifically mediates the capacity for recollection. Finally, regarding functional neuroimaging data, a recent study by Daselaar et al. (2006a) used confidence ratings to distinguish between recollection and familiarity. Confirming patient and animal findings, they found that the hippocampus showed selective activity for high confidence retrieval (recollection), whereas parahippocampal and rhinal activity showed a gradual function (familiarity) with confidence.

Thus, based on patient, animal, and functional neuroimaging evidence, we can infer that resource and binding deficits are tied to age-related changes in PFC and MTL (hippocampus), respectively. In the remainder of this chapter, we focus on how the structure and function of PFC and MTL change as a result of the aging process, and in the final section, we discuss a possible link between these behavioral and neurobiological changes.

3.28.2 Effects of Aging on PFC and MTL Anatomy and Physiology

The effects of aging on the brain occur at many levels from genes to gross anatomy. Reviewing this large research domain is beyond the scope of this chapter. Here, we focus on PFC and MTL and mention only three examples of cerebral aging measures that have been directly related to cognitive decline in aging humans: brain atrophy, declining white matter integrity, and dopamine deficits.

3.28.2.1 Brain Atrophy

In postmortem and *in vivo* studies, the brains of older adults tend to have lower volumes of gray matter than young adult brains (Resnick et al., 2003). These volume declines are not always related to a loss of cells but can also be ascribed to lower synaptic densities in older adults (Terry, 2000). Cross-sectional studies suggest that the volume of gray matter declines linearly with age, whereas white matter volume increases during childhood, plateaus during young adulthood and middle age, and declines during old age, an inverted U function (Raz et al., 2005).

Apart from differential age effects on gray and white matter volume, the relation between age and brain volume is also not uniform across different brain regions. The region most affected is the PFC, whereas other regions, such as the occipital cortex, are relatively unaffected by the aging process (Raz et al., 1997). With an average decline rate of between 0.9% and 1.5% per year, the frontal lobes show the steepest rate of atrophy (Pfefferbaum et al., 1998; Resnick et al., 2003; Raz et al., 2005).

The disproportionate effect of aging on PFC volume, together with the finding that age-related differences tend to be larger on tasks assumed to depend on PFC function, has led to the proposal that age-related deficits are primarily the result of frontal decline (for a review, see West, 1996). Indeed, frontal atrophy has been shown to correlate with cognitive deficits mediated by frontal regions. For example, Gunning-Dixon and Raz (2003) found that in a large group of older adults, perseveration errors on the WCST negatively correlated with prefrontal volume. However, other brain regions, including the basal ganglia (Bugiani et al., 1978; Schwartz et al., 1985) and the thalamus (Petersen et al., 2000; Gallo et al., 2004), also show a pronounced decline in brain volume with increasing age. In fact, in the last decades of normal life, volumetric changes in PFC do not differ from those in other neocortical areas (Resnick et al., 2000; Salat et al., 1999).

MTL volume also declines with age, though not all subregions (e.g., entorhinal cortex, hippocampus, parahippocampal gyrus) are equally affected. For example, as shown in **Figure 3**, a recent longitudinal study found that in healthy older adults, the hippocampus showed substantial atrophy, whereas the entorhinal cortex did not (Raz et al., 2005). Furthermore, studies have shown that the rate of hippocampal atrophy increases with age (Scahill et al., 2003; Raz, 2004). In one study, for example, this rate was an average of 0.86% per year in the whole sample (26–82 years) but 1.18% when considering only individuals over 50 years of age (Raz, 2004). A review of 12 studies estimated that after the age of 70 this rate may be as high as 1.85% per year (see Raz et al., 2005). The differential effects of aging on hippocampus and entorhinal cortex is very interesting, because the entorhinal cortex is one of the regions first affected by AD (Braak et al., 1993). As discussed later, together with recent fMRI evidence of dissociations between hippocampal and rhinal functions in aging (Daselaar et al., 2006b), these findings have implications for the early diagnosis of AD.

Several studies have suggested that the decline in hippocampal volume contributes to age-related deficits in EM (Golomb et al., 1993, 1994; Lupien et al., 1998; Sperling et al., 2003). For instance, Golomb et al. (1993)

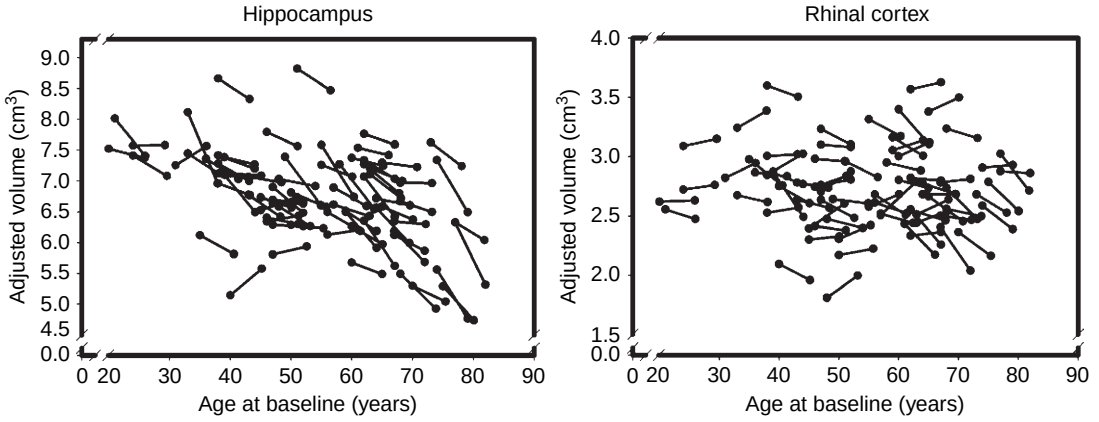

Figure 3 Longitudinal changes in volumes of hippocampus and rhinal cortex as a function of baseline age. From Raz N, Lindenberger U, Rodrigue KM, et al. (2005) Regional brain changes in aging healthy adults: general trends, individual differences and modifiers. *Cereb. Cortex* 15: 1676–1689.

investigated the link between hippocampal atrophy and memory performance in a group of healthy older adults. They found that, after controlling for such factors as age, education, and vocabulary skills, individuals with hippocampal atrophy performed less well on memory tests compared with those with no decline. Furthermore, as part of another longitudinal study on memory function, Golomb et al. (1996) found a significant correlation between hippocampal atrophy across a 3.8-year span and decline in memory performance in a group of older adults (mean age, 68.4 years). Additionally, Persson and colleagues (2005) found reduced hippocampal volume in a group of older adults whose episodic memory performance declined across a decade compared with that of a group whose memory performance remained stable.

3.28.2.2 Declining White Matter Integrity

In addition to declining gray matter, aging is also accompanied by reduced white matter integrity. White matter is composed of myelinated axons, which are essential for efficient neural transmission. When we age, myelin undergoes a number of significant changes including splitting of the myelin layers, increase in myelin volume resulting in redundant myelin sheets around axons, and finally, a breakdown of myelin (Wozniak and Lim, 2006).

A method to study the integrity of white matter *in vivo* is an MRI technique termed diffusion tensor imaging (DTI). This technique measures the magnitude and directionality of water diffusion within the brain. Without barriers, the movement of water is uniform in all directions. In the presence of barriers such as cell membranes, fibers, and myelin, the diffusion is greater in a certain direction and is termed anisotropic. Using DTI, the fractional anisotropy (FA) can be computed, indicating the degree of anisotropy in a particular area. Since degradation of white matter structure will result in a lower FA value, this measure can be used as an index of white matter integrity (Sullivan and Pfefferbaum, 2006).

Several DTI studies have shown that the integrity of white matter deteriorates with advancing age (Salat et al., 2005; Sullivan et al., 2006). For instance, Salat and colleagues calculated whole-brain maps of FA to determine whether particular fiber systems of the brain are preferentially vulnerable to white matter degeneration. The results showed significant age-related decline in FA in frontal white matter, the internal capsule, and the genu of the corpus callosum. However, FA in temporal and posterior regions was relatively preserved (**Figure 4**). These findings indicate that fiber tracts in PFC are more vulnerable to age-related degeneration than those within MTL regions. Similarly, Sullivan and colleagues (2006) found that frontocallosal fibers showed a much steeper rate of age-related decline than fibers in more posterior regions of the brain.

Reductions in FA have also been linked to a decline in cognitive abilities in older adults (Sullivan et al., 2001; Madden et al., 2004; Charlton et al., 2006). For example, a recent study by Charlton et al. (2006) investigated the relationship between white matter structure and cognition in 106 healthy middle-aged and elderly adults. They calculated correlations between DTI measures and performance on a test battery assessing executive function, working

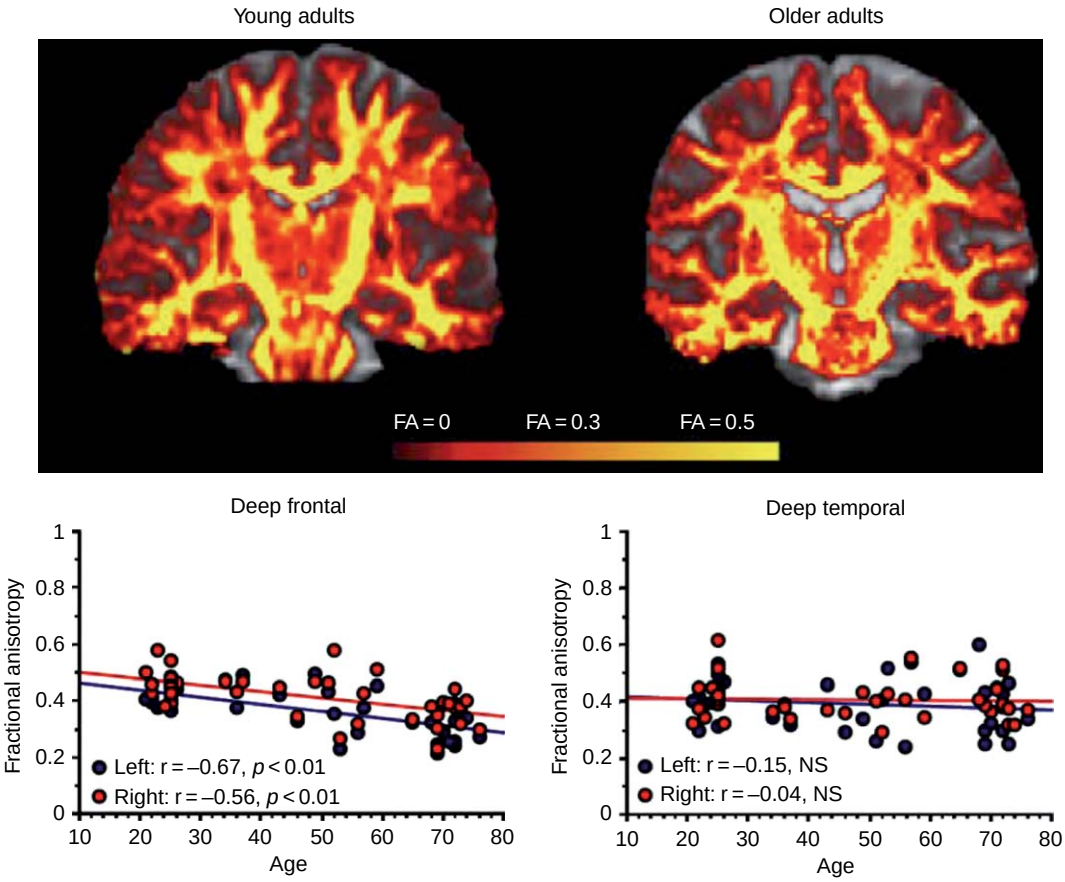

Figure 4 Steeper age-related decline in fractional anisotropy (FA) in frontal than in temporal white matter tracts. Adapted from Salat DH, Tuch DS, Greve DN, et al. (2005) Age-related alterations in white matter microstructure measured by diffusion tensor imaging. *Neurobiol. Aging* 26: 1215–1227.

memory, and information-processing speed. The results indicated a reduction in FA with age, which correlated with reduced performance in all three cognitive domains. However, after controlling for age, FA parameters correlated with working memory but not with the other two cognitive domains. These results indicate that white matter damage is an important factor in age-related cognitive decline and that working memory operations are particularly vulnerable to this type of cerebral aging.

3.28.2.3 Dopamine Deficits

Aging affects not only brain anatomy but also brain physiology, including the function of neurotransmitter systems, such as serotonin, acetylcholine, and dopamine (Strong, 1998). Associated with volume decrements in PFC are decreases in dopamine (DA) concentration and transporter availability (Volkow et al., 2000). Additionally, dopamine D_2 receptor density declines at a rate of 8% per decade, beginning in the 40s. There is abundant evidence that DA systems play an important role not only in motor operations but also in higher-order cognitive processes. DA function can be measured *in vivo* using PET (Bäckman and Farde, 2005).

There is strong evidence of age-related losses in pre- and postsynaptic DA markers, which may reflect decreases in the number of neurons, the number of synapses per neuron, and/or the expression of receptor proteins in each neuron. D_1 and D_2 receptor binding declines from early adulthood at a rate of 4–10% per decade, and this decline is correlated with the decline of dopamine transporter, possibly reflecting a common causal mechanism. DA loss with aging has been observed in frontal, temporal, and occipital cortices as well as in hippocampus and thalamus (Kaasinen et al., 2000; Inoue et al., 2001). The magnitude of extrastriatal DA decline mirrors that observed within the striatum itself. Given the

cognitive role of frontostriatal loops, age-related striatal DA deficits could also account for age-related cognitive deficits associated with PFC dysfunction. Moreover, age-related deficits in DA binding have been observed in PFC, as well as in posterior cortical and hippocampal regions. Evidence is mixed as to whether these declines are linear (see Reeves et al., 2002) or exponential (Bannon and Whitty, 1997; Rinne et al., 1998; Ghilardi et al., 2000) across adulthood.

The relationship between age-related changes in DA and age-related cognitive differences has been examined in only a small number of studies. Despite the paucity of data, findings are remarkably consistent. Age deficits in striatal DA have been associated with reduction in episodic memory (Bäckman et al., 2000; Erixon-Lindroth et al., 2005), executive function (Volkow et al., 1998; Mozley et al., 2001; Erixon-Lindroth et al., 2005), and motor performance (Wang et al., 1998; Mozley et al., 2001). Furthermore, several studies have also found that striatal DA markers serve as a significant predictor of cognitive performance, after controlling for the effects of age (Bäckman et al., 2000; Volkow et al., 1998), as well as that age-related cognitive deficits are mediated by reductions in striatal DA functioning (Erixon-Lindroth et al., 2005).

3.28.2.4 Summary

In sum, results indicate that the brain undergoes significant structural changes with age, but age-related atrophy differs across and within regions. Regarding volumetric measures of gray matter, studies have shown that the frontal lobes exhibit the highest rate of decline, and posterior regions the most moderate decline. The MTL also shows substantial atrophy in healthy aging, but the rate of decline differs for different subregions. For instance, whereas the hippocampus shows a marked decline, the rhinal cortex is relatively preserved in healthy aging. Measures of white matter volume and integrity (i.e., FA) also show differential aging effects throughout the brain. Similar to gray matter decline, age-related white matter degradation and DA dysfunction are greater in anterior compared with posterior regions. Correlations between these measures and cognitive function emphasize the importance that these changes have on cognitive functions. Finally, age-related decline in both pre- and postsynaptic DA markers also tends to follow this anterior–posterior gradient of decline. These patterns coincide with behavioral findings that show greater age-related performance decrements in cognitive functions mediated by frontal functioning (see West, 1996). In general, age-related decline in brain anatomy and physiology is most pronounced within PFC but is also present in MTL regions, particularly in the hippocampus. Based on existing evidence that PFC and MTL play key roles in executive and binding functions, these changes can readily account for the deficits reported in behavioral EM studies. The next section discusses functional neuroimaging studies, which provide a bridge between behavioral and anatomical findings by directly measuring age-related differences in brain activity during the performance of cognitive tasks.

3.28.3 Effects of Aging on PFC and MTL Activity

Before reviewing the findings of functional neuroimaging studies of EM, it is useful to first describe two patterns of age-related differences in brain activity that are consistently found in PFC and MTL. In the case of PFC, the most consistent finding has been an age-related reduction in lateralization. This evidence has been conceptualized in a model called Hemispheric Asymmetry Reduction in Older Adults (HAROLD), which states that, under similar conditions, PFC activity tends to be less lateralized in older than in younger adults (Cabeza et al., 2002). This model is supported by functional neuroimaging, electrophysiological, and behavioral evidence in the domains of episodic memory, semantic memory, working memory, perception, and inhibitory control (Cabeza, 2002).

In the case of MTL, the most consistent finding has been an age-related reduction in activity. However, recent studies suggest that not all MTL regions show reduced activity in older adults. Indeed, some MTL regions show preserved or increased activity in older adults, possibly reflecting differential age effects on various EM processes. In this section, we first review the effects of aging on PFC activation in encoding and retrieval tasks. Then we turn to the effects of aging on MTL activation as it relates to these cognitive processes. Although the number of studies is still too limited to identify clear patterns in the data, and a considerable amount of variability still remains unexplained, we try to emphasize the most consistent findings across studies.

3.28.3.1 PFC

3.28.3.1.1 Encoding

Functional imaging studies of encoding and aging have investigated a wide variety of stimuli, including words, word pairs, faces, and scenes. Despite this variety of stimuli, PFC findings have been quite consistent: older adults typically show reduced left PFC activity during encoding compared with younger adults. However, there is some evidence suggesting that this effect may be modulated by whether encoding is intentional or incidental. In intentional encoding conditions, participants are asked to learn information for a subsequent memory test, while in incidental encoding conditions, a memory test is not mentioned and participants are only asked to perform a certain task (semantic or nonsemantic). In terms of the resource deficit hypothesis, intentional encoding tasks provide less environmental support than incidental encoding tasks and, thus, are more dependent on PFC-mediated executive functions. Following, we consider first intentional encoding studies, then incidental encoding studies, and finally, studies comparing intentional vs. incidental encoding.

3.28.3.1.1.(i) Intentional encoding studies In a PET study by Grady et al. (1995), young and older adults intentionally encoded pictures of faces followed by a recognition test. Regarding encoding-related PFC activity, they found that older adults showed less activity in the left PFC than younger adults.

In another PET study by Cabeza et al. (1997), young and older adults intentionally encoded a list of word pairs for subsequent cued recall and recognition tests. During encoding, older adults showed increased activity in several regions, including the insula, but reduced activity in occipitotemporal and left prefrontal regions. Importantly, Cabeza and colleagues noted that younger adults selectively recruited the left PFC, whereas older adults showed equivalent activity in left and right PFC (i.e., HAROLD). Since younger adults and older adults had similar memory scores on both cued recall and recognition tasks, they interpreted the additional recruitment of right PFC by older adults as compensatory.

In another PET study of encoding and aging, Anderson et al. (2000) assessed intentional encoding of moderately associated word-pairs under conditions of full and divided attention. During full attention, they found a pattern similar to the one observed in the PET study by Cabeza and colleagues (1997). Whereas the older adults showed reduced activity in left PFC, they showed increased activity in right PFC, leading to bilateral frontal activity in older adults.

3.28.3.1.1.(ii) Incidental encoding studies Age-related differences in PFC activation have also been shown when investigating levels of processing at encoding. When comparing deep and shallow encoding of words, Stebbins et al. (2002) reported greater activity in both younger adults and older adults for the deep relative to the shallow encoding condition. However, the older adults showed decreased activation in left PFC. Furthermore, decreased performance on neuropsychological tests correlated with reduced PFC activity. As a result of the reduced left PFC activity, PFC activity in older adults was more symmetric than in younger adults, again in accord with the HAROLD model.

Rosen et al. (2002) also studied deep and shallow encoding of words in younger adults and older adults. However, they distinguished between older adults with high and low memory scores based on a neuropsychological test battery. They reported equivalent left PFC activity but greater right PFC activity in the old-high memory group relative to younger adults. In contrast, the old-low memory group showed reduced activity in both left and right PFC. As a result, the old-high group showed a more bilateral pattern of PFC activity than younger adults (HAROLD).

Similarly, using a verbal encoding/recognition task, Daselaar et al. (2003b) compared groups of high- and low-performing older adults, divided *post hoc* based on their memory scores. During the semantic encoding task (pleasant/unpleasant decisions), all groups showed left lateralized activations patterns, but PFC activity was slightly less lateralized in the low-performing elderly, and even less so in the high-performing elderly. Consistent with the results of Cabeza et al. (2002), these findings support the compensatory interpretation of HAROLD.

Morcom et al. (2003) used event-related fMRI to study subsequent memory for semantically encoded words. Recognition memory for these words was tested after a short and a longer delay. At the short delay, performance in older adults was equal to that of younger adults at the long delay. Under these conditions, activity in left inferior PFC was greater for subsequently recognized than forgotten words and was equivalent in both age groups. However,

older adults showed greater right PFC activity than younger adults, again resulting in a more bilateral pattern of frontal activity (HAROLD).

Gutchess et al. (2005) studied subsequent picture memory using a deep processing task. While young and older adults showed equivalent activity in right PFC, the older adults showed increased activity in the left PFC. Since picture encoding in younger adults was associated with bilateral PFC activity, these findings suggest a selective recruitment of left PFC, which may be compensatory.

A recent study by Dennis et al. (2006) used hybrid blocked/event-related analyses to distinguish between transient and sustained subsequent memory effects during deep incidental encoding of words. Subsequent memory was defined as parametric increases in encoding activity as a function of a combined subsequent memory/confidence scale. This parametric response was measured in each trial (transient activity) and in blocks of eight trials (sustained activity). Similar to the study conducted by Gutchess et al., subsequent memory analyses of transient activity showed age-related increases in left PFC. At the same time, subsequent memory analyses of sustained activity showed age-related reductions in right PFC. Contrary to Stebbins et al.'s study (2002), these findings suggest that during semantic classification, older adults can show even greater PFC-mediated semantic processing than young adults. Additionally, the decline in sustained subsequent memory activity in PFC may involve age-related deficits in sustained attention that impact encoding processes. The results underline the importance of investigating aging effects on both transient and sustained neural activity.

Finally, Persson and colleagues (2006) used longitudinal behavioral data to identify two groups of older adults that differed with regard to whether their performance on tests of episodic memory remained stable or declined over a decade. During incidental encoding of words, both groups showed equivalent activation in left PFC, but the elderly subjects with the greatest decline in memory performance showed additional right PFC activity. Moreover, mean DTI measures (FA) in the anterior corpus callosum correlated negatively with activation in right PFC. These results demonstrate that cognitive decline is associated with differences in the structure as well as function of the aging brain and suggest that contralateral PFC recruitment is either caused by structural disruption or is a compensatory response to such disruption.

3.28.3.1.1.(iii) Intentional versus incidental encoding Grady and colleagues (1999) compared intentional vs. incidental encoding conditions across various stimuli (e.g., words, pictures). They scanned participants during shallow (uppercase/lowercase, picture size), deep (living/nonliving), and intentional encoding conditions. Overall, picture encoding resulted in greater activity in visual and MTL regions, while word encoding yielded greater activity in left PFC and left lateral temporal cortex. However, deep encoding produced greater left PFC activity, while intentional encoding yielded greater right PFC activity. Though older adults showed the same patterns, the overall level of activity was reduced. Interestingly, researchers did not find a difference in deep vs. intentional encoding of pictures, indicating that age-related differences were greater for words than for pictures.

The same research group conducted another study comparing intentional and incidental encoding conditions, this time using faces as study items (Grady et al., 2002). Convergent with their earlier study investigating intentional face encoding (Grady et al., 1995), older adults showed decreased activity in left PFC compared with younger adults and diminished connectivity between frontal and MTL areas during both encoding conditions.

Despite the lack of activation differences across encoding instructions in the studies reported by Grady et al., a more recent study did find age-related frontal differences for intentional encoding instructions. Logan et al. (2002) reported that during self-initiated, intentional encoding instructions, older adults compared with younger adults showed less activity in left PFC but greater activity in right PFC, resulting in a more bilateral activity pattern (HAROLD). Results were similar for intentional encoding of both verbal and nonverbal material. Interestingly, further exploratory analyses revealed that this pattern was present in a group of old-older adults (mean age, 80), but not in a group of young-older adults (mean age, 67), suggesting that contralateral recruitment is associated with more pronounced age-related cognitive decline. At the same time, the decrease in left PFC was not present in older adults during incidental encoding instructions, suggesting that frontal reductions can be remediated by providing environmental support during encoding (**Figure 5**).

3.28.3.1.1.(iv) Summary To summarize encoding studies, the most consistent finding was an age-related reduction in left PFC activity. This

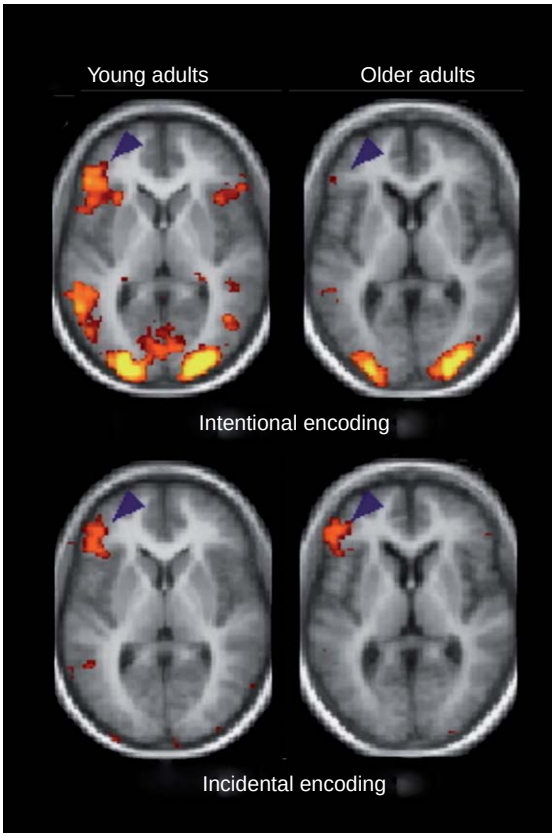

Figure 5 Reduced left PFC activity in older compared with younger adults during intentional encoding, but similar activity during incidental encoding. Adapted from Logan JM, Sanders AL, Snyder AZ, Morris JC, and Buckner RL (2002) Under-recruitment and nonselective recruitment: Dissociable neural mechanisms associated with aging. *Neuron* 33: 827–840.

finding was more frequent for intentional than for incidental encoding studies, suggesting that, in line with the resource deficit hypothesis, the environmental support provided by a deep semantic encoding task may attenuate the age-related decrease in left PFC activity. This effect was found within subjects in the study by Logan et al. (2002). The difference between intentional vs. incidental encoding conditions suggests an important strategic component in age-related memory decline. The reduction in left PFC activity was often coupled with an increase in right PFC activity, leading to a bilateral pattern of PFC activity in older adults (HAROLD). Importantly, extending to encoding a finding originally reported for retrieval (Cabeza et al., 2002), two studies that divided older adults into high and low performers found the HAROLD pattern only in the high-performing group (Rosen et al., 2002; Daselaar et al., 2003b). These findings provide direct support for the compensation account of HAROLD.

3.28.3.1.2 Retrieval

In line with the resource deficit hypothesis, age-related deficits in episodic retrieval tend to be more pronounced for recall and context memory tasks than for recognition tasks (Spencer and Raz, 1995). However, considerable differences in activity have also been observed during simple recognition tasks. We first review studies looking at recognition processes and then examine those that focus on recall and different forms of context memory.

3.28.3.1.2.(i) Recognition memory The face encoding study by Grady et al. (1995) also included a face recognition test. During this task, older adults showed reduced activity in parietal and occipital regions but equivalent activity to young adults in right PFC. This last finding contrasts with the age-related reduction in left PFC activity found in the same study during face encoding. Based on these results, the authors suggested that age effects are more pronounced on encoding than on retrieval. As noted below, however, many subsequent PET and fMRI studies have found reliable age-related changes in PFC activity during episodic retrieval.

The word-pair encoding study by Cabeza et al. (1997) also included a word-pair recognition task. During this task, older adults showed reduced activity in right PFC but increased activity in other brain regions, such as the precuneus. The age-related reduction in right PFC contrasts with the lack of age effects in this region's activity in Grady et al.'s (1995) study. This inconsistency could reflect differences in stimuli (faces vs. words) or retrieval processes (recognition of items vs. recognition of pairs).

The age-related reduction in right PFC activity during recognition was replicated by Madden et al. (1999), using a single-word recognition task. Additionally, this study found an age-related increase in left PFC. This age-related increase extended to recognition a finding previously reported for recall by Cabeza et al. (1997), which is reviewed here. As in the previous recall study, the age-related increase in left PFC led to a more bilateral pattern in older adults (i.e., HAROLD). In a subsequent study, Madden et al. (1999) reanalyzed the recognition data using a stepwise regression method that distinguished between exponential (tau) and

Gaussian (mu) components of RT distributions. Young adults showed a correlation between mu and right PFC activity, whereas the older adults showed correlations in left and right PFC regions related to both mu and tau. Since tau is associated with task-specific decision processes, and mu with residual sensory coding and response processes, the authors concluded that attentional demands were greater for older adults, leading to the recruitment of additional regions. These findings suggest that the retrieval network is more widely distributed in older adults.

Daselaar et al. (2003b) used event-related fMRI to study recognition of words in younger adults and older adults. Based on recognition performance in the scanner, older adults were divided into old-high and old-low groups. During recognition, compared with baseline, the old-low group showed much increased activity throughout the brain relative to the other groups. In addition, the old-low group and younger adults showed bilateral PFC activity, whereas the old-high group showed a more left lateralized pattern of frontal activity. In other words, the old-low group showed a nonselective increase in global brain activity, whereas the old-high group showed a selective recruitment of left PFC. The authors interpreted these findings in terms of strategic retrieval differences. Interestingly, when correctly recognized old words were compared with correctly rejected new words, these group differences disappeared. The difference in activity between these two trial types is generally considered to be a correlate of retrieval success. Hence, these findings suggest that age-related differences in episodic recognition primarily reflect strategic search deficits.

Velanova et al. (2006) also investigated differences between young and older adults during word retrieval in an easy (15 study repetitions) and a difficult (one study repetition) recognition task. Although many correlates of retrieval were similar between the groups, including medial and lateral parietal responses to successful recognition, older adults showed increased recruitment of PFC regions relative to young adults during the difficult condition. This effect was not significant during the easy condition. Moreover, the timing of increased recruitment in older adults occurred at relatively late stages of the retrieval event. These findings suggest that older adults fail to engage appropriate PFC-mediated executive processes at early stages of retrieval, and as a result, PFC involvement is extended at late stages to compensate.

3.28.3.1.2.(ii) Recall and context memory The aforementioned word-pair study by Cabeza et al. (1997) included not only a recognition test but also a cued-recall test. During recall, older adults showed weaker activity in the anterior cingulate and left temporal cortex. In addition, older adults showed weaker activations in right PFC than the younger adults. Conversely, older adults showed greater activity than younger adults in left PFC. The net result was that PFC activity during recall was right lateralized in younger adults but bilateral in older adults. The authors noted this change in hemispheric asymmetry and interpreted it as compensatory. This was the first study identifying the HAROLD pattern and the first one suggesting the compensatory interpretation of this finding. As noted, this study also compared age-related changes in activity during recall and recognition. These changes were more pronounced during recall than during recognition, consistent with behavioral evidence that recall is more sensitive to aging.

Bäckman et al. (1997) found a result similar to Cabeza et al. (1997), using word-stem cued recall instead of word-pair cued recall: younger adults activated right PFC, whereas older adults activated both left and right PFC (HAROLD). Also using word pairs, Anderson et al. (2000) investigated the effects of divided attention on cued recall. They reported negligible effects of divided attention in both groups. However, under full attention conditions, older adults showed weaker activations primarily in right PFC but stronger activations primarily in left PFC, suggesting an attenuation of the right-lateralized pattern shown by younger adults (HAROLD).

Cabeza et al. (2000) investigated item and temporal-order memory tasks. In the item task, a word pair was presented consisting of one studied word and one new word, and participants indicated which word was studied. In the temporal-order task, both words were studied, and participants indicated which of the two words appeared later in the study list. They reported that younger adults showed increased activation in right PFC for temporal-order compared with item memory, whereas older adults did not. In contrast, the activations during item memory were relatively unaffected by age. These findings are in line with the resource deficit hypothesis, indicating that memory deficits in older adults are a result of PFC dysfunction and that context memory is more heavily dependent on the frontal lobes than item memory is.

In another study of context memory by Cabeza and colleagues (2002), younger adults, high-performing

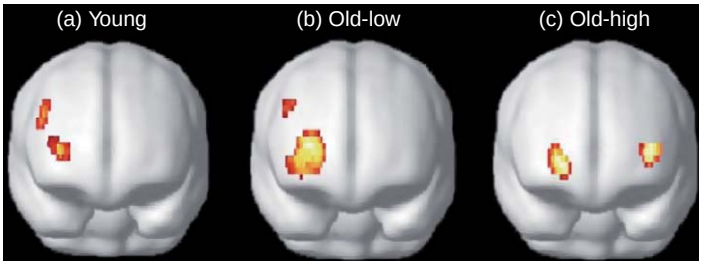

Figure 6 PFC activity during EM retrieval was right-lateralized in young (a) and low-old (b) participants, but bilateral in old-high (c) subjects. From Cabeza R, Anderson ND, Locantore JK, and McIntosh AR (2002) Aging gracefully: Compensatory brain activity in high-performing older adults. *Neuroimage* 17: 1394–1402.

older adults (old-high), and low-performing older adults (old-low) studied words presented auditorily or visually. During scanning, they were presented with words visually and made either old/new decisions (item memory) or heard/seen decisions (context memory). Consistent with their previous results, younger adults showed right PFC activity for context trials, whereas older adults showed bilateral PFC activity (HAROLD). Importantly, however, this pattern was only seen for the old-high adults, supporting a compensation account of the HAROLD pattern (**Figure 6**).

3.28.3.1.2.(iii) Summary Summarizing the studies on PFC and retrieval, the HAROLD pattern has been found more frequently in studies using tasks with little environmental support, including recall and context memory tasks than during simple item recognition. This was exemplified in the study by Cabeza et al. (1997), which included both recall and recognition tasks. These findings suggest a three-way interaction between age, executive demand, and frontal laterality. Importantly, distinguishing between old-high and old-low adults, the study by Cabeza et al. (2002) provided direct evidence for the compensation account of HAROLD.

3.28.3.2 MTL

Frontal activations in aging showed both reductions and increases across aging, as well as shifts in lateralization of activation. On the other hand, activation within the MTL generally shows age-related decreases compared with that seen in younger adults. However, some studies show a shift in the foci of activation from the hippocampus proper to more parahippocampal regions in aging. Evidence for such a shift is presented later, where appropriate, and is discussed further in the conclusions.

3.28.3.2.1 Encoding

Though the binding deficit hypothesis would predict age-related reductions in MTL activity, particularly during associative encoding, reductions have been found during encoding of individual items as well. We first discuss studies focusing on individual item encoding and then discuss the results of the only study reporting MTL differences using an associative encoding task.

3.28.3.2.1.(i) Individual item encoding In their study examining face encoding, Grady et al. (1995) found that older adults showed less activity not only in the left PFC but also in MTL compared with younger adults. Furthermore, they found a highly significant correlation between hippocampus and left PFC activity in younger adults, but not in older adults. Based on these results, they concluded that encoding in older adults is accompanied by reduced neural activity and diminished connectivity between PFC and MTL areas.

Daselaar et al. (2003a) investigated levels of processing in aging using a deep (living/nonliving) vs. shallow (uppercase/lowercase) encoding task. Despite seeing common activation of regions involved in a semantic network across both age groups, activation differences were seen when comparing levels of processing. Older adults revealed significantly less activation in left anterior hippocampus during deep relative to shallow classification. The researchers concluded that under-recruitment of MTL regions contributes, at least in part, to age-related impairments in encoding.

Similarly, the same group showed decreased activity in the MTL for poor-performing older adults compared with young and high-performing elderly. Despite similar PFC activation, Daselaar et al. (2003b) found that the older adults showed decreased activity in the left hippocampus during successful

encoding of words. Based on these findings, they concluded that MTL dysfunction during encoding is an important factor in age-related memory decline.

Similar to Daselaar et al. (2003b), Gutchess et al.'s (2005) study of subsequent picture memory observed reduced activity in the MTL for subsequently remembered items, even when older adults were not divided into high- and low-memory groups. Additionally, older adults exhibited a significant negative correlation between inferior frontal and parahippocampal activity, whereas younger adults did not. These results suggest that those older adults exhibiting the least involvement of the parahippocampal region conversely activated PFC areas the most.

Similar results were reported in the study by Dennis et al. (2006), which distinguished between transient and sustained subsequent memory for words. In line with Gutchess et al., they found that older adults showed a reduced transient subsequent memory effect in the hippocampus coupled with an increased effect in left PFC. These data suggest that PFC regions could be activated in a compensatory manner to offset declines in MTL activations in older adults.

3.28.3.2.1.(ii) Associative encoding Mitchell et al. (2000a) conducted the only fMRI study reporting MTL differences in an associative encoding task. In each trial, participants were presented with an object in a particular screen location and had to hold in working memory the object, its location, or both (combination trials). Combination trials can be assumed to involve the binding of different information into an integrated memory trace. Older adults showed a deficit in accuracy in the combination condition but not in the object or location conditions. Two regions were differentially involved in the combination condition in younger adults but not in older adults: a left anterior hippocampal region and an anteromedial PFC region (right BA 10). According to the authors, disruption of a hippocampal–PFC circuit may underlie binding deficits in older adults.

3.28.3.2.1.(iii) Summary In line with the binding deficit hypothesis, Mitchell and collegues found age-related reductions in MTL activity specifically during associative encoding. Yet several other studies also found age-related MTL reductions during encoding of individual items (Daselaar et al., 2003a,b; Gutchess et al., 2005; Dennis et al., 2006). Moreover, the study by Daselaar et al. (2003b) directly linked reduced MTL activity during single-word encoding to impaired performance on a subsequent recognition test. These findings suggest that age-related binding deficits play a role not only in complex associative memory tasks but also in simpler item memory tasks. One explanation for these results is that, in general, item memory tasks also have an associative component. In fact, the deep processing tasks used in these tasks are specifically designed to invoke semantic associations in relation to the study items. As discussed in the next section, recollection of these associations can be used as confirmatory evidence during EM retrieval. The results from two studies suggest that PFC regions might be activated in a compensatory manner to offset declines in MTL activations in older adults (Gutchess et al., 2005; Dennis et al., 2006). In particular, using correlational analyses, Gutchess et al. (2005) found that the older adults who showed the least MTL activity also showed the greatest PFC activity. These findings suggest that older adults may try to compensate for deficits in binding mediated by MTL by recruiting additional executive processes mediated by PFC.

3.28.3.2.2 Retrieval

In contrast to encoding, MTL differences during retrieval involve not only decreases but also age-related increases. This pattern has been observed during recognition memory tasks as well as cued recall and autobiographical retrieval tasks.

3.28.3.2.2.(i) Recognition memory Cabeza et al. (2004) investigated the effects of aging on several cognitive tasks including a verbal recognition task. Within the medial temporal lobes, they found a dissociation between a hippocampal region, which showed weaker activity in older adults than in younger adults, and a parahippocampal region, which showed the converse pattern. Given evidence that hippocampal and parahippocampal regions are, respectively, more involved in recollection vs. familiarity (Aggleton and Brown, 1999; Yonelinas, 2002), this finding is consistent with the notion that older adults are more impaired in recollection than in familiarity (e.g., Parkin and Walter, 1992; Jennings and Jacoby, 1993). Indeed, the age-related increase in parahippocampal cortex suggests that older adults may be compensating for recollection deficits by relying more on familiarity. Supporting this idea, older adults had a larger number of K responses than younger adults, and these responses were positively correlated with the parahippocampal activation.

A recent follow-up study by the same group showed a similar pattern of results (Prince et al., 2005). Young and older adults made old/new

judgments about previously studied words, followed by a confidence judgment from low to high. On the basis of previous research (Yonelinas, 2001), recollection was measured as an exponential change in brain activity as a function of confidence and familiarity, and as a linear change. The results revealed a clear double dissociation within MTL: Whereas recollection-related activity in the hippocampus was reduced by aging, familiarity-related activity in rhinal cortex was increased by aging (see **Figure 7(a)**). These results suggested that older adults compensated for deficits in recollection processes mediated by the hippocampus by relying more on familiarity processes mediated by rhinal cortex. Supporting this interpretation, within-participants regression analyses based on single-trial activity showed that recognition accuracy was determined by only hippocampal activity in young adults but by both hippocampal and rhinal activity in older adults. Also consistent with the notion of compensation, functional connectivity analyses showed that correlations between the hippocampus and posterior regions associated with recollection were greater in younger adults, whereas correlations between rhinal cortex and bilateral PFC regions were greater in older adults (see **Figure 7(b)**). The latter effect suggests a top-down modulation of PFC on rhinal activity in older adults. The finding of preserved rhinal function in healthy older adults has important clinical implications, because this region is impaired early in AD (Killiany et al., 2000; Pennanen et al., 2004).

3.28.3.2.2.(ii) Cued recall, autobiographical retrieval, and context memory In addition to increases in left PFC during word-stem cued recall, Bäckman and colleagues (1997) found increased MTL activation in older adults. Just as the increased left PFC activation resulted in more bilateral frontal activation for older adults, increased activation in left MTL had the same effect: Compared with younger adults, older adults show more bilateral MTL activity. It should be noted that this bilateral activation was not accompanied by increased performance, as older adults recalled only about half as many words as did younger adults.

This HAROLD pattern within MTL was also observed in a recent study using event-related fMRI. Maguire and Frith (2003) investigated the recall of autobiographical events gathered in a pre-scan interview. Although the groups activated largely the same regions, they observed a striking difference in the MTL. Younger adults showed left lateralized hippocampal activity, whereas older adults showed bilateral activity in the MTL. These findings suggest that HAROLD extends beyond the PFC not only to other cortical regions (as shown by several studies) but also to subcortical areas.

3.28.3.2.2.(iii) Summary In sum, retrieval studies have found both increases and decreases in MTL activity. The findings by Daselaar and colleagues suggest that at least some of these increases reflect a shift from recollection-based (hippocampus) to familiarity-based (rhinal cortex) retrieval. Furthermore, their functional connectivity findings suggest that the greater reliance on familiarity processes in older adults may be mediated by a top-down frontal modulation.

3.28.3.2.3 Linking cognitive theories to age-related changes in PFC and MTL

In the first part of this chapter, we discussed behavioral evidence indicating how EM encoding and retrieval performance changes as a function of aging. We also discussed two important cognitive hypotheses that have been put forward to account for age-related deficits in EM – the resource deficit hypothesis and the binding deficit hypothesis. In the following sections, we discussed how aging affects the anatomy and function of two brain regions thought to be critical to EM function, PFC and MTL. Here, we connect these behavioral and neurobiological findings by linking the resource and binding deficit hypotheses to PFC and MTL function in older adults. Finally, returning to the beginning of the chapter, we discuss the relevance of these findings in terms of the clinical distinction between healthy and pathological deficits in EM.

3.28.3.3 Resource Deficit Hypothesis and PFC Function

As described in the behavioral section of this chapter, the resource deficit hypothesis postulates that aging reduces attentional resources, and as a result, older adults have greater difficulties with cognitive tasks, including EM tasks, that require greater self-initiated processing. This hypothesis predicts that age-related differences should be smaller when the task provides a supportive environment that reduces attentional demands. Among other findings, the resource deficit hypothesis is supported by evidence that when attentional resources are reduced in younger adults, they tend to show EM deficits that resemble those of older adults (Jennings and Jacoby, 1993; Anderson et al., 1998).

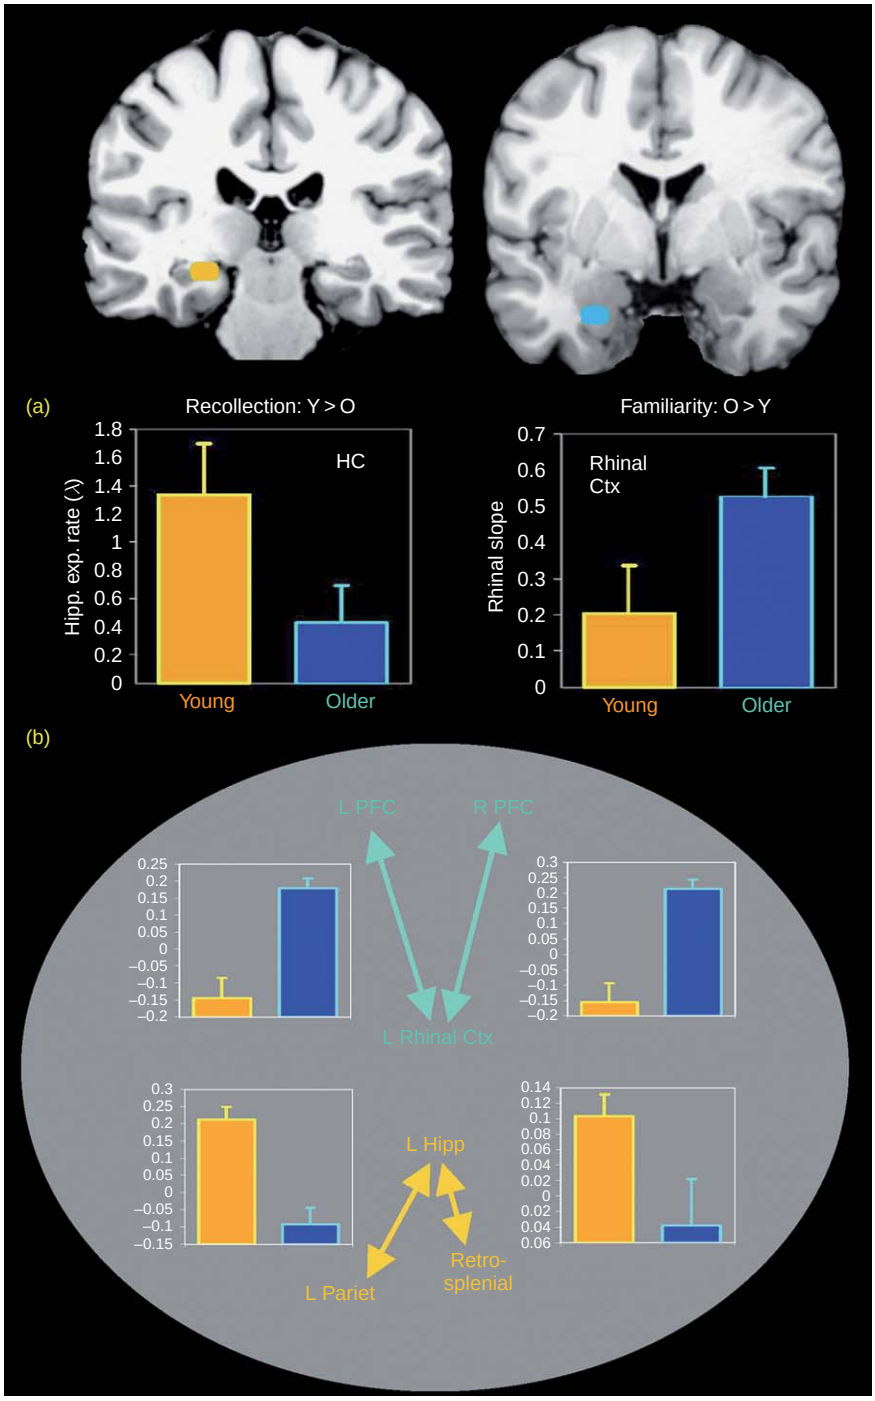

Figure 7 (a) The effects of aging yielded a double dissociations between two MTL subregions: Whereas recollection-related activity (exponential increase) in the hippocampus was attenuated by aging, familiarity-related activity (linear decrease) in the rhinal cortex was enhanced by aging. The hippocampal exponential rate parameter (λ) provides a measure of the sharpness of the exponential increase of the perceived oldness function in the hippocampus. The rhinal slope parameter provides a measure of the steepness of the perceived oldness function in the rhinal cortex. (b) Younger adults showed greater connectivity between the hippocampus and posterior regions associated with recollection, whereas older adults showed greater correlations between rhinal cortex and bilateral PFC regions. The latter effect suggests a top-down modulation of PFC on rhinal activity in older adults. Adapted from Daselaar SM, Fleck MS, Dobbins IG, Madden DJ, and Cabeza R (2006b) Effects of healthy aging on hippocampal and rhinal memory functions: An event-related fMRI study. *Cereb. Cortex* 16: 1771–1782.

Regarding neural correlates, Craik (1983) proposed that older adults' deficits in processing are related to a reduction in the efficiency of PFC functioning. As discussed in this chapter, there is much evidence in support of this idea. First, anatomical and physiological studies indicate that PFC is one of the brain regions most affected by the aging process. This region shows the most prominent gray matter atrophy and the most widespread degeneration of white matter integrity, as well as a substantial loss of DA modulation. Moreover, functional neuroimaging studies have found age-related changes in PFC activity that are generally in line with the resource deficit hypothesis.

Given the critical role of PFC in managing attentional resources, the resource deficit hypothesis predicts that age-related changes in PFC activity will be larger for tasks involving greater self-initiated processing and/or less environmental support. The results of functional neuroimaging studies are generally consistent with this prediction. During EM encoding, age-related decreases in left PFC activation were found frequently during intentional encoding conditions (which provide less environmental support) but rarely during incidental encoding conditions (which provide greater environmental support). Similarly, during EM retrieval, age-related differences in PFC activity were usually larger for recall and context memory tasks (which require greater cognitive resources) than for recognition memory tasks (which require fewer cognitive resources). Thus, in general, age effects on PFC activity tend to increase as a function of the demands placed on cognitive resources.

However, not all age-related changes in PFC activity suggested decline; on the contrary, many studies found age-related increases in PFC that suggested compensatory mechanisms in the aging brain. In particular, several encoding and retrieval studies found activations in contralateral PFC regions in older adults that were not seen in young adults. Importantly, experimental comparisons between high- and low-performing older adults (Cabeza et al., 2002; Rosen et al., 2002) demonstrated the beneficial contribution of contralateral PFC recruitment to memory performance in older adults. Moreover, a recent study using transcranial magnetic stimulation (TMS) found that in younger adults, episodic retrieval performance was impaired by TMS of right PFC but not of left PFC, whereas in older adults it was impaired by either right or left PFC stimulation (Rossi et al., 2004). This result indicates that the left PFC was less critical for younger adults and was used more by older adults, consistent with the compensation hypothesis.

It is important to note that resource-deficit and compensatory interpretations are not incompatible. In fact, it is reasonable to assume that the recruitment of additional brain regions (e.g., in the contralateral PFC hemisphere) reflects an attempt to compensate for reduced cognitive resources. One way in which older adults could counteract deficits in the particular pool of cognitive resources required by a cognitive task is to tap into other pools of cognitive resources. If one task is particularly dependent on cognitive processes mediated by one hemisphere, the other hemisphere represents an alternative pool of cognitive resources. Thus, in the case of PFC-mediated cognitive resources, if older adults have deficits in PFC activity in one hemisphere, they may compensate for these deficits by recruiting contralateral PFC regions. Moreover, age-related decreases suggestive of resource-deficits and age-related increases suggestive of compensation have often been found in the same conditions. For example, intentional encoding studies have shown age-related decreases in left PFC activity coupled with age-related increases in right PFC, leading to a dramatic reduction in hemispheric asymmetry in older adults (ie., HAROLD).

3.28.3.4 Binding Deficit Hypothesis and MTL Function

As noted in the first part of the chapter, the binding deficit hypothesis postulates that age-related memory deficits are primarily the result of difficulties in encoding and retrieving novel associations between items. This hypothesis predicts that older adults are particularly impaired in EM tasks that involve relations between individual items or between items and their context. Given that relational memory has been strongly associated with the hippocampus (Eichenbaum et al., 1994), this hypothesis also predicts that older adults will show decreased hippocampal activity during memory tasks, particularly when they involve relational information.

As noted in the preceding parts of the chapter, anatomical, physiological, and functional neuroimaging studies have identified considerable age-related changes not only in PFC but also in MTL regions. For instance, the MTL also shows substantial atrophy in aging. Yet the rate of decline differs for different subregions. Whereas the hippocampus shows a marked decline, the rhinal cortex is relatively preserved in healthy aging (**Figure 3**). This finding is in line with the idea that age-related memory deficits are

particularly pronounced during relational memory tasks, which depend on the hippocampus.

In line with anatomical findings, functional neuroimaging studies have found substantial age-related changes in MTL activity during both encoding and retrieval. Several studies have found age-related decreases in both hippocampal and parahippocampal regions. During encoding, however, declines in hippocampal activation are also seen for encoding of individual features in healthy older adults (Grady et al., 1995; Schiavetto et al., 2002; Daselaar et al., 2003a,b; Gutchess et al., 2005). Finally, during retrieval, some studies found decreases in hippocampal activity (Cabeza et al., 2004, 2005), but also greater activity in older than younger adults in parahippocampal (Cabeza et al., 2004), rhinal (Cabeza et al., 2005), or contralateral MTL (Bäckman et al., 1997; Maguire and Frith, 2003) regions, which may be compensatory.

In general, age-related changes in MTL activity are consistent with the binding deficit hypothesis. Consistent with this hypothesis, age-related reductions in hippocampal activity were found during the encoding of complex scenes, which involve associations among picture elements (Gutchess et al., 2005), and during deep encoding of words, which involves identification of semantic associations (Daselaar et al., 2003a,b; Dennis et al., 2006). Finally, a recent study specifically associated age-related reductions in hippocampal activity with recollection, which involves recovery of item-context associations (Daselaar et al., 2006b). Yet it should be noted that age-related changes in MTL activity were often accompanied by concomitant changes in PFC activity. Hence, in these cases, it is unclear whether such changes signal MTL dysfunction or whether they are the result of a decline in executive processes mediated by PFC regions. However, studies using incidental encoding tasks with minimal self-initiated processing requirements have also identified age-related differences in MTL activity without significant changes in PFC activity (Daselaar et al., 2003a,b).

As in the case of PFC, not all age-related changes in MTL activity suggest decline; several findings suggest compensation. First, similar to the bilateral pattern frequently observed in PFC, older adults have also demonstrated bilateral hippocampal recruitment while performing memory retrieval tasks (Maguire and Frith, 2003). Second, during retrieval, older adults have been found to show reduced activity in the hippocampus but increased activity in other brain regions such as the parahippocampal gyrus (Cabeza et al., 2004) and the rhinal cortex (Daselaar et al., 2006b). These results were interpreted as a recruitment of familiarity processes mediated by parahippocampal regions in order to compensate for the decline of recollection processes that are dependent on the hippocampus proper. These results fit well with the relational memory view (Cohen and Eichenbaum, 1993; Eichenbaum et al., 1994), which states that the hippocampus is involved in binding an item with its context (recollection), whereas the surrounding parahippocampal cortex mediates item-specific memory processes (familiarity). As noted in the behavioral section of the chapter, this distinction is supported not only by functional neuroimaging data in healthy young adults (Daselaar et al., 2006a) but also by lesion data from both humans (Yonelinas et al., 2002) and animals (Fortin et al., 2004).

3.28.3.5 Healthy versus Pathological Aging

As mentioned at the beginning of this chapter, one of the biggest challenges in cognitive aging research is to isolate the effects of healthy aging from those of pathological aging. A general review of the structural neuroimaging literature suggests that healthy aging is accompanied by greater declines in frontal regions compared with MTL (Raz et al., 2005). In contrast, pathological aging is characterized by greater decline in MTL than in frontal regions (Braak et al., 1993; Kemper, 1994). In fact, functional neuroimaging evidence suggests that prefrontal activity tends to be maintained or even increased in early AD (Grady, 2005). Thus, these findings suggest that memory decline in healthy aging is more dependent on frontal than MTL deficits, whereas the opposite pattern is more characteristic of pathological aging (see West, 1996; Buckner, 2004, for reviews). In view of these findings, clinical studies aimed at an early diagnosis of age-related pathology have mainly targeted changes in MTL (Nestor et al., 2004). Yet the studies reviewed in this chapter clearly indicate that healthy older adults are also prone to MTL decline. Hence, rather than focusing on MTL deficits alone, diagnosis of age-related pathology may be improved by employing some type of composite score reflecting the ratio between MTL and frontal decline.

In terms of MTL dysfunction in healthy and pathological aging, it is also critical to assess the specific type or loci of MTL dysfunction. Critically, a decline in hippocampal function can be seen in both healthy aging and AD. Thus, even though hippocampal volume decline is an excellent marker of concurrent AD (Scheltens et al., 2002), it is not a reliable measure for distinguishing normal aging from early stages of

the disease (Raz et al., 2005). In contrast, changes in the entorhinal cortex are not apparent in healthy aging (**Figure 3**), but they are present in early AD patients with only mild impairments (Dickerson et al., 2004). In a discriminant analysis, Pennanen and colleagues (2004) showed that, although hippocampal volume is indeed the best marker to discriminate AD patients from normal controls, the volume of the entorhinal cortex is much better in distinguishing between incipient AD (mild cognitive impairment, MCI) and healthy aging. Finally, it should be noted that, despite the rigorous screening procedures typical of functional neuroimaging studies of healthy aging, it remains possible that early symptoms of age-related pathology went undetected in some of the studies reviewed in this chapter.

3.28.3.6 Summary

In this chapter, we reviewed behavioral, anatomical, and functional neuroimaging evidence highlighting the role of PFC and MTL regions in age-related decline in EM function. The chapter focused on two major factors thought to underlie age-related memory decline and strongly linked to PFC and MTL function, namely, deficits in executive function and deficits in binding processes. In line with a reduction in PFC and MTL function, we discussed behavioral studies indicating that age deficits are most pronounced on tasks that put a great demand on executive and binding operations, respectively. We also discussed anatomical studies indicating a general decline with age in the anatomy and physiology of PFC and MTL. Linking these behavioral and anatomical findings, we discussed functional neuroimaging studies that generally showed age-related decreases in PFC and MTL activity during both EM encoding and retrieval. Yet some of these studies also found preserved or increased levels of PFC or MTL activity in older adults, which may be compensatory. Regarding PFC, several EM studies have found an age-related increase in contralateral PFC activity leading to an overall reduction in frontal asymmetry in older adults (HAROLD). As discussed, studies that divided older adults into high and low performers provided strong support for the idea that HAROLD reflects a successful compensatory mechanism. Regarding MTL, several EM studies reported age-related decreases in MTL activity, particularly during EM encoding. Yet studies of EM retrieval have also found age-related increases in MTL activity. Recent findings suggest that at least some of these increases reflect a compensatory shift from hippocampal-based recollection processes to parahippocampal-based familiarity processes. In sum, in view of the substantial changes in PFC and MTL that take place when we grow older, a reduction in EM function seems inevitable. Yet our review also suggests that some older adults may cope well with this reduction by shifting to alternative brain resources within PFC and MTL that can compensate for the general deficits in executive and binding operations underlying age-related EM decline.

3.29 Alzheimer's Disease: Neurostructures

A. M. Brickman, Columbia University, New York, NY, USA

M. S. Buchsbaum, Mount Sinai School of Medicine, New York, NY, USA

3.29.1 Introduction

3.29.1.1 Early Alzheimer's Disease and Mild Cognitive Impairment

Alzheimer's disease (AD) is a neurodegenerative disorder that primarily affects elderly individuals and is characterized by a progressive and gradual decline in cognitive, functional, and behavioral abilities. Despite relatively good characterization of the clinical progression of AD, its underlying pathophysiological mechanisms are still poorly understood. The diagnostic criteria for AD require the presence of a primary memory disorder with at least one other affected cognitive domain and an associated deficit in activities of daily living (McKhann et al., 1984). It is now well recognized, however, that by the time an individual meets these frank diagnostic criteria, the pathologic progression of the disease has reached a more moderate severity. As a result, investigators are increasingly attempting to diagnose AD in its

'preclinical' stage, which has led to a relatively new diagnostic entity termed 'mild cognitive impairment' (MCI). The MCI classification comprises individuals who are at elevated risk for developing dementia because they have subjective cognitive complaints and have objective evidence of suboptimal cognitive function (Petersen and Morris, 2005).

Despite recent refinements in the characterization of the phenotype of AD, there has been an emphasis on the development of several important disease-related biological measurements. Currently, the sensitivity and specificity for separating early AD and controls by neuropsychological assessment (sensitivity 95%, specificity 89%) (Salmon et al., 2002) and magnetic resonance imaging (MRI) (Laakso et al., 1998) (hippocampal volume sensitivity 82%, specificity 97%, see also Matsuda et al., 2007) are similar. The development of objective biological markers for AD pathology and disease severity, in conjunction with neuropsychological evaluation, is crucial for several reasons. First, pharmacological interventions for disease modification may only be effective for individuals who are at risk for developing AD or who are at the earliest stages of the disease. Second, biomarkers that reflect disease pathology are needed to evaluate the effectiveness of interventions in reversing the disease process. Finally, biological measurement can increase specificity of the AD diagnosis by differentiating processes that are due to AD pathology from other neurodegenerative dementias and cognitive changes due to normal or average aging.

3.29.1.2 Structural Brain Imaging

Recent advances in the acquisition and analysis of MRI data afford the remarkable capability of visualizing and quantifying age-associated changes in brain morphology. Structural MRI protocols can be used to examine macrostructural changes – gross differences in tissue volume that reflect parenchymal atrophy – or microstructural changes – fiber tract integrity and pathology that can be altered due to subtle changes in myelin-associated pathology. In the current chapter, we explore the role of structural MRI as a potential diagnostic tool and its utility as a disease biomarker in the characterization of Alzheimer's patients. In conjunction with other imaging modalities and with detailed clinical data, structural MRI has emerged as a promising biological tool that has received a large amount of study in the context of AD characterization.

Before considering the role of MRI in characterizing macro- and microstructural changes seen in AD, it is important to examine what we have learned about the normal aging process from MRI. A fundamental problem of diagnosing AD at its earliest stages lies in the ability to disentangle clinical or biological changes that are attributable to normal aging from those that are due to a neurodegenerative process. Here, we discuss the patterns of neuromorphological changes that appear in normal aging captured by MRI and evidence that age-associated neuropsychological changes are at least somewhat attributable to the observed brain structural changes.

3.29.2 Normal Aging and Brain Volume Loss

3.29.2.1 Total Brain Volume across the Life Span

Over the past 20 years, investigators have used structural MRI to examine the macrostructural changes across the healthy life span. While there has been variability in findings across studies, perhaps due to discrepancies in methodology and sample characteristics, some consistent patterns have emerged. In terms of total brain volume, one large cross-sectional study that quantified total paranchymal volume across the entire life span demonstrated that the brain volume of individuals aged 71–80 years was smaller than that of healthy 2- and 3-year-old participants (Courchesne et al., 2000). Age-associated total volume loss has been shown in both research samples (Resnick et al., 2000; Good et al., 2001) and in population studies (DeCarli et al., 2005). Total brain volume may begin to decline as early as age 30, continue linearly until about age 60, and then decline at a more precipitous rate. In one of the few longitudinal examinations of total brain volume, Resnick and colleagues showed an annual decline of about $5.4 \pm 0.3\,cm^3$ in healthy individuals above age 60. The ventricular system, which may provide an index of global brain atrophy (**Figure 1**), is reported to increase at a rate of about 3% annually (Raz and Rodrigue, 2006).

3.29.2.2 Total Brain Gray versus White Matter Macrostructural Loss

There is some debate in the literature regarding the relative prominence of gray versus white matter structural changes associated with normal aging (Peters and Rosene, 2003). Age-associated white matter loss may

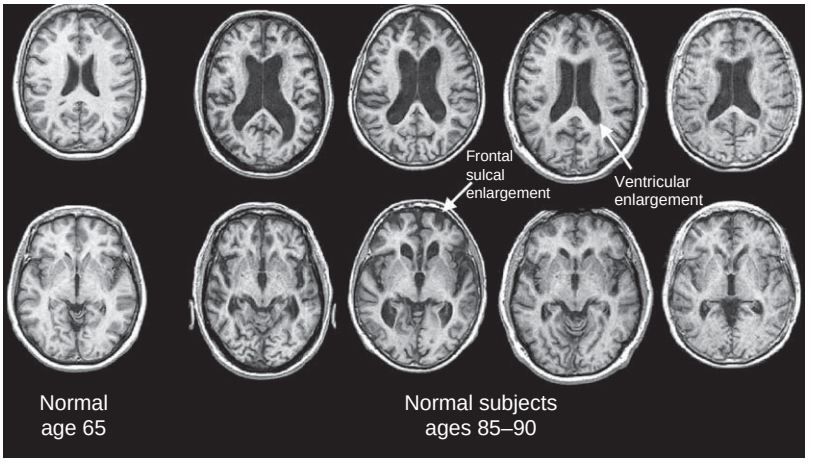

Figure 1 MRI in normal elderly and normal very old subjects. Note ventricular enlargement, frontal sulcal enlargement, and greater prominence of sulcal markings in very old subjects ages 85–90.

be a manifestation of myelin degeneration (Peters, 2002) and consistent with the idea that the aging brain is characterized by deficient neuronal connectivity (Albert, 1993). Indeed, several studies have demonstrated either a relatively greater age-associated decline in white matter than gray matter or white matter decline in the absence of gray matter decline (Guttmann et al., 1998; Franklin et al., 2002; Bartzokis et al., 2003; Resnick et al., 2003). However, the opposite pattern has also been observed: age-associated gray matter changes have been observed in the absence of white matter changes (Blatter et al., 1995; Thompson et al., 2003; Sullivan et al., 2004). Discrepancies may be due to a number of factors. First, white matter may increase up to age 45–55 and then begin to decrease (Bartzokis et al., 2001) so that white matter loss may only appear in quite old samples (**Figure 2**). Second, and similarly, approaches to segmentation (e.g., probabilistic, Bayesian, pixel intensity driven) may differ across laboratories both in terms of segmentation algorithm and intensity thresholds. Finally, white matter changes may be subtle and heterogeneous and could best be captured through examination of white matter microstructure or white matter pathology.

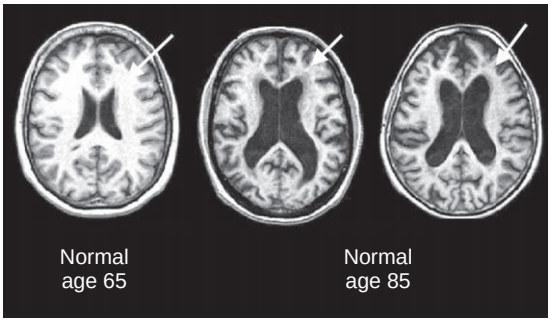

Figure 2 Reduced white matter in over-85-year-old normal individuals.

3.29.2.3 Total White Matter Microstructural Changes

In addition to white matter volume, which can be appreciated with T1-weighted high-resolution anatomical MR images, there has been a recent emphasis on the quantification of anisotropy and white matter hyperintensities (WMH) on diffusion-weighted and FLAIR-weighted or T2-weighted imaging, respectively. The most commonly derived measurement from diffusion tensor imaging (DTI) is fractional anisotropy (FA). Because white matter fibers are mostly highly organized in parallel orientation, water motion is restricted, causing FA measurements derived from white matter to be relatively more anisotropic than gray matter or cerebrospinal fluid (CSF). Anisotropy refers to the orientation and coherence of white matter fiber tracts and may be a more sensitive marker of the integrity of myelin sheaths than examination of bulk volume. For example, studies have been inconsistent in demonstrating bulk volume white matter change as a function of normal aging, but diffusion tensor studies have been much more unified in revealing anisotropic changes across the life span (Nusbaum et al., 2001; O'Sullivan et al., 2001; Pfefferbaum and Sullivan, 2003; Head et al., 2004; Sullivan and Pfefferbaum, 2006), which may be linear beginning at about age 20 (Pfefferbaum

and Sullivan, 2003). In terms of regional distribution of age-associated anisotropic changes, DTI studies have generally mirrored positive volumetry studies in demonstrating an anterior-to-posterior gradient of effects (Head et al., 2004; Pfefferbaum et al., 2005; Salat et al., 2005).

WMH are areas of increased lucency appearing on FLAIR- or T2-weighted images. They can be discrete, or punctate, or may appear more confluent with the lateral ventricles (**Figure 3**). Until recently, WMH were considered clinically irrelevant, but a culmination of sample- and population-based research has demonstrated their functional significance (Malloy et al., 2007). With the exception of those that appear as smooth 'rims' or 'caps' along the surface of the lateral ventricles, WMH are thought to be ischemic in nature and reflect rarefaction of myelin, breakdown of vessel endothelium, and microvascular disease (Fazekas et al., 1993). The presence of WMH is common among normal elderly adults, and chronological age appears to be the most salient predictor of severity (Jernigan et al., 1991; de Leeuw et al., 2001). Vascular risk factors, such as hypertension, also account for much variability in severity of WMH (de Leeuw et al., 2001).

3.29.2.4 Regional Differences in Brain Volume Loss with Age

3.29.2.4.1 Lack of uniformity of brain volume loss

Although consideration of total brain volume across the life span is important in establishing gross anatomical changes, a closer examination of regional effects can help identify specific neurobiologic systems that selectively decline with age. Normal aging is associated with a 'posteriorization' of the pattern of preserved tissue. In cortical areas, there appears to be a consistent anterior-posterior gradient in degree of atrophy across the adult life span, with greater frontal than posterior atrophy and indication from functional imaging that cognitive functions may be mediated by more posterior locations with advancing age (e.g., Hazlett et al., 1998). Comprehensive findings of age-associated regional decline have been reviewed in great detail elsewhere (Raz, 2000, 2004; Raz and Rodrigue, 2006). In this chapter we will focus on the frontal lobe, the area of greatest decline, and the temporal lobe, the area most altered in AD.

3.29.2.4.2 Frontal lobe volume loss and aging

Most studies that have examined regional cortical effects with aging report that the greatest amount of age-associated volumetric loss occurs in frontal cortical regions (DeCarli et al., 1994; Raz et al., 1997; Salat et al., 1999; Tisserand et al., 2002; Resnick et al., 2003), followed by the temporal lobes (Cowell et al., 1994; Sullivan et al., 1995), with relative sparing of the occipital lobes and primary sensory regions (Bartzokis et al., 2001; Good et al., 2001). A recent review by Raz and Rodrigue (2006) nicely contrasts cross-sectional structural MRI studies and longitudinal studies, and a review by Hedden (Hedden and Gabrieli, 2005) emphasizes frontal-striatal aging with more posterior sparing.

Although MRI studies have shown consistent age-associated reductions in frontal lobe volume, it is unclear whether the changes are due to selective reduction of tissue type within specific frontal subregions. To address this issue, we examined age-related relative gray and white matter volume changes in four discrete prefrontal brain regions (Brickman et al., 2005). Seventy neurologically and cognitively healthy adults were recruited, with 10

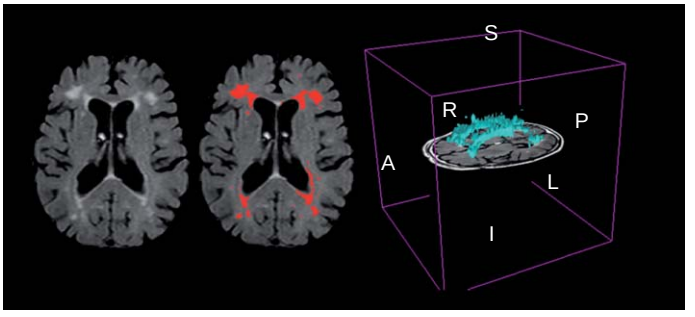

Figure 3 White matter hyperintensity surrounding ventricular cavity and extending into prefrontal region in patient with AD. Left: skull-stripped FLAIR image. Middle: Computer algorithm identifies hyperintensity regions. Right: Hyperintensities represented in three dimensions in cyan. Note shape similar to ventricular cavity.

subjects represented in each age decade from 20s to 80s, and scanned with high-resolution structural MRI. Prefrontal regions were segmented into orbital (Brodmann Areas [BA]: 11, 12, 47), medial/cingulate (BA: 24, 25, 32), dorsolateral (BA: 44, 45, 46), and lateral (BA: 8, 9, 10) gray and white matter using a stereotaxic atlas method (**Figure 4**). Total frontal lobe volume declined linearly across the seven decades, with the lateral and cingulate frontal areas showing the greatest amount of decline (**Figure 5**). In general, gray matter showed a gradual decline across the decades, whereas white matter remained

(middle) Perry atlas with computer drawn sectors and (right) matching coronal MRI with computer-drawn sectors. Middle row: (left) Perry atlas in 3D position within MRI brain surface and (right) computer-drawn sectors as skeleton. Bottom row: Change in age per year for each of the Brodmann areas of the brain: color scale shows relative change per year × 1000.

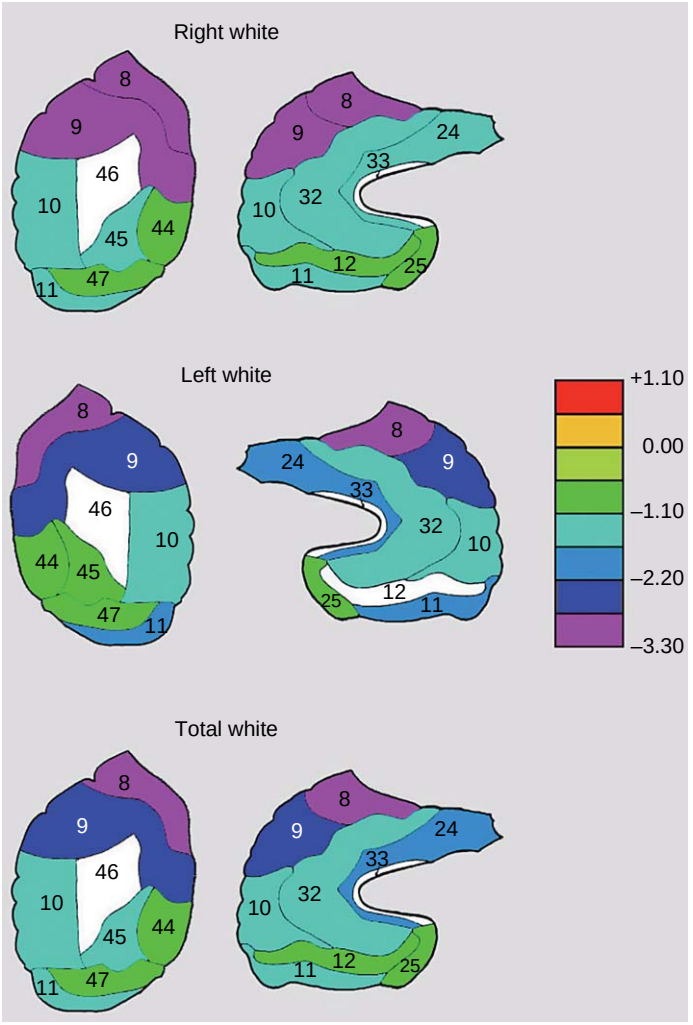

Figure 5 Rate of change of relative gray matter volumes in prefrontal cortex of 70 normal controls ages 20–90. Greatest rate of volume loss is in dorsolateral areas 8 and 9 and, in the medial frontal lobe, area 32.

relatively stable until the last two decades, particularly in lateral, dorsolateral, and orbital regions. These findings are consistent with others that have suggested that white matter decline may be more prominent among the very old (Salat et al., 1999; Raz et al., 2005).

Findings of subcortical gray matter structures that are involved in frontal circuitry have been less consistent. Most (Krishnan et al., 1990; Jernigan et al., 1991; McDonald et al., 1991; Murphy et al., 1992; Raz et al., 1995; Gunning-Dixon et al., 1998; Zimmerman et al., 2006) but not all (Raz et al., 2000) studies that have examined the caudate nucleus have shown an age-associated volumetric loss. Those examining the putamen have been less consistent; some have demonstrated that increased age is associated with decreased volume (McDonald et al., 1991; Gunning-Dixon et al., 1998; Raz et al., 2000), and others have shown no significant difference in the putamens of older subjects relative to younger (Murphy et al., 1992). In our own study (Brickman et al., 2003), increased age was associated with a decrease in the absolute size of the caudate and no change in absolute putamen size. However, when considering the relative size of the two structures, increased age was associated with an increase in putamen size and no differences in caudate size, indicating a relative age-associated preservation of these structures. Findings regarding the thalamus have been similarly discrepant (Raz and Rodrigue, 2006).

3.29.2.4.3 Temporal lobe volume loss and aging

In detailed studies comparing the frontal, temporal, parietal, and occipital lobe volumes, Allen et al. (2005) found temporal lobe volume was relatively stable from age 20 to 60 but then decreased and was best fit with a cubic function. In contrast, frontal lobe gray declined in a linear trend across the life span.

Some investigators have reported age-associated decline in hippocampal volume (**Figure 6**) (Murphy et al., 1996; Mu et al., 1999; Pruessner et al., 2001; Raz et al., 2004), while others have not (Sullivan et al., 1995; Good et al., 2001). Longitudinal analyses of hippocampal volume have suggested a 1.5% volume loss per year in healthy individuals ranging in age from 18 to 42 years (Pruessner et al., 2001), though another longitudinal study observed a similar rate of decline but only among individuals over 50 (Raz et al., 2004).

Differences in hippocampus findings across studies may be due to quantification protocols. For example, Raz et al. (2004) explicitly compared age effects in the entorhinal cortex to the hippocampus proper and found a selective age-associated decline in the hippocampus only. Good et al. (2001), who did not show a cross-sectional association between age and hippocampal density, used voxel-based morphometry (VBM), which involves nonlinear spatial normalization of the MR images that may distort small structures.

3.29.2.4.4 Multivariate approaches to regional brain loss with age

Past examinations of neuromorphological changes across the healthy adult life span have primarily relied on region-of-interest or voxel-based approaches. While these cross-sectional and longitudinal efforts have illuminated a tremendous amount of information about structural changes, they do not consider the relationship among brain regions. We recently conducted the first study that has applied a multivariate 'covariance' approach to understanding distributed patterns of age-associated morphological change (Brickman et al., 2007). Using a multivariate approach based on principal components analysis and the subprofile scaling model, which captures sources of between- and within-group variation, patterns of gray and white matter were identified that could reliably discriminate between younger and older participants. Consistent with previous efforts, these patterns included anterior cortical regions, but they also included widespread posterior cortical and subcortical regions. Forward application of the patterns to an independent sample (Brickman et al., in press) showed good stability of the identified gray matter pattern, but not white matter. The findings were similar to a recent study by Alexander and colleagues, who also used a principal components approach (Alexander et al., 2006).

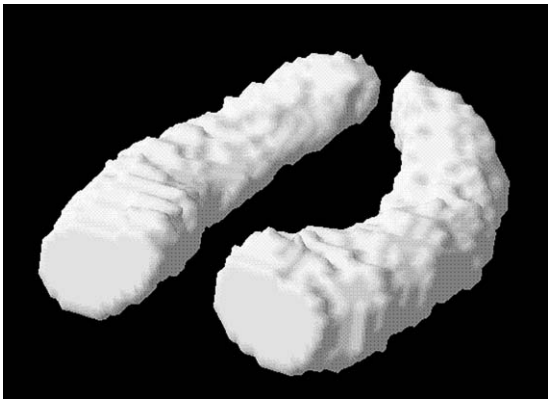

Figure 6 Three-dimensional representation of hippocampus based on tracing of 70 coronal slices. Hippocampus is viewed from the back of the head looking down and forward.

3.29.3 Cognition and Brain Volume Loss across the Normal Adult Life Span

3.29.3.1 Executive Function and Frontal Lobe Aging

The exact pattern of changes in neuropsychological function across the adult life span remains somewhat elusive. One compelling, though controversial (Greenwood, 2000; Band et al., 2002), theory, termed 'Frontal Aging Hypothesis' (West, 1996, 2000) proposes that cognitive functions mediated by the frontal lobes are most vulnerable to the effects of age and selectively decline in normal, healthy aging. Although cognitive functions supported by more posterior regions clearly decline in normal aging (Greenwood, 2000; Small, 2001), the theory argues that there is greater magnitude of decline for processes mediated by the frontal lobes.

Executive function refers to a set of cognitive processes involved in complex goal-directed behavior, adaptation, planning, cognitive flexibility, and allocation of attentional resources (Loring, 1999). Although the construct is somewhat heterogeneous, comprised of several components, there is good consensus in the neuropsychological literature for its standard

assessment (Lezak, 1995). Executive function is thought to be mediated by the frontal lobes (Elliott, 2003) and by frontal-striatal circuitry (Alexander et al., 1986; Alexander and Crutcher, 1990; Chow and Cummings, 1999; Lichter and Cummings, 2001). Several lines of research indeed demonstrate particular age-associated decline in executive functioning (Whelihan and Lesher, 1985; Ardila and Roselli, 1989; Daigneault et al., 1992; MacPherson et al., 2002). In our own study, cluster analysis was applied to performance on a battery of neuropsychological tests to define three cognitive profiles among healthy older adults (Gunstad et al., 2006). Relative to younger adults, older participants clustered in to one of three neuropsychologically defined groups: one with relatively poor performance across all cognitive domains, one with selective executive impairment alone, and one with executive impairment and psychomotor slowing. Despite the heterogeneity in neuropsychological profiles, all groups evidenced a consistent reduction on performance of executive tests relative to younger adults.

3.29.3.2 Normal Age-Associated Cognitive Decline Is Partially Attributable to Morphological Change

A critical question is whether the morphological changes observed with normal aging account for some of the cognitive changes that occur across the adult life span. On a face-valid level, normal age-associated cognitive changes are characterized primarily by a decline in executive abilities, and structural changes show a general pattern of anterior-to-posterior age-associated atrophy or anisotropic changes and increases in WMH, suggesting a link between the two. More recent work has addressed this issue by comparing regional morphology to performance on batteries of neuropsychological tests. Indeed, several reports suggest that age-associated morphological changes mediate normal age-associated cognitive decline. Gunning-Dixon and Raz (2003) reported age-related variability on a task of executive functioning that was mediated by prefrontal cortex volumes. Raz and colleagues (Raz et al., 1998) also examined the relationship between several cortical volumes and performance on cognitive tests of executive functioning, working memory, explicit memory, and priming in healthy adults across the life span. Findings indicated that a decrease in dorsolateral prefrontal gray matter volume mediated age-related cognitive deficits on a test of executive functioning. Further support for a role of the prefrontal cortex in age-associated cognitive decline was provided in a longitudinal voxel-based morphometry study (Tisserand et al., 2004), where age-related cognitive decline was associated with decreased gray matter density in prefrontal and medial temporal lobes. We showed that chronological age interacts with the gray matter volume of the lateral frontal lobe in predicting a summary score of executive test performance, suggesting a stronger relationship between lateral frontal lobe volume and executive functioning among older healthy adults (Zimmerman et al., 2006). Similarly, we demonstrated that relative frontal lobe white matter volume mediated the association between chronological age and performance on tasks of executive ability and declarative memory (Brickman et al., 2006). Using a multivariate approach, we demonstrated that the degree to which older adults evidenced a regional pattern of age-associated grey and white matter atrophy was associated with performance on tests of executive function and memory (Brickman et al., 2007).

3.29.3.3 Hippocampal Aging and Memory Function

A particularly important consideration when discussing normal aging in the context of AD is the specific role of the hippocampus. While it is arguable that many cortical and subcortical areas are involved with several aspects of cognition, it has long been known that medial temporal lobe structures, particularly the hippocampus and its anatomically related structures, play a specialized role in learning and memory (Scoville and Milner, 1957; Rempel-Clower et al., 1996). However, attempts to understand the relationship between the size of the hippocampus and memory function have been remarkably mixed (Van Petten, 2004). A recent meta-analysis reported that, on average, the association between hippocampal volume and memory test performance was negative among studies that included children and young adults and positive among studies that included older adults (Van Petten, 2004). Notably, the consistency of the observed relationship among older adults was weak, and the average magnitude of the correlation coefficients between hippocampal volume and memory test performance among older adults was small. This important observation highlights the heterogeneity in reported hippocampal volume effects on cognition among healthy older adults and suggests that the volume of the

hippocampus may be positively related to cognition only in the face of age-associated pathology.

3.29.3.4 White Matter Microstructure and Cognition

Relatively few studies have examined the impact of age-related differences in anisotropy and their impact on cognition. One study showed that decreases in anisotropy in the anterior limb of the internal capsule were associated with poorer performance on a visual target detection task (Madden et al., 2004). A recent study by Grieve and colleagues demonstrated significant age-associated decreases in anisotropy in prefrontal and parietal regions, which were associated with performance on neuropsychological tests of executive function (Grieve et al., 2007).

The severity of WMH is also associated with poorer cognitive abilities among older adults (Gunning-Dixon and Raz, 2000). Cook and colleagues (Cook et al., 2002) identified an association between subcortical WMH volume and cognitive functioning in older adults who performed within normal limits on neuropsychological tests. A recent report from the Framingham study showed that older individuals with greater WMH volumes performed significantly worse on visuospatial, visual scanning, speed, and learning tasks (Au et al., 2006).

In summary, a long history of examination of cognitive changes with normal aging and their neuroanatomical correlates reveals a general pattern with a large amount of heterogeneity. The 'frontal aging hypothesis' is one convenient approach to summarizing the changes observed with normal aging; cognitive abilities, such as executive functions, which are mediated by frontal lobe circuitry, appear to decline with age at the greatest rate. Structural changes parallel these findings, with an anterior-posterior gradient of age-associated atrophic changes. Findings regarding the relative age-associated differences in white and gray matter bulk volume are still inconsistent, but advances in white matter imaging with diffusion- and FLAIR-weighted sequences suggest that white matter changes may be largely microstructural in nature. Finally, whether normal age-associated changes in hippocampal volume impact cognitive abilities is still unclear; one reasonable possibility for discrepant findings is that hippocampal structure impacts cognition only in the face of pathology.

3.29.4 Alzheimer's Disease and MCI as Cognitive Disorders

AD is a cognitive disorder that can only be definitively diagnosed through microscopic examination of brain tissue. Most antemortem diagnostic schemes (McKhann et al., 1984; American Psychiatric Association, 1994) require a significant decline in memory function accompanied by an impact on functional abilities. It is therefore not surprising that neuropsychological measures of memory ability, particularly delayed recall on list-learning tests, have been repeatedly demonstrated to discriminate between those meeting diagnostic criteria for AD and otherwise similar elderly control subjects (Welsh et al., 1991), even among very mildly impaired individuals (Salmon et al., 2002). Although memory impairment is the defining cognitive feature of AD, differences between mildly affected AD patients and neurologically healthy controls or individuals with other types of dementia have been reported in other cognitive domains such as global cognitive status (Salmon et al., 2002), verbal fluency (Monsch et al., 1992; Salmon et al., 2002), and executive function (Lafleche and Albert, 1995). As, by definition, the cognitive deficits in AD are progressive, patients ultimately evidence severe deficits across domains, and in later stages of the disease, the neuropsychological profile is defined by severe global impairment.

Although neuropsychological evaluation can detect AD with a high degree of sensitivity and specificity when individuals meet diagnostic criteria (Salmon et al., 2002), it is now clear that the disease pathology is present up to years before individuals reach the point of frank cognitive impairment (Morris et al., 2001). To deal with this issue, the term 'mild cognitive impairment' has been applied to describe individuals who may be at particular risk for future dementia because their cognitive abilities fall between what would be expected for normal aging and the degree of severity seen in frank dementia (Petersen et al., 1999). A major thrust in defining the construct has been the assumption that secondary prevention is more effective than tertiary prevention (Petersen, 2007), underlying the necessity for the identification of the disease at its earliest possible point. Current algorithms for diagnosis of MCI draw a distinction between 'amnestic' subtypes and 'nonamnestic' subtypes, based on the whether memory is the primary cognitive domain evidencing abnormal ability in the

context of essentially normal functional activities (Petersen, 2004). Ostensibly, it is the amnestic MCI subtype that is most specifically associated with future development of AD. It is important to note that the concept of MCI would be largely irrelevant if there were objective clinical tools that could identify Alzheimer's pathology at its earliest manifestations in the brain. Nonetheless, the development and subsequent refinement of the MCI concept have increased diagnostic sensitivity and specificity and have stimulated the need for the identification of biomarkers. In the following section we explore the structural changes associated with AD and MCI that have been identified with MRI.

3.29.5 Brain Volume Changes in Alzheimer's Disease

3.29.5.1 Total Brain Volume

One of the more consistent findings in the structural neuroimaging literature involving AD is that markers of total brain atrophy, including total brain volume or relative volume to total intracranial space, are accentuated, and ventricular size or amount of sulcal cerebral spinal fluid is reduced compared to controls. These measures may provide information about the overall health of the brain or may provide relative markers for overall stage of the disease, but tell us little about specific neurobiological underpinnings. Nonetheless, both cross-sectional (Seab et al., 1988; Murphy et al., 1993; Lehericy et al., 1994; Ohnishi et al., 2001) and longitudinal (Cuénod et al., 1993; Fox et al., 1996, 1999; Tanabe et al., 1997; Chan et al., 2001a, 2003; Du et al., 2001; Thompson et al., 2003) data show marked reduction of total brain volume or expansion of the ventricular system, including increases in the AD brain, that is related to the severity of the disease (Seab et al., 1988; Murphy et al., 1993; Fox et al., 1996, 1999). Rates of total brain volume decline per year have been reported to range from less than 1% to greater than 12%, with an average reported *per annum* percentage loss of total volume loss of about 3.6% (Ramani et al., 2006). While the rate of total brain atrophy is greater in AD and in individuals who eventually develop AD than in matched controls, markers of total brain atrophy are not specific to the AD diagnosis. Thus, measures of total brain volume may be useful in staging severity of the disease but may have very little differential diagnostic clinical utility.

3.29.5.2 Regional Brain Changes

The earliest clinical application of structural neuroimaging to dementia by de Leon (de Leon et al., 1979), Tsai (Tsai and Tsuang, 1979), and others alerted researchers to the potential of the approach. An early application to AD was for the purpose of ruling out other brain pathologies, such as cortical infarction or diffuse cerebral vascular disease, that may account for the cognitive changes observed in the patient (McKhann et al., 1984). However, researchers quickly began to recognize the potential utility of MRI for the appreciation of more subtle aspects of the disease. The majority of structural MRI studies of AD have asked the question, "Are there aspects of morphology that can reliably differentiate patients with AD from otherwise similar older adults?" In more recent years, this question has been refined to parallel developments in the clinical nosology of AD. For example, newer studies focus on morphological differences among individuals with MCI, AD, and matched controls. Furthermore, improvement in the resolution of acquired structural MRI scans has advanced our ability to quantify smaller brain structures with good reliability, and recent efforts have been informed by pathological studies of AD in identifying regions of interest that are affected at the earliest stages of the disease. As reviewed in the sections that follow, more posterior regions of the brain tend to show abnormalities in AD, while frontal lobe change (reviewed in the section titled 'Frontal lobe volume loss and aging') has been characteristic of normal aging (**Figure 7**).

Longitudinal analysis of changes in brain structure and the use of baseline analysis of morphology to predict future decline have been other recent methodological advancements in the understanding of brain structure in AD. Finally, although not the focus of this review, the combination of structural

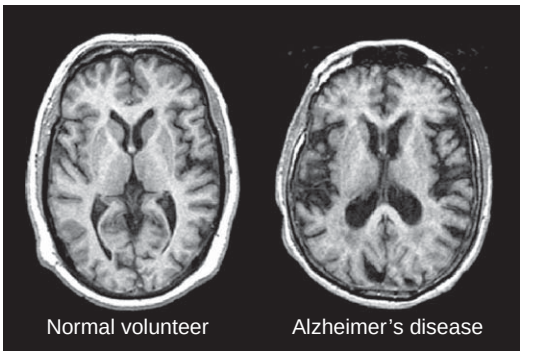

Figure 7 Typical MRI in AD.

imaging protocols and functional brain analysis might ultimately be the most powerful approach to *in vivo* characterization of the AD brain.

3.29.5.2.1 Frontal and parietal lobes

Despite the marked frontal lobe changes observed in normal aging, relatively few investigators have examined gross lobar volumetric decreases in AD outside of the temporal lobe findings reviewed in the next section. One report suggested that AD patients in mild stages of the disease have reduced left, but not right, frontal lobe volumes compared to controls (Laakso et al., 1998); others have reported bilateral frontal lobe volumetric reduction in more advanced stages (Rusinek et al., 1991; DeCarli et al., 1995). AD-related volumetric loss has also been reported in the parietal lobes (Foundas et al., 1997; Kidron et al., 1997) and occipital lobes (Rusinek et al., 1991). Effect sizes for frontal lobe volume in AD versus normal volunteers and frontotemporal dementia versus normal volunteers were 0.63 (our computation) and 1.86, respectively. In this study, due to very large standard deviation in anterior temporal lobe size in AD (mean 28.8, SD 30.5), temporal lobe effects size for AD versus normal volunteers was only 0.21 (our computation).

3.29.5.2.2 Temporal lobe structures

One early study that quantified total hippocampal volume showed about a 40% reduction among individuals in early to moderate stages of dementia severity (Seab et al., 1988). This finding is generally consistent with other reports of bilateral hippocampal proper volume loss, ranging from about 10% (Killiany et al., 2002) up to about 60% (Bobinski et al., 1995; reviewed in Ramani et al., 2006). In fact, most studies that have quantified total hippocampal volume have indeed shown significant volume reduction in AD patients compared to matched controls (Krasuski et al., 1998; Bobinski et al., 1999; Csernansky et al., 2000; Du et al., 2001). Thus, the culmination of evidence suggests reliable and marked volume loss in the hippocampus proper in mild, moderate, and severe AD.

Pathological studies confirm, however, that the earliest deposition of the AD-defining β-amyloid plaque occurs in the entorhinal cortex (Hyman et al., 1984, 1990; Arnold et al., 1991; Braak et al., 1993; Gómez-Isla et al., 1996). Recent advances in visualizing the boundaries of medial temporal lobe structures and more reliable region-of-interest (ROI) protocols have allowed for the quantification of the entorhinal cortex *in vivo*. These advances have led to the effort to increase the specificity of volumetric studies in AD. Juottonen and colleagues (Juottonen et al., 1998) used a histologically based protocol to identify and measure the entorhinal, perihinal, and temporopolar cortices of patients with AD versus controls. The authors found a 40% volume reduction that was specific to the entorhinal cortex. Volume reductions in the entorhinal cortex discriminated between patients and controls with 92% accuracy. While this finding is reminiscent of the observed 40% reduction in the hippocampus proper in AD (Seab et al., 1988), authors that have specifically contrasted entorhinal cortex and hippocampus volume within the same subjects have observed an important dissociation. For example, Killiany and colleagues (Killiany et al., 2002) observed about a 60% reduction in entorhinal cortex volume but only a 10% reduction in hippocampus volumes among patients with AD compared to controls. Other reports have shown more subtle differences, but usually in the same direction, with relatively greater entorhinal cortex volume reduction than hippocampus volume reduction in AD (Bobinski et al., 1999; Du et al., 2001). Further, the degree of entorhinal cortex atrophy in AD is correlated with the distribution of neurofibrillary tangles, one of the defining pathological markers of AD (Bobinski et al., 1999).

While hippocampus and entorhinal cortex volume analysis appears to reliably differentiate those with AD from matched controls, discrimination from other age-associated neurodegenerative diseases based on these measures alone is poor (de Leon et al., 2007). For example, global atrophy rates are similar between patients diagnosed with AD and those diagnosed with Lewy body dementia (Hashimoto et al., 1998; Barber et al., 1999; O'Brien et al., 2001; Minoshima et al., 2002), and entorhinal cortex and hippocampus volume are similarly affected in individuals with frontotemporal dementia (Frisoni et al., 1999; de Leon et al., 2007).

Generalized atrophy in the temporal lobe has also been reported (Cuénod et al., 1993; Killiany et al., 1993; Kidron et al., 1997; Juottonen et al., 1998), although one study that examined the volume of the superior temporal gyrus showed no difference between AD patients and controls (Bobinski et al., 1999).

Although morphometric studies of the hippocampus and entorhinal cortex in AD are important in establishing the ability to use structural MRI to visualize pathologically related volumetric loss, the more

critical issue is whether MRI can be used to detect AD-related changes at earlier stages of the disease. Thus, many authors have cross-sectionally compared individuals with MCI to matched controls. As noted, MCI can be thought of as a 'preclinical' state of AD, and so-called 'conversion rates' to meeting full diagnostic criteria for AD have been reported to be remarkably high by some research groups (Petersen, 2004, 2007), although 'MCI' is not necessarily synonymous with 'early AD,' and several individuals meeting criteria for MCI do not ultimately convert (Petersen et al., 2001; Ritchie et al., 2001; Larrieu et al., 2002). Studies that have used MRI to compare MCI patients to controls have demonstrated statistically reliable increased amounts of medial temporal lobe atrophy in the former group (Kaye et al., 1997; Jack et al., 1999; Visser et al., 1999; Karas et al., 2004; reviewed in Mosconi et al., 2007). Not surprisingly, within the medial temporal lobe, significant volume reduction in the hippocampus and entorhinal cortex has been reported among patients with MCI or very early AD compared to healthy controls, with values falling in the intermediate range between controls and more-moderately demented AD patients (Juottonen et al., 1998; Bobinski et al., 1999; De Toledo-Morrell et al., 2000; Xu et al., 2000; Chan et al., 2001b; Dickerson et al., 2001; Du et al., 2001; Pennanen et al., 2004; Wolf et al., 2004; Bell-McGinty et al., 2005; Apostolova et al., 2006; Devanand et al., 2007).

In addition to AD- and MCI-associated atrophic changes seen in hippocampus and entorhinal cortex, several studies have attempted to identify other disease-associated structural changes (Atiya et al., 2003; Ramani et al., 2006). These areas have generally paralleled the distribution of AD pathology and will be reviewed briefly here. Significant AD-related atrophy has been observed in other medial temporal lobe structures besides the entorhinal cortex and hippocampus, including parahippocampal gyrus (Kesslak et al., 1991; Ikeda et al., 1994; Jack et al., 1997; Callen et al., 2001; Suzuki et al., 2003) and amygdala (Scott et al., 1991; Lehericy et al., 1994; Jack et al., 1997; Krasuski et al., 1998). Effect sizes for the difference between controls and AD patients were larger for the amygdala (1.28) than hippocampus (0.99), indicating the salience of amygdala change (Basso et al., 2006).

3.29.5.2.3 Corpus callosum

Similar to studies of normal aging, there has been a recent interest in white matter volume and white matter markers of pathology among patients with AD. Janowsky and colleagues (Janowsky et al., 1996) compared the size of the corpus callosum in patients with AD versus controls and found significant reductions in the former. Teipel and colleagues (Teipel et al., 2002) studied the longitudinal progression of corpus callosum volume in AD and found an average annual rate of decline in the splenium of about 12% among patients relative to 1.5% in controls, and the rate of corpus callosum change was significantly related to the rate of clinical decline among the patient group. The splenium, isthmus, the body, and the rostral portion of the genu of the corpus callosum were significantly reduced in volume in AD (Chaim et al., 2007). Further, the size of the corpus callosum was related to the severity of scores on a test of memory.

3.29.5.2.4 Fornix and mamillary bodies

Significantly smaller volumes were observed in the fornix and mammillary bodies in patients with AD as compared with healthy controls and MCI participants (Copenhaver et al., 2006).

3.29.5.3 Longitudinal Analyses

Cross-sectional studies suggest that volumes of structures within the medial temporal lobe can be used to dissociate among groups of patients and roughly map onto the severity of the associated cognitive symptoms, as MCI and AD diagnoses are primarily based on severity of cognitive symptoms. More powerful approaches to understanding the structural underpinnings of the cognitive loss seen in MCI and AD include longitudinal analyses, structural analysis of baseline characteristics in the prediction of future cognitive decline, and individual differences studies comparing structural volumes to specific cognitive symptoms. Indeed, longitudinal analyses of AD patients compared to controls consistently show a greater rate of general atrophy among the patient group (Fotenos et al., 2005), which can be observed even within a 3- to 6-month longitudinal follow-up period (Bradley et al., 2002). Using boundary shift methods, Fox and colleagues have shown that individuals carrying the familial AD gene are dissociable from matched controls at baseline and in terms of greater atrophy rates over time (Ridha et al., 2006), as well as an increased likelihood of classification as AD among those with sporadic forms of the disease (Ridha et al., 2006). Boundary shift methodology as well as other anatomical mapping techniques allow for increased reliability in analysis of longitudinal

MRI data (Thompson et al., 2004). But traditional ROI approaches have also reliably dissociated longitudinal rates of change in AD from normal aging. For example, Weiner and colleagues, using manual tracing ROI approaches, demonstrated that the rate of volumetric loss of the entorhinal cortex among patients with AD was five times greater than that of controls and that the rate of volumetric loss was greater in entorhinal cortex relative to areas of cortex (Ezekiel et al., 2004). The pattern of results has generally paralleled that seen in cross-sectional studies of AD. That is, *per annum,* volume loss in AD patients ranges from about 3–4% in AD patients and about 0.4–1.5% in controls for the hippocampus proper, and 6–7% in patients and about 1.5% in controls for the entorhinal cortex (Jack et al., 1998, 2000; Du et al., 2001; Schott et al., 2003; reviewed in Ramani et al., 2006).

Most investigators agree that there are significant atrophic changes in medial temporal lobe structures among patients with MCI and AD that are much more marked than those observed in normal aging. A critical question is whether aspects of brain morphology at one point in time can predict future decline from one state to another (i.e., normal to MCI, MCI to AD). One study measured hippocampus volumes in 80 patients meeting diagnostic criteria for MCI and followed them longitudinally for an average of 32 months (Jack et al., 1999). Of the 80 participants, 27 converted to AD; baseline hippocampal volume significantly predicted future conversion to AD (relative risk = 0.69), even after controlling for relevant variables, such as neuropsychological test scores and age. Results from the same research group suggested that among MCI patients who cognitively decline, the rate of atrophy within the hippocampus is greater than in those who remain cognitively stable (Jack et al., 2000). Other studies have supported these general findings using visual rating scales or manual tracing hippocampus ROI protocols (Visser et al., 2002), although both classification accuracy and sensitivity appear to benefit from analysis of both hippocampus volume and other medial temporal lobe structures (Convit, 2000). Much like the cross-sectional data, volume of the entorhinal cortex best discriminates between those destined to decline cognitively and those who remain relatively stable (Killiany et al., 2000, 2002; Dickerson et al., 2001; Devanand et al., 2007). Volume decrease in the fornix and mamillary bodies has been suggested to become apparent at the point of conversion from MCI to AD (Copenhaver et al., 2006).

3.29.5.4 White Matter

3.29.5.4.1 White matter macrostructure

Bulk volume reduction of white matter has been a focus of recent investigation, with particular emphasis on the corpus callosum. Studies have been reliable in demonstrating volume reduction in this region (Janowsky et al., 1996; Hampel et al., 1998; Pantel et al., 1999; Black et al., 2000). Consistent with the crossing of temperoparietal fibers in the body of the corpus callosum, correlations between neuropsychological test scores and corpus callosum volume have been observed (Janowsky et al., 1996; Black et al., 2000; Chaim et al., 2007).

3.29.5.4.2 White matter microstructure

Several diffusion-based indices have been used to understand microstructural abnormalities associated with AD and MCI (Ramani et al., 2006). Among the more common is diffusion tensor imaging, which has been used by some research groups to lend support to a 'myelin-centered model' of pathological aging (Bartzokis, 2004; Bartzokis et al., 2004a,b). The distribution of anisotropic abnormalities in AD follows the observed volumetric changes and the known distribution of AD pathology (**Figure 8**). One study that compared measures of anisotropy among younger healthy adults, older healthy adults, and patients with AD found that older adults had significantly reduced measures of anisotropy in anterior regions, but that AD evidenced a reduction in anisotropy in more posterior regions without additional change in anterior regions (Head et al., 2004). Similarly, fractional anisotropy was reduced in white matter of the splenium of the corpus callosum but not the genu (Teipel et al., 2002; Naggara et al., 2006; Stahl et al., 2007). In an interesting analysis of FA using a multivariate approach, of 21 voxel regions with positive peak loadings consistent with decreased FA in AD, 16 were posterior to the anterior commissure (Teipel et al., 2002). The findings suggest that AD can be differentiated from normal aging by more posterior involvement of white matter myelin-associated pathology. Not all studies have shown this pattern consistently, however; anistropic changes in AD have been reported throughout most cortical and subcortical regions (Ramani et al., 2006). For example, Bozzali and colleagues showed widespread decreases in fractional anisotropy, including areas of frontal, temporal, and parietal lobes, with relative sparing of posterior cortex among patients with AD compared to matched controls (Bozzali et al., 2002). Others have

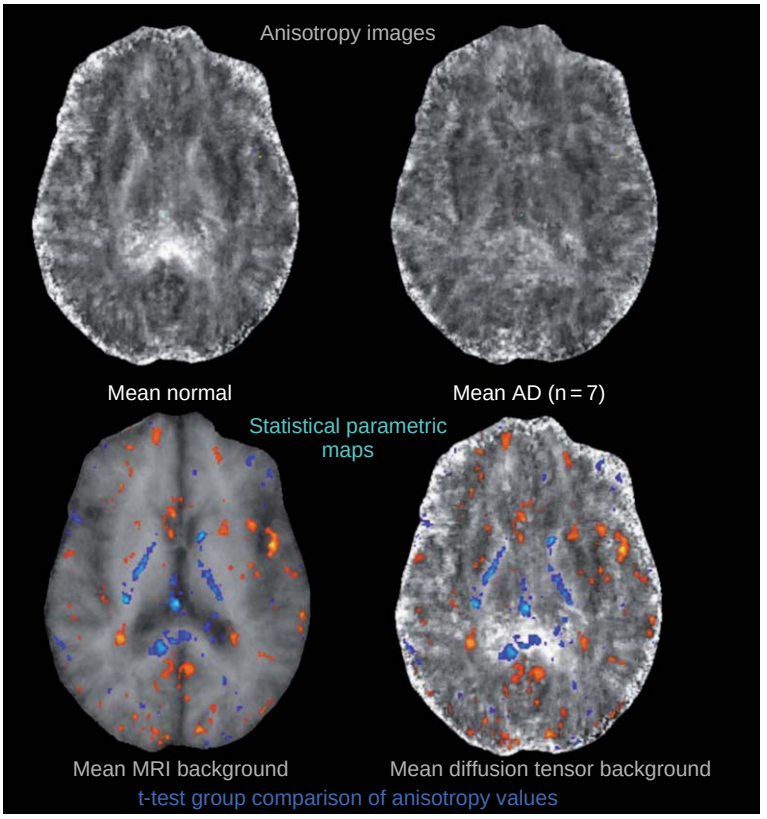

Figure 8 Comparison of seven normal individuals and seven patients with AD. Blue areas are $p < .05$, relative anisotropy in patients lower than normal controls. Note blue areas are posterior, in posterior limb of internal capsule and splenium but not genu of internal capsule.

shown relative sparing of occipital lobe white matter anisotropy in the context of more anterior DTI deficits among patients with AD (Takahashi et al., 2002). Marked anisotropic changes in AD may be evident later in the disease course, as one study that used DTI with MCI patients noted only reductions in diffusivity but not in fractional anisotropy (Fellgiebel et al., 2004).

Observations of increased WMH on FLAIR- or T2-weighted images in individuals with MCI and AD have partially suggested that cerebrovascular disease somehow interacts with AD pathology (Skoog, 2000; Launer, 2002; Kalaria, 2003; Malloy et al., 2007). For example, WMH are more prevalent and severe in AD patients compared to nondemented but demographically similar older adults (Scheltens et al., 1992), and older adults who are not demented but who have increased WMH burden are at higher risk for the development of AD (Vermeer et al., 2003; Prins et al., 2004). Van der Flier and colleagues (van der Flier et al., 2004) found that volume of the medial temporal lobe and severity of WMH independently predicted AD diagnosis, but that the two measures interacted, suggesting a synergistic effect. However, Bigler and colleagues found that, after controlling for total brain volume, WMH burden did not account for additional variance in performance on a test of global cognitive function (Bigler et al., 2002). This finding is consistent with other reports that measures of regional and global atrophy are more strongly associated with cognition than WMH volume alone (Mungas et al., 2001).

3.29.6 Summary

In summary, structural neuroimaging studies have revealed morphological patterns in MCI and AD that are defined primarily by medial temporal lobe atrophy, especially the entorhinal cortex and hippocampus. As the severity of the disease progresses, more regions become atrophic, and moderate to severe stages of dementia are associated with profound global atrophy. The rate and degree of regional

and total brain atrophy are associated with the severity of cognitive symptoms, risk of future cognitive decline, and rate of cognitive decline. Micro- and macrostructural white matter changes are prevalent in patients with AD and may interact with degree of atrophy in their contribution to cognitive function, although atrophy appears to account for relatively more cognitive deficit.

The pattern of structural changes seen in AD in the context of normal aging may suggest that AD is simply 'accelerated' aging. However, a careful consideration of the extant literature would lend greater support for a 'multiple factor framework' of aging and dementia (Buckner, 2004). Normal aging is characterized primarily by a decline in anterior brain systems. This is evident from the structural imaging studies that have demonstrated a relatively greater normal age-associated volume loss, together with white matter microstructural changes, in frontal and frontal-subcortical circuitry and from neuropsychological studies that show a relatively greater decline in frontal lobe–mediated cognitive tasks. AD impacts the temporal lobes, with the earliest involvement in the entorhinal cortex, and its defining cognitive symptom is a loss of hippocampus-mediated memory. It is important to note, however, that AD occurs in the context of aging, so that the pathological changes associated with AD are embedded, and perhaps interacting, with the normal age-associated changes. As the cognitive and neurobiological changes seen with normal aging are in fact quite heterogeneous, it is very difficult to disentangle 'normal' from 'pathological' changes in elderly individuals. Ultimately, multiple functional and structural imaging modalities combined with detailed neuropsychological and neurological evaluation may provide the most diagnostic and disease monitoring specificity and sensitivity.

4.01 Introduction and Overview

J. D. Sweatt, University of Alabama at Birmingham, Birmingham, AL, USA

4.01.1 Introduction

This fourth volume of the *Comprehensive Handbook of Learning and Memory* delves deeply into the cellular and molecular mechanisms mediating lasting changes in behavior, changes that occur in response to environmental signals. This volume is indeed the most comprehensive description in existence concerning the genetics, biochemistry, and cell biology of memory formation. Cumulatively, the reviews in this volume describe an impressive range of processes underlying memory, from atom-level resolution in some paradigms to cell circuit-level mechanisms in others, and essentially all points in between. Moreover, the phylogenetic range of the contents is equally impressive, with descriptions of memory processes in animal systems on a continuum from one of the simplest, *Caenorhabditis elegans*, to the most complex, humans.

It is striking that while the chapters in this volume deal with specific cellular and molecular mechanisms, there are in most chapters strong and direct tie-ins to behavior in the living animal. This appealing aspect of these studies arises in large part from three historical developments, in my opinion. First, many of the invertebrate systems were specifically chosen because the animal lent itself to bridging from behavior to cells to molecules. Thus tying the molecules and cells to the behavior was built into the experimental design of these studies from the outset. A second development was the advent of the technical capacity to genetically engineer mice through means of homologous gene recombination. This allowed those interested in the molecular basis of vertebrate memory to bridge from molecule to behavior within a single animal and ushered in a new era in neurobiology. The final development is more sociological than technical. Many of the leading investigators in the area of molecular and cellular mechanisms of memory actually started out as behavioral psychologists. Therefore, tying molecular and cellular mechanisms directly back to the behaving animal always was an intellectual emphasis for them. This established a culture within the subdiscipline that placed a priority on interdisciplinary studies bridging from molecules to behavior.

In the current era, we also are compelled to always consider the relevance of our basic neurobiological studies to the human condition. Advances over the last 20 years in our understanding of the basic molecular and cellular biology of memory have laid the foundation for a capacity to develop new treatments for human diseases of learning and memory. This is not an abstract principle but rather a declarative statement concerning important recent advances in the field. Descriptions of these recent advances are contained in many chapters, and sections of chapters, in this volume. These descriptions are not split out

into a separate translational or disease section of the volume, but rather are distributed throughout in places appropriate to their specific intellectual milieu. I find this a more satisfying concept for organization of the volume, and an accurate representation of the ongoing cross talk between human and basic science studies of learning and memory.

A final comment is that in many ways this volume is a snapshot of the state of scientific understanding of the neurobiology of learning and memory at the beginning of the twenty-first century. Thus, besides being a valuable resource for contemporary scientists, I believe this volume will provide a useful historical reference point as well. I am only emboldened to make this statement because of the very many outstanding scholars and scientists who have contributed their individual chapters to this work and because of the exceptionally important discoveries by the many scientists that they cite therein.

4.01.2 Organization

The organization of the volume is fairly straightforward considering the complexity of the topic at hand (see **Figure 1**). Part 1, the introduction and overview component, is this chapter and Chapter 4.02. I am very grateful to Eric Kandel, Craig H. Bailey, Angel Barco, and Robert D. Hawkins for their contribution in writing Chapter 4.02. I commissioned Eric and his colleagues to write a personal overview of contemporary discoveries and approaches in the learning and memory field. I expected that they would deliver a very readable and interesting review concerning the overall topic of the molecular and cellular biology of memory formation, describing a diverse set of model systems and approaches. They certainly hit the mark in this regard. Unbeknownst to them, I also anticipated that they might write an excellent bridge chapter that would serve to help guide a knowledgeable reader into the much more detailed following chapters in the book. When I received and read their chapter I was delighted that they had achieved this as well. I strongly encourage anyone looking for a conceptual starting point for considering the detailed molecular and cellular basis of memory, as described in this overall volume, to begin by reading Chapter 4.02.

Part 2 of the volume, comprising Chapters 4.03–4.19, covers model systems-level and cellular-level approaches to investigating learning and memory. This part can be broadly subdivided into five sections (more specific descriptions of the contents of each section will be given): Section 1 deals with nonassociative learning mechanisms. Section 2 discusses associative learning and memory, as investigated in invertebrate model organisms. Section 3 makes an important transition and describes studies of associative and spatial memory in vertebrates. Section 4 reviews topics related to memory disruption, and section 5 describes types and forms of plasticity at the cellular and synaptic level that underlie memory formation and storage.

The last section of Part 2, describing cellular mechanisms and synaptic plasticity, also serves as a foundation for and transition to Part 3 of the volume. Part 3 covers molecular-level approaches and emerging areas of discovery. This second half of the book has five sections as well: Section 1 deals with the *N*-methyl-D-aspartate (NMDA) receptor and its immediate biochemical targets. Section 2 describes genomic and postgenomic signaling. Section 3 covers the important areas of synaptic structure and signaling, and section 4 covers plasticity of cell structure and retrograde synaptic signaling. Section 5, the final section, is admittedly based on a subjective assessment on my part. This section highlights what I consider to be several emerging areas of investigation that will have a large impact on our thinking about cellular and molecular mechanisms of memory formation in the near future.

Having delivered this brief overview, in the remainder of this chapter I will describe more specifically the contents of Parts 2 and 3 of the volume (see **Figure 1**).

4.01.2.1 Part 2A: Systems-Level Approaches

4.01.2.1.1 Nonassociative learning

In this first major section of the book, we will start by covering the simplest forms of learning, that is, nonassociative forms of learning and memory. Studies of these simple forms of learning and memory have yielded great insights into the enormous complexity of information acquisition and storage in the nervous system, when approached at the cellular and molecular levels. In Chapter 4.03, one of the pioneers of this type of work, Jack Byrne, provides a review of studies of sensitization and habituation using invertebrate model systems.

This overview chapter is then followed by a description of sensitization and habituation in the *C. elegans* model system by Cathy Rankin, who pioneered the adaptation of this organism for use in

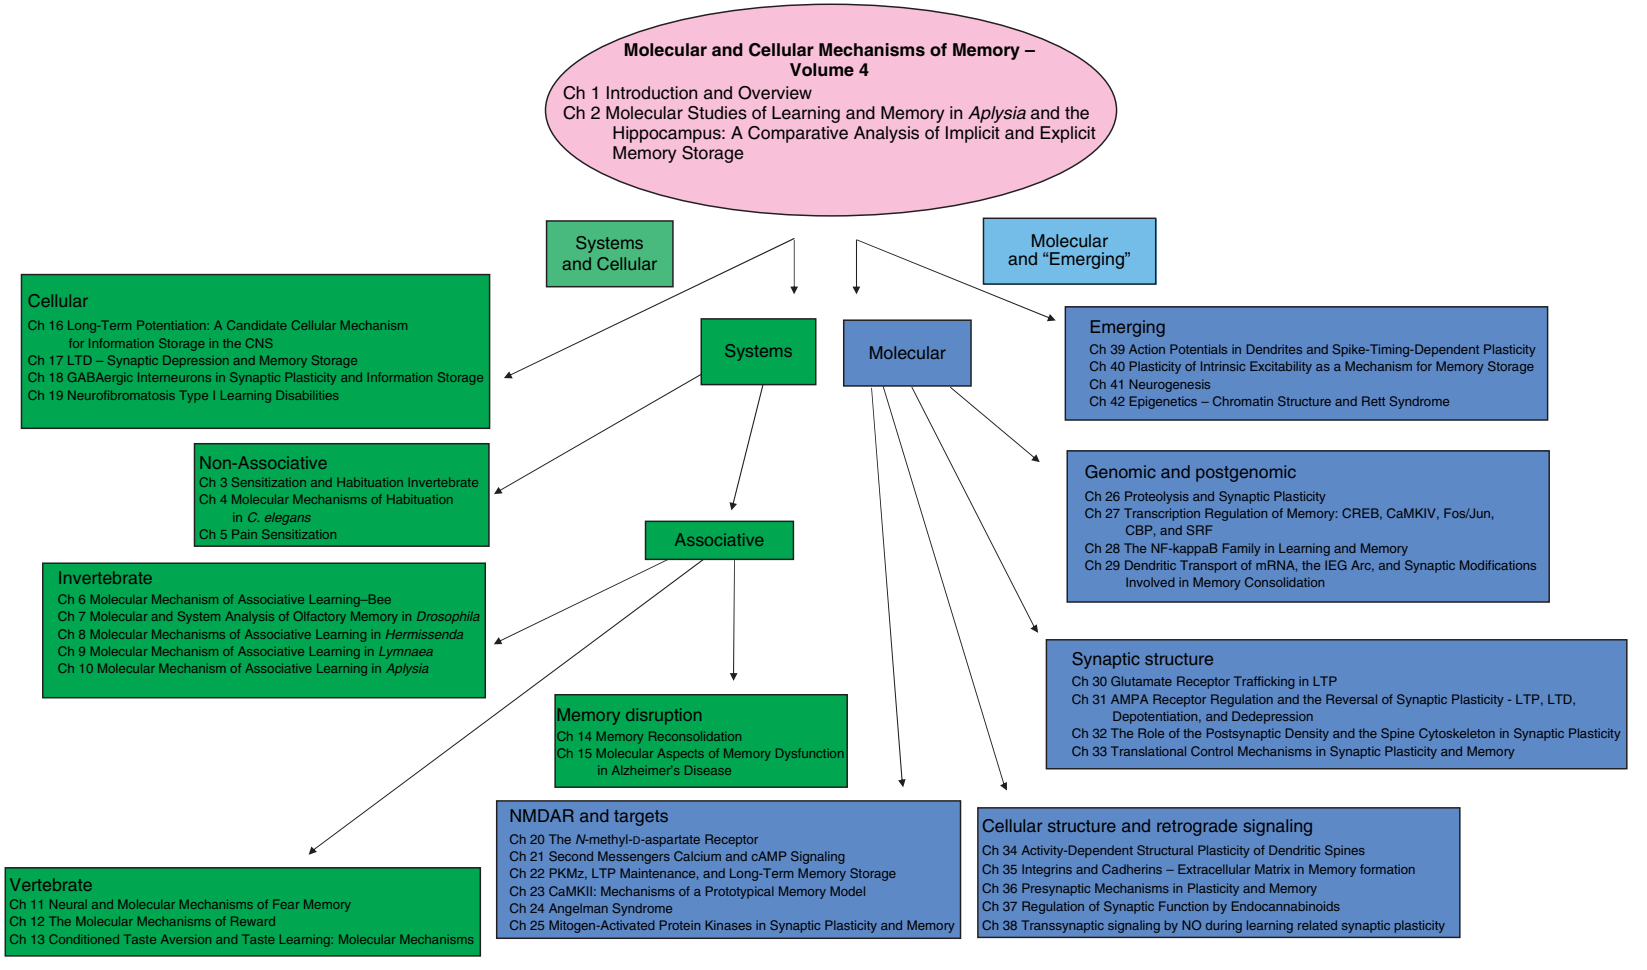

Figure 1 Contents and organization of Volume 4 of the *Comprehensive Handbook of Learning and Memory*. This volume covers molecular and cellular mechanisms of memory formation. This figure describes the overall organization and major topic areas of the volume.

behavioral studies. Studies of this sort in *C. elegans* have a particularly important context, for this organism stands apart from all others in that its entire anatomical structure and developmental program have been determined at the cellular level. Thus behavioral studies in *C. elegans* have the potential to bring an unprecedented level of certainty to understanding the neural circuitry underlying specific behaviors. In addition, *C. elegans* is a powerful genetic model system in its own right, allowing the potential to combine anatomy, genetics, and behavior in a unique fashion, as is illustrated by the studies in Chapter 4.04.

Nonassociative learning in vertebrates, especially humans, tends to not receive the same level of attention among learning and memory neurobiologists that higher-order forms of learning receive. However, sensitization and habituation are also of great relevance in humans in the clinical setting. Chapter 4.05 describes pain sensitization in vertebrate model systems, highlighting interesting parallels between molecular mechanisms of vertebrate associative learning (that will be described later in the volume) and mechanisms of nonassociative learning in these same animals. In addition, this chapter reminds us of the great significance of studying nonassociative learning and memory in the modern context of translational biomedical research.

4.01.2.1.2 Associative learning and memories of contingency

The next major section transitions us to more complex forms of learning and memory, that is, associative forms wherein an animal learns a predictive or contingent relationship between two environmental signals. Of course, this associative relationship must be represented at the molecular level in some fashion in the nervous system, and the memory for the relationship must be stored there as well. Thus, the associative learning section explores the fascinating question of how contingencies and associations are represented at the molecular and cellular level in the nervous system, and how unique molecular events produced by associative stimuli trigger lasting cellular changes manifest as memory.

4.01.2.1.3 Associative learning in invertebrate models

We first explore these questions in a series of chapters describing studies of associative conditioning in invertebrates. Each of five chapters gives an overview of a particular organismal system, describing the animal, its ethologically relevant behaviors and capacity for forming associations, the underlying circuitry, and the known cellular and molecular mechanisms contributing to altered behavior in response to associative environmental stimuli. These chapters thus provide a useful overview of the different organisms and approaches, and more detailed information about cellular and molecular mechanisms.

We are fortunate to have leading investigators for each of five unique model systems contributing to this section. In Chapter 4.06, Uli Mueller and his colleagues describe the honeybee system. Chapter 4.07 provides us with a review of learning and memory studies in the granddaddy of all genetic model systems, *Drosophila*, from Thomas Preat and his group. In Chapter 4.08, Terry Crow and his collaborators review the *Hermissenda* system, and in Chapter 4.09 George Kemenes introduces us to *Lymnaea.* Finally in this section, in Chapter 4.10 Jack Byrne describes *Aplysia* associative conditioning and reviews the unique molecular and cellular components of associative learning and memory in this system.

In editing and reviewing these chapters, I noted several interesting commonalities across these systems, which I would like to comment on in passing. First, these are interesting systems to read about, because I suspect that many readers will be introduced to these systems for the first time through this volume. Second, considerable cleverness is evident on the part of the scientists using these systems, in adapting ethologically relevant behaviors in the animal to the laboratory setting, and in undertaking very detailed molecular and cellular studies in conjunction with that approach. Finally, the types of associations these relatively simple animals are capable of making is astonishing in many instances. Many of you reading about these organisms for the first time will be surprised at the complex environmental contingencies that slugs and bugs are capable of learning.

4.01.2.1.4 Associative learning in vertebrate models

The next section moves up the phylogenetic tree to explore associative learning and memory in vertebrate systems. As this volume focuses on molecular and cellular mechanisms, all three of these chapters describe studies utilizing rodents. In Chapter 4.11, Glenn Schafe and Joe LeDoux lend their synaptic selves to the effort of describing rodent fear conditioning and its underlying cellular and molecular basis.

Their chapter describes the impressive body of literature that has been able to take studies of this particular behavior into the realm of specific cellular and molecular mechanisms, in the anatomically complex vertebrate central nervous system (CNS). These studies have allowed the delineation of mechanisms that encode a complex environmental contingency and allow the manifestation of appropriate behavioral change. In Chapter 4.12, Eric Nestler and Catharine Winstanley describe studies of the flip side of behavioral conditioning, reward-reinforced behaviors. They present an overview of reward systems in the vertebrate CNS, and describe how these systems can be co-opted to reinforce addictive behaviors. Once again, the level of understanding of the cellular and molecular mechanisms at work in these processes is quite impressive. Finally, in Chapter 4.13 in this section Kobi Rosenblum describes taste learning and conditioned taste aversion in rodents. The cortically based systems at work here, as well as the quasi-declarative nature of taste memorization, make this a fascinating system for study. Indeed, it is likely that taste learning and memory are among the most sophisticated types of information processing that rodents are capable of.

4.01.2.1.5 Memory disruption

The robustness and long-lived nature of memory are two of the most impressive aspects of the phenomenon, and indeed these attributes compelled many neuroscientists to be interested in learning and memory in the first place. Against this backdrop, the possibility of loss of previously established memories, and the loss of the capacity for new memory formation, are particularly compelling for many of us to consider. In Chapter 4.14, Cristina Alberini and Stephen Taubenfeld discuss the need for memories that have already been formed to undergo a complex process of re-establishment after every instance of recall, a phenomenon referred to as memory reconsolidation.

In Chapter 4.15, Lennart Mucke, Jeannie Chin, and Eric Roberson describe molecular mechanisms underlying the most debilitating disease of memory in existence, Alzheimer's disease (AD). This is one of the most prominent areas of biomedical research extant in the United States and Europe at present. I also would like to highlight this chapter by Mucke and colleagues for another reason. Their chapter sits at a position in this volume immediately preceding roughly 20 subsequent chapters that detail the cellular and molecular underpinnings of memory. A striking attribute of their chapter is the large number of cellular and molecular processes that are disrupted in AD, processes that are subsequently discussed in a basic science context in further chapters of this volume. I note this for two reasons. First, it is impressive and somewhat discouraging that so many of the molecular mechanisms implicated in normal memory formation are potentially disrupted in AD. Second, on a more practical side Chapter 4.15 serves as a valuable cross-reference for the biomedical relevance of understanding the detailed cellular and molecular processes described in the final sections of this volume.

4.01.2.2 Part 2B: Cellular-Level Approaches

In Chapter 4.16 of the volume, we transition from larger systems-level analyses involving whole organisms to descriptions of more specific cellular and molecular processes involved in learning and memory. I chose to make this transition with a chapter describing long-term potentiation (LTP), perhaps the cellular keystone of higher-order vertebrate memory formation. Directly indicative of that fact, and of the seminal contribution made by Tim Bliss and Terje Lomo in their discovery of LTP, every chapter after this transition point makes some reference to LTP, to a greater or lesser extent depending on the specific topic under review. Thus Chapter 4.16 provides a foundation for all subsequent chapters in this volume. More significantly, Bliss and Lomo's discovery of LTP provides an essential foundation for the modern understanding of the molecular and cellular basis of vertebrate memory formation.

The undoubted importance of LTP notwithstanding, synaptic long-term depression (LTD) plays crucial roles in vertebrate CNS function and memory formation as well. In Chapter 4.17, Christian Hansel and Mark Bear describe LTD, the conceptual mirror image of LTP. They also provide a nice coverage of the functional and behavioral significance of LTD and highlight that the phenomenon is not simply a cellular antagonist of potentiation, but rather a mnemonic mechanism in its own right.

The importance of plasticity of inhibitory synapses and cells has historically been under-appreciated. In Chapter 4.18, Chris McBain and his colleagues describe both the plasticity of inhibitory cells and synapses, and the importance of plasticity of inhibitory circuits in memory and cognitive function. To reinforce this message, in Chapter 4.19 Alcino

Silva and his collaborators describe learning and memory deficiencies associated with neurofibromatosis type 1 and describe their intriguing series of studies that identified disruption of inhibitory synapse function as a basis for human learning and memory deficits in this disorder. These two complementary chapters close out the systems and cellular section of the volume and set the stage for the detailed molecular descriptions of the final part of the volume.

4.01.2.3 Part 3A: Molecular-Level Approaches

Starting with Chapter 4.20, we begin to dissect the complex molecular systems that subserve learning, memory, and memory storage. The molecular complexity of memory is indeed awe-inspiring and not to be taken lightly. One must remember that the molecular machinery of vertebrate memory may underlie the most complex biological process in existence, at least that is concretely identifiable at this point. Chapters 4.20–4.38 describe individual components of this machinery in a comprehensive and organized fashion.

These chapters proceed in an order roughly approximating the order of molecular information flow in a neuron participating in the formation of a memory. Thus we start with a description of the NMDA subtype of glutamate receptor and its immediate molecular targets in the cell in Chapters 4.20–4.25. The next section, Chapters 4.26–4.29, describes signaling to the nucleus and the genome contained therein and reviews transcriptional and posttranscriptional mechanisms involved in memory formation. Both the immediate targets of the NMDA receptor and the altered transcriptional readout impinge upon the synapse to effect altered cell function and signaling, a critical step in the plasticity that underlies memory. Chapters 4.30–4.33 describe the translational and posttranslational mechanisms that underlie altered synaptic function in memory. Finally, it is clear that transcriptional, translational, and posttranslational mechanisms all ultimately mediate altered cell structure and communication in memory formation. These alterations involve both the pre- and postsynaptic compartments, and encompass the physical and molecular structure of both the neuron and the extracellular space. These components of the memory machinery are described in Chapters 4.34–4.38.

4.01.2.3.1 The NMDA receptor and its immediate targets

What better place to start a description of the molecular basis of memory than with the NMDA receptor itself? After all, it is both a molecular coincidence detector and a known key component of vertebrate memory formation. Chapter 4.20 describes NMDA structure and function and highlights that the NMDA receptor is in fact a huge molecular machine in its own right. In Chapter 4.21, Dan Storm and Kristin Eckel-Mahan describe two of the immediate effectors of the NMDA receptor, as well as other plasticity-related receptors: calcium and cyclic adenosine monophosphate (cAMP).

The next three chapters then discuss two memory molecules that are capable of converting a transient signal into a lasting effect in the cell – protein kinase C (PKC) and calcium/calmodulin-dependent protein kinase II (CaMKII). Chapter 4.22, by Todd Sacktor, describes the roles of PKC and especially of the PKMzeta isoform in synaptic plasticity and memory. Chapter 4.23 brings us a description by Roger Colbran of the ways and means by which CaMKII can be regulated and persistently activated to serve as an information storage device. Chapter 4.24 by Ed Weeber and his colleagues highlights the clinical relevance of studies of CaMKII regulation, by focusing on Angelman mental retardation syndrome and disruptions of hippocampal CaMKII regulation in this human learning and memory disorder.

Finally in this section, Ray Kelleher describes the mitogen-activated protein kinase (MAPK) pathways and their roles in synaptic plasticity and memory formation. Chapter 4.25 covers one of the essential signal integration pathways in plasticity and memory formation, a pathway that also is a prototype regulator of gene transcription and protein translation. The description of this pathway helps us transition to the next section of the volume, dealing with transcriptional regulation and mRNA trafficking.

4.01.2.3.2 Genomic and postgenomic signaling

Genomic signaling in the context of synaptic plasticity and memory formation involves two basic components: Getting a signal to the transcription regulatory machinery to alter expression of the appropriate gene targets, and getting the newly transcribed mRNAs to the right places in the cell. Chapters 4.26–4.30 deal with various fascinating aspects of these processes.

Chapter 4.26 by Ashok Hegde describes a critical gene target in *Aplysia* sensitization and synaptic

facilitation, a ubiquitin C-terminal hydrolase. Ashok's chapter describes an interesting molecular system that demonstrates an important role for protein degradation in plasticity and memory, and also involves an interesting interplay of transcriptional and posttranslational regulation in order to generate a lasting signal in a neuron.

The next two chapters describe important transcription factors in plasticity and memory, those proteins that help directly translate a genome-level signal into the appropriate direct transcriptional change. In Chapter 4.27, Sheena Josselyn and Christy Cole describe transcription regulation by cAMP response element binding protein (CREB) and CREB-associated pathways, highlighting the first transcription factor to be clearly linked to synaptic plasticity and memory formation. In Chapter 4.28, Molly Meffert describes a pathway recently introduced to the plasticity and memory field, nuclear factor kappa B (NFκB). While NFκB signaling is fairly new material for most neurobiologists, in fact this pathway has long been one of the premier pathways for study in immune system transcriptional regulation.

Once changes in gene expression are triggered in the nucleus, the products of those changes must find the right site within the neuron for their residence. In Chapter 4.29, Oz Steward discusses the prototype marker for neuronal mRNA trafficking in the mammalian CNS, Arc. Studies of Arc trafficking have shed important new light on the existence and mechanisms of specific mRNA targeting in neurons, especially in the context of activity-dependent cellular plasticity and the mechanisms that tell targeted molecules where to go in the neuron, a process referred to as synaptic tagging.

Targeted molecules end up in specific sections of the neuron and at specific synapses. Thus we have completed a conceptual loop through the neuron – from the NMDA receptor at a synapse, to the nucleus, and back to a targeted synapse. Therefore in the next section we return to a discussion of synaptic mechanisms and receptors. However, it is important to remember that plasticity at synapses occurs not only (nor even predominantly) in response to genome-originating signals, but also in response to locally generated signals. Therefore, the next section deals with the synapse and its receptors not only as targets of transcriptional regulation, but also as targets of posttranslational modification and localized alterations in protein synthesis.

4.01.2.3.3 Synaptic structure and signaling

This is a substantial section that describes several of the most popularly studied and clearly important mechanisms in synaptic plasticity and memory. Indeed, in the mammalian CNS the processes described in this section are of paramount relevance. This is because the postsynaptic compartment and its environs are both the quintessential functional compartment for receiving externally generated signals, and a known locus for change at the molecular level in plasticity and behavioral memory.

In Chapter 4.30, Michael Browning and his colleagues describe mechanisms of glutamate receptor trafficking and regulation, focusing on those mechanisms operating during synaptic plasticity and memory. Rick Huganir and Hey-Kyoung Lee follow in Chapter 4.31 by reviewing a fascinating set of mechanisms controlling bidirectional regulation of glutamate receptor function during synaptic potentiation and depression. These two chapters provide a nice overview of the mechanism for dynamic regulation of glutamate receptor function in synaptic plasticity and memory.

Of course, glutamate receptors and their many associated signaling molecules sit within a specialized synaptic machine – the postsynaptic density (PSD). In Chapter 4.32, Mary Kennedy reviews the structure and function of the PSD and brings to bear sophisticated kinetic modeling approaches to help us understand how this machine achieves its effects. In Chapter 4.33, Eric Klann and Nahum Sonnenberg describe the necessity of protein synthesis for synaptic plasticity and memory, with an emphasis on localized dendritic protein synthesis being involved in these processes.

4.01.2.3.4 Plasticity of cellular structure and retrograde signaling

Molecular changes associated with memory formation are not limited to a single postsynaptic compartment, but rather encompass associated presynaptic and structural changes as well. Moreover, even in the case where a single postsynaptic site might undergo alteration, its presynaptic partner can change in concert. In Chapter 4.34, Lucas Pozzo-Miller and Christopher Chapleau describe activity-dependent structural changes in dendritic spines as an example of neuronal structural change in plasticity and memory. In Chapter 4.35, Ron Davis reviews the role of the extracellular matrix in the maintenance of synaptic structural change, focusing

specifically on integrins and cadherins. Chapter 4.36 by Craig Powell and Pablo Castillo describes presynaptic mechanisms in plasticity, covering both plasticity of the presynaptic terminal and evidence that changes at this locus are involved in various forms of memory. In considering how signals may get from the postsynaptic compartment to the presynaptic compartment, David Lovinger enlightens us with Chapter 4.37, describing regulation of synaptic function by endocannabinoids. Finally for this section, Bob Hawkins reprises the retrograde signaling theme by reviewing the role of nitric oxide in synaptic plasticity (Chapter 4.38).

4.01.2.4 Part 3B: Emerging Areas

The final section of the volume covers a somewhat disparate set of topics that nevertheless have two things in common. First, the topics of this section, in my opinion, are emerging areas of emphasis in the plasticity and memory field, topics that have the potential to give us fundamentally new perspectives on several aspects of CNS and neuronal function underlying behavioral change. Second, these mechanisms have in common that they affect or involve the entire neuron.

In Chapter 4.39, Jack Waters and Fritjof Helmchen describe back-propagating action potentials in dendrites and their capacity to regulate both the magnitude and direction of synaptic plasticity. This is followed by Chapter 4.40, where Jack Byrne and Ricccardo Mozzachiodi describe plasticity of intrinsic cellular properties, such as altered excitability, as a locus of plastic change. Neurogenesis has emerged as a viable mechanism contributing to memory formation in the adult, in complete contrast to the dogma of only a few years ago. In Chapter 4.41, Rusty Gage, Sebastian Jessberger, and James Aimone review adult neurogenesis and its mechanisms of control and the implications of this system for a potentially new cellular basis of memory. Finally, in Chapter 4.42 Jonathan Levenson and Marcelo Wood describe recent discoveries implicating epigenetic mechanisms of long-term regulation of gene expression in plasticity and memory formation.

These provocative topics may force us to consider that the entire neuron may be a locus of the engram and a site of information storage in the CNS. Thus, while synapse specificity is a powerful attribute in terms of specifying connections in a behavior-mediating circuit, synapse-specific changes may be embedded within a neuron that has had its basic properties changed in a cell-wide fashion as well. Both processes may act in concert to enable learning and memory, and the four chapters of this final section presage this potential paradigm shift in our thinking concerning vertebrate memory formation.

Acknowledgements and Thank-Yous

The Editors at Elsevier Publishing have been great to work with on this project. Executing a book series of the scope and magnitude of the *Comprehensive Handbook of Learning and Memory* is no small feat. In this vein, I would like to thank the Elsevier publishing group for deciding to invest in this project and for giving me and the other editors the opportunity to participate. I in particular wish to thank Johannes Menzel for his support and encouragement, and Joanna DeSouza for the immense amount of work she put in on organizing the series. I also am very appreciative to Vicki Hixon, who works with me at the McKnight Brain Institute at UAB, for all the tremendous help she gave me, and always with a smile. My wife, Kim Strifert, supported me throughout, from London to Houston to Memory Lane (see **Figure 2**).

I also am very grateful to Jack Byrne for inviting me to participate as a volume editor and contributor to the series. The series is both visionary and timely, and Jack has provided great leadership as editor. I sincerely appreciate the opportunity to participate. Jack, Randolph Menzel, Howard Eichenbaum, and Roddy Roediger are all not only outstanding scientists but also fine colleagues, and I thank them all for their many suggestions and for the valuable

Figure 2 Memory Lane is a state of mind, a fascinating topic of scientific inquiry, and a small road outside of Trussville, Alabama, USA. The editor of this volume dwells on all three.

brainstorming that they did not only for the overall series but for my volume as well.

Most important is recognizing the tremendous debt that I owe to the authors of the individual chapters in this volume. I have been consistently and thoroughly impressed at the quality of the chapters that the authors provided for this book. I thank them to begin with for even agreeing to provide a chapter at all. I thank them tremendously and in every instance for the superb quality of the material that they produced – a reflection of their professionalism, integrity, and scholarship.

4.02 Molecular Studies of Learning and Memory in *Aplysia* and the Hippocampus: A Comparative Analysis of Implicit and Explicit Memory Storage

C. H. Bailey, College of Physicians and Surgeons of Columbia University, New York, NY, USA

A. Barco, Instituto de Neurociencias de Alicante (UMH-CSIC), San Juan de Alicante, Spain

R. D. Hawkins and E. R. Kandel, College of Physicians and Surgeons of Columbia University, New York, NY, USA

4.02.1 Introduction

Modern behavioral and biological studies have revealed that memory is not a unitary faculty of the mind but consists of distinct families of mental processes that can be grouped into at least two general categories, each with its own rules (Polster et al., 1991; Squire and Zola-Morgan, 1991). Explicit or declarative memory is the conscious recall of knowledge about people, places, and things and is particularly well developed in the vertebrate brain. Implicit or nondeclarative memory is memory for motor and perceptual skills as well as other tasks and is expressed through performance, without conscious recall of past experience. Implicit memory includes simple associative forms of memory, such as classical and operant conditioning, and nonassociative forms, such as sensitization and habituation. Explicit and implicit memory have been localized to different neural systems within the brain (Milner, 1985; Polster et al., 1991; Squire, 1992). As first shown by Brenda Milner in her neuropsychological studies of the patient H.M., explicit memory is critically dependent on structures in the medial temporal lobe of the cerebral cortex, including the hippocampal formation. Implicit memory is a family of different processes that are represented in a number of brain systems including

the cerebellum, the striatum, the amygdala, and in the simplest cases, the sensory and motor pathways recruited during the learning process for particular perceptual or motor skills. As a result, implicit memory can be studied in a variety of simple reflex systems, including those of higher invertebrates, whereas explicit memory is best studied in mammals.

Two experimental model systems have been extensively studied as representative examples of these two forms of memory storage: sensitization in the marine snail *Aplysia californica* as an example of implicit memory, and spatial memory formation in rodents as an example of explicit memory. We use them here as points of comparison to consider similarities and differences in implicit and explicit memory storage.

4.02.2 Short-Term, Intermediate-Term, and Long-Term Forms of Storage Mechanisms

Recent studies of simple forms of implicit memory in higher invertebrates and more complex forms of explicit memory in mammals suggest that changes in the strength and structure of synaptic connections underlie these diverse forms of memory storage (Kandel, 2001). For both implicit and explicit memory, two general types of storage mechanisms have been described: short-term memory lasting minutes and long-term memory lasting days, weeks, or longer. This temporal distinction is reflected in specific mechanisms for the synaptic plasticity that underlie each form of behavioral memory as well as specific molecular requirements for each of these two forms of synaptic plasticity. The short-term forms involve the covalent modifications of preexisting proteins by a variety of kinases and are expressed as alterations in the effectiveness of preexisting connections. In contrast, the long-term forms require *de novo* gene expression and the synthesis of new mRNAs and proteins. Moreover, the long-term forms often are associated with the growth of new synaptic connections. For both implicit and explicit memory storage, the synaptic growth is thought to represent the final and self-sustaining change that stabilizes the long-term process. In addition to short- and long-term memory, there are, for most types of learning, a family of intermediate processes that last one or more hours and often require translation but not transcription. These can be produced by various behavioral training protocols or in simplified neuronal systems using repeated or prolonged stimulation.

In this chapter, we discuss and compare critical synaptic sites and the underlying cellular and molecular mechanisms of short-term, intermediate-term (**Figure 1**), and long-term (**Figure 2**) memory storage that have been identified by neurobiological studies of elementary forms of implicit memory in *Aplysia* and explicit memory storage in rodents.

4.02.2.1 Implicit Memory: Sensitization and Classical Conditioning of the Gill-Withdrawal Reflex in *Aplysia*

The central nervous system (CNS) of *Aplysia* contains only approximately 20,000 large and frequently identifiable nerve cells, clustered into nine major ganglia. The ability to identify many of the individual neurons of this nervous system and record their activity has made it possible to define the major components of the neuronal circuits of specific behaviors and to delineate the critical sites and underlying mechanisms used to store memory-related representations.

The cellular and molecular mechanisms contributing to implicit memory storage have been most extensively studied for the gill- and siphon-withdrawal reflex of *Aplysia* (Carew and Sahley, 1986; Byrne and Kandel, 1996; Kandel, 2001). As is true for other types of defensive reflexes, the gill- and siphon-withdrawal reflex can be modified by several different forms of implicit learning. We begin by focusing on *sensitization,* a form of learned fear, evident as an elementary form of nonassociative learning of this defensive behavior. When a light touch is applied to the siphon of *Aplysia,* the animal responds by withdrawing its siphon and gill. This response can be enhanced or sensitized when the animal is presented with a noxious (fear-inducing) stimulus such as a tail shock. As is the case with other forms of memory, the memory for sensitization of the withdrawal reflex is graded as a function of training: A single tail shock produces short-term sensitization that lasts for minutes, whereas repeated tail shocks given at spaced intervals produce long-term sensitization that can last for several weeks (Castellucci et al., 1986). The reflex also exhibits classical conditioning, an associative form of learning. Here the siphon stimulus is presented in a paired fashion just before the tail shock so that the animal learns about the predictive relationship between the two stimuli. Enhancement of the withdrawal reflex is greater and longer lasting with paired training (classical conditioning), compared with unpaired training or training with the tail shock alone (sensitization) (Carew et al., 1981, 1983; Antonov et al., 2001).

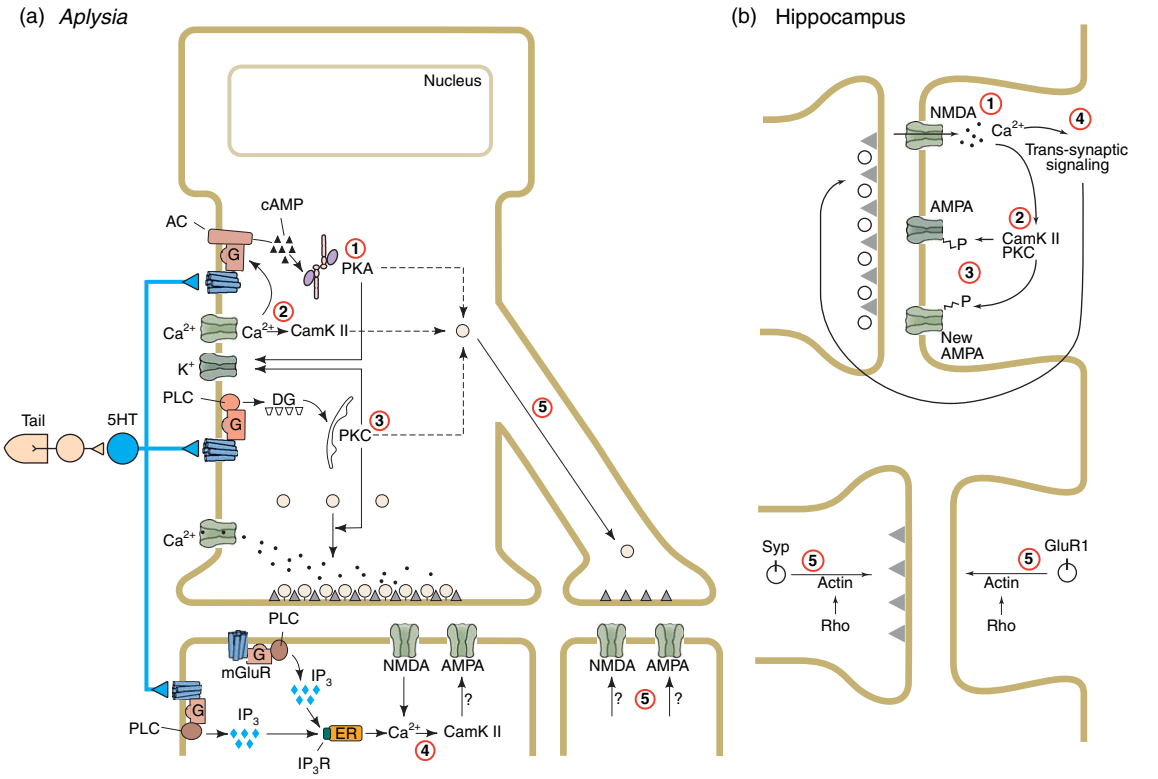

Figure 1 Mechanisms of short- and intermediate-term memory formation in *Aplysia* and hippocampus. (a) *Aplysia.* Different forms of short- and intermediate-term synaptic plasticity contributing to learning and memory in *Aplysia* involve different combinations of pre- and postsynaptic molecules including (1) presynaptic cyclic adenosine monophosphate–dependent protein kinase, (2) presynaptic Ca^{2+} and CamKII, (3) presynaptic protein kinase C, (4) postsynaptic Ca^{2+} and CamKII, and (5) recruitment of pre- and possibly postsynaptic molecules to seed potential new synaptic sites. (b) Hippocampus. Early-phase long-term potentiation in the CA1 region of hippocampus involves (1) Ca^{2+} influx through postsynaptic *N*-methyl-D-aspartate (NMDA) receptor channels, (2) activation of protein kinases including CamKII and PKC, (3) increased conductance of existing adenosine monophosphate (AMPA) receptor channels and membrane insertion of new AMPA receptors, (4) the engagement of trans-synaptic signaling, which can enhance presynaptic transmitter release, and (5) recruitment of pre- and postsynaptic molecules to seed potential new synaptic sites. See the text for details.

The relative simplicity of the neuronal circuit underlying these behavioral modifications – including direct monosynaptic connections between identified mechanoreceptor sensory neurons and their follower cells (Castellucci et al., 1970) – has allowed reduction of the analysis of short- and long-term memory for sensitization and classical conditioning to the cellular and molecular level. This monosynaptic sensory to motor neuron connection, which is thought to be glutamatergic (Dale and Kandel, 1993; Trudeau and Castellucci, 1993; Conrad et al., 1999), can be reconstituted in dissociated cell culture. Here the tail shocks are replaced with brief applications of serotonin (5-HT), a modulatory transmitter normally released by sensitizing stimuli in the intact animal (Glanzman et al., 1989; Mackey et al., 1989; Marinesco and Carew, 2002). This simplified *in vitro* model system reproduces what is observed during behavioral training. A single brief application of 5-HT produces a short-term change in synaptic effectiveness (short-term facilitation, or STF), whereas repeated and spaced applications of 5-HT produce changes in synaptic strength that can last as long as the cells survive in culture (long-term facilitation, or LTF) (Montarolo et al., 1986). Facilitation is also larger and longer lasting if the presynaptic sensory neuron fires action potentials just before the application of 5-HT, analogous to classical conditioning (Eliot et al., 1994a; Schacher et al., 1997; Bao et al., 1998).

4.02.2.2 Explicit Memory: Spatial Memory in Rodents

Mice have a well-developed capability for certain types of explicit memory. In particular, the brain of rodents is

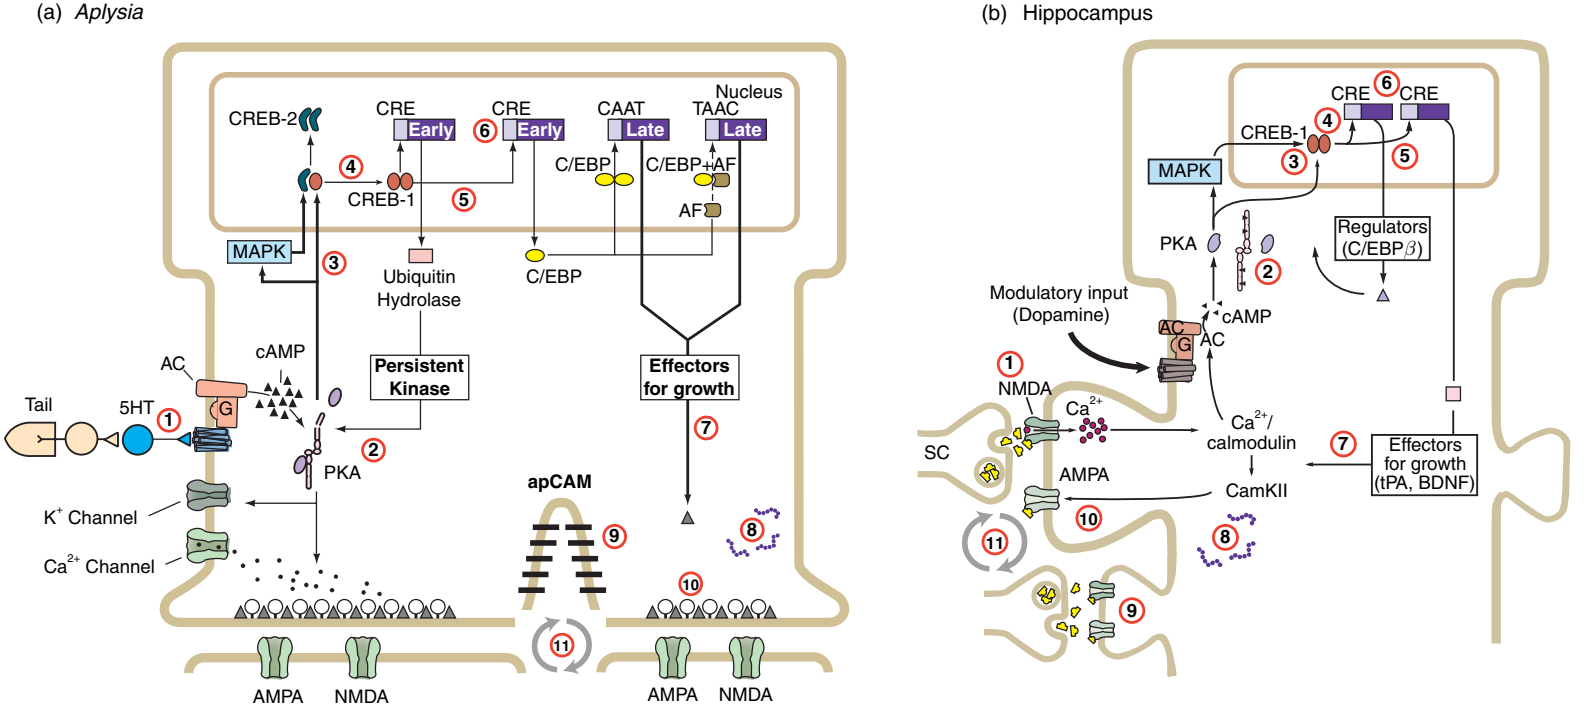

Figure 2 Mechanisms of long-term memory formation. Long-term synaptic plasticity contributing to learning and memory in both *Aplysia* (a) and hippocampus (b) involves a sequence of cellular and molecular mechanisms including (1) neurotransmitter release and short-term strengthening of synaptic connections, (2) equilibrium between kinase and phosphatase activities at the synapse, (3) retrograde transport from the synapse to the nucleus, (4) activation of nuclear transcription factors, (5) activity-dependent induction of gene expression, (6) chromatin alteration and epigenetic changes in gene expression, (7) synaptic capture of newly synthesized gene products, (8) local protein synthesis at active synapses, (9) synaptic growth and the formation of new synapses, (10) activation of preexisting silent synapses, and (11) self-perpetuating mechanisms and the molecular basis of memory persistence. The location of these events, which may act in part to stabilize some of the changes that occur during short- and intermediate term plasticity, moves from the synapse (1–2) to the nucleus (3–6) and then back to the synpase (7–11). Molecular details are discussed in the text.

highly adapted for navigating complex spatial environments. The hippocampus, a key subcortical structure in the mammalian brain, is particularly important for spatial learning and memory and represents a significant percentage of the forebrain in rodents. A remarkable feature of the hippocampus is its regularity along its cross-sectional axis, presenting large arrays of neurons aligned in distinct layers, namely, the CA1, CA3, and dentate gyrus fields. Four major pathways connect these three regions and the entorhinal cortex. This highly organized cellular anatomy has facilitated the electrophysiological analysis of these pathways both *in vivo* and *in vitro*. The phenomenon of long-term potentiation (LTP), currently thought to be the cellular correlate or, at least, a requirement for explicit memory formation in the hippocampus, was first described in the perforant pathway of the hippocampus of rabbits by Bliss and Lomo (1973) over 30 years ago. At about this time it was also appreciated that the hippocampal pyramidal neurons of the CA1 region, which undergo LTP in response to stimulation of the Schaffer collateral pathways, encode space: they are 'place cells.' These cells fire when the animal moves to a specific spatial location, suggesting that this brain region may contain the cellular substrate for the formation of spatial maps (O'Keefe and Dostrovsky, 1971). A large number of lesion, pharmacological, and genetic experiments have confirmed that the Schaffer collaterals, the connections between CA3 and CA1 pyramidal neurons, play a major role in the encoding and storage of spatial memories. As with *Aplysia,* it is possible to distinguish two stages during LTP in the Schaffer collateral pathway: an early, short-term stage (E-LTP), which lasts minutes and can be induced by stimulating the hippocampal slice with a single 100-Hz train of 1 s duration, and a later, long-term stage (L-LTP), which lasts much longer and can be induced by four or more repeated 100-Hz trains (Huang and Kandel, 1994; Martin et al., 2000).

4.02.3 Cellular and Molecular Mechanisms Underlying Short- and Intermediate-Term Forms of Implicit and Explicit Memory Storage

4.02.3.1 Short-Term Memory Involves Covalent Modifications of Preexisting Proteins and Short-Term Enhancement of Preexisting Synaptic Connections

These mechanisms were first explored in *Aplysia* (Schwartz et al., 1971; Brunelli et al., 1976; Kandel and Schwartz, 1982). 5-HT released *in vivo* during sensitization, or applied directly to cultured *Aplysia* neurons, binds to cell surface receptors on the sensory neurons and promotes the production of the diffusible second messenger cyclic adenosine monophosphate (cAMP) by activating the enzyme adenylyl cyclase (AC). This increase in internal concentration of cAMP results in a short-term increase in synaptic strength of the sensory-to-motor-neuron connection (STF). This facilitation is partially a result of the enhanced release of the transmitter glutamate by the sensory neuron onto its follower cells and is accompanied by an increase in the excitability of the sensory neuron attributable to the depression of specific sets of potassium channels, a broadening of the action potential, and an increase in Ca^{2+} influx in the presynaptic terminal (Klein et al., 1982; Castellucci et al., 1986; Dale et al., 1988; Eliot et al., 1993; Byrne and Kandel, 1996). In addition, the changes in cAMP and Ca^{2+} levels triggered by the activation of 5-HT receptors and ion channels regulate the activity of different kinases and phosphatases that control the duration and strength of the changes in synaptic efficiency, as we discuss later.

Many aspects of the basic cellular mechanisms that trigger LTP formation in the hippocampus of mammals recapitulate those found in *Aplysia,* suggesting a basic similarity in the cellular underpinnings for explicit and implicit memory. The primary excitatory neurotransmitter in this case is also glutamate. Again, second messengers are activated by synaptic stimulation, and several of these are similar in both systems. In hippocampal pyramidal neurons, synaptic release of glutamate triggers Ca^{2+} influx through *N*-methyl-D-aspartate receptors (NMDAR) and activation of several kinases including Ca^{2+}/camodulin-dependent protein kinase (CamKII), protein kinase C (PKC), and mitogen-activated protein kinase (MAPK). Spaced trains of high-frequency stimulation can also activate cAMP-dependent protein kinase (PKA) through the Ca^{2+}/calmodulin-mediated stimulation of postsynaptic adenylyl cyclase (Blitzer et al., 1995). In *Aplysia,* these second messengers mediate the transient reinforcement of synaptic connections by covalent modifications of channel closure and the enhancement of neurotransmitter release at presynaptic terminals (Martin et al., 2000; Kandel, 2001). In the hippocampus, expression of the early phase of LTP (E-LTP) involves both an increase in the number of postsynaptic alpha-amino-3-hydroxyl-5-methyl-4-isoxazolepropionate receptors (AMPARs) in the plasma membrane and the phosphorylation of specific subunits

and consequent modification of the biophysical properties of the channel (Malenka and Bear, 2004). E-LTP can, with certain stimulation parameters, also involve an increase in presynaptic transmitter release (Voronin and Cherubini, 2003).

4.02.3.2 Different Protocols Engage Different Combinations of Second Messenger Mechanisms

Studies of facilitation of the sensory-to-motor-neuron synaptic connection in *Aplysia* first demonstrated that even slightly different variations in the learning paradigm or in the pattern of synaptic stimulation recruit different second messenger mechanisms alone or in combination. This insight first emerged in a comparison of sensitization and dishabituation, two related forms of nonassociative learning that differ depending on the state (rested or depressed) of the reflex (Byrne and Kandel, 1996; Antonov et al., 2005). Sensitization results in the strengthening of a reflex response. On the synaptic level, this leads to the facilitation of rested synapses, which can be mimicked by a brief exposure to 5-HT. This involves activation of adenylyl cyclase and PKA in the sensory neuron, leading to reduced K^+ current, increased action potential duration, increased Ca^{2+} influx, and increased transmitter release, as described earlier. A longer exposure to 5-HT recruits, in addition, activation of PKC, which can also further increase the duration of action potentials in the presynaptic sensory neuron. Dishabituation, the strengthening of a previously habituated reflex, is reflected in the facilitation at depressed synapses. This involves PKC as well, but in this case it acts through a mechanism that is independent of spike broadening and is thought to involve vesicle mobilization. The spike broadening–independent component of facilitation may also involve Ca^{2+}/CamKII (Nakanishi et al., 1997).

In addition, as first appreciated by Ghirardi et al. (1995; see also Sutton and Carew, 2000; Sharma et al., 2003b), longer exposure to 5-HT can induce intermediate-term facilitation, which requires protein synthesis and involves MAP kinase as well as PKA or (under some circumstances) PKC.

The ability of different mechanisms to be recruited depending on experimental variables such as the pathway (Zalutsky and Nicoll, 1990), induction protocol (Grover and Teyler, 1990), saline composition (Larkman et al., 1992), and stage of development (Grosshans et al., 2002; Jensen et al., 2003) also applies to hippocampal LTP. For example, LTP in neonatal animals primarily involves PKA, whereas in more mature animals it involves CamKII (Yasuda et al., 2003).

4.02.3.3 Many Protocols Involve Pre- and Postsynaptic Mechanisms

Although the short-term mechanisms described for facilitation in *Aplysia* following sensitization or for depression following habituation have been found to be presynaptic, intermediate-term facilitation can also involve postsynaptic mechanisms including intracellular Ca^{2+} release from inositol-1,4,5-trisphosphate (IP3)-sensitive stores, activation of CamKII or PKC, and AMPA receptor insertion (Chitwood et al., 2001; Roberts and Glanzman, 2003; Jin et al., 2004, 2005; Li et al., 2005). To investigate the precise roles of pre- and postsynaptic mechanisms with intermediate protocols, Jin et al. (2004, 2005) examined facilitation induced by either a single, brief 5-HT exposure typically used to produce short-term facilitation (1 min, 50 $\mu mol\ L^{-1}$) or a more prolonged (10 min, 20 $\mu mol\ L^{-1}$) 5-HT exposure following a single pretest (rested) at sensory-motor neuron synapses in isolated cell culture. The facilitation with either protocol lasted more than 30 min compared with test alone controls, but the 10-min exposure to 5-HT produced larger facilitation than a 1-min exposure. With a 1-min exposure, bath application of an inhibitor of PKA (KT5720) or injection of a peptide inhibitor of PKA into the presynaptic sensory neuron reduced the facilitation, as did bath application of an inhibitor of CamKII (KN93) or presynaptic injection of a peptide inhibitor of CamKII (CamKII 281-309). By contrast, bath application of an inhibitor of PKC (Go6983) or injection of 1,2-bis(2-aminophenoxy)ethane-*N,N,N′,N′*-tetraacetic acid (BAPTA) into the postsynaptic motor neuron had no significant effects. None of the bath-applied inhibitors affected homosynaptic depression or basal synaptic transmission. These results suggest that, with a short application of 5-HT that produces short-term facilitation, presynaptic PKA and CamKII play critical roles, and that PKC and postsynaptic Ca^{2+} are not involved.

With the 10-min 5-HT protocol that is thought to produce intermediate-term facilitation, bath application of an inhibitor of PKA (KT5720) or presynaptic injection of the PKA inhibitor did not have a significant effect, but bath application of inhibitors of either PKC (Go6983) or CamKII (KN93) reduced the facilitation. The facilitation is mediated in part by presynaptic mechanisms, since injection of a peptide

inhibitor of PKC (PKC 19-31) into the presynaptic sensory neuron also reduced the facilitation by 10-min exposure to 5-HT (although presynaptic injection of a peptide inhibitor of CamKII did not.) However, it also is mediated in part by postsynaptic mechanisms, since injection of either BAPTA or CamKII 281-309 into the postsynaptic motor neuron also reduced facilitation. By contrast, postsynaptic injection of PKC 19-31 did not reduce the facilitation. These results indicate that with a longer 5-HT application presynaptic PKC plays an important role (as it does with dishabituation), and postsynaptic Ca^{2+} and CamKII are also important, suggesting that not only the specific kinases involved but also their site of action may depend on the duration of 5-HT exposure. Thus, whereas facilitation with a short application of 5-HT is presynaptic, facilitation with a longer 5-HT exposure involves both presynaptic (PKC) and postsynaptic (Ca^{2+} and CamKII) mechanisms.

These findings are not restricted to dissociated cell culture but are also seen in a reduced preparation of the behaving animal. Facilitation of sensory-motor neuron excitatory postsynaptic potentials (EPSPs) in a semi-intact preparation during actual behavioral sensitization also involves different mechanisms and sites depending on the training protocol (Antonov et al., 2005, 2006). Short-term sensitization produced by a single tail shock leads to synaptic facilitation, which involves presynaptic PKA and CamKII that produce transient spike broadening as well as some longer-lasting mechanisms of facilitation. Intermediate-term sensitization produced by a train of four shocks also involves presynaptic PKA and CamKII and, in addition, involves postsynaptic Ca^{2+} and CamKII, which are recruited with a slight delay after the shock. After that delay, the pre- and postsynaptic mechanisms both contribute and are more than additive.

Classical conditioning (like intermediate-term facilitation induced by 5-HT) involves not only pre- but also postsynaptic mechanisms. Thus, facilitation of sensory-motor neuron EPSPs during classical conditioning in a semi-intact preparation can be blocked either by injecting a peptide inhibitor of PKA into the sensory neuron or by injecting BAPTA into the motor neuron (Antonov et al., 2003), providing the strongest evidence to date that either activity-dependent facilitation or Hebbian LTP contributes to synaptic plasticity underlying behavioral learning. In addition, conditioning is accompanied by increases in evoked firing and membrane resistance of the sensory neuron, and those presynaptic effects are also blocked either by injecting an inhibitor of PKA into the sensory neuron or by injecting BAPTA into the postsynaptic motor neuron. These results suggest that the pre- and postsynaptic mechanisms are not independent but, rather, interact through retrograde signaling.

At least under some conditions pre- as well as postsynaptic mechanisms have also been found to contribute to early-phase LTP in hippocampus (Arancio et al., 1995, 1996, 2001; Malgaroli et al., 1995; Ryan et al., 1996; Zakharenko et al., 2003; Ninan and Arancio, 2004; Wang et al., 2005; Lu and Hawkins, 2006; Ninan et al., 2006). As in *Aplysia,* in several cases inhibitors injected into the pre- and postsynaptic neurons have more than additive effects (Arancio et al., 2001; Wang et al., 2005; Lu and Hawkins, 2006), suggesting that the pre- and postsynaptic mechanisms of LTP are not independent but, rather, act synergistically.

The sensory-to-motor-neuron synapses of the gill- and siphon-withdrawal reflex of *Aplysia* also exhibit plasticity that underlies another elementary form of nonassociative learning – habituation. Habituation is probably the most ubiquitous form of learning in animals, including man. It is a process whereby an animal learns through repeated exposure that the consequences of a weak stimulus are neither noxious nor rewarding. As a result, and in contrast to sensitization, the animal learns to ignore the stimulus. For example, *Aplysia* will initially respond to a weak tactile stimulus to the siphon with a brisk withdrawal of the gill and siphon. But with repeated stimulation, the animal learns to ignore the stimulus and exhibits progressively smaller reflex responses.

As is the case with sensitization, the memory for habituation can exist in both a short-term and long-term form. A single training session of 10 stimuli produces a memory that lasts for 10 or 15 min (Pinsker et al., 1970). In contrast, four repeated training sessions of 10 stimuli each produce a memory that persists for at least 3 weeks (Carew et al., 1972). Both the short-term and long-term behavioral modifications are reflected by a decrease in the strength of the sensory-to-motor-neuron connection. The synaptic depression resulting from habituation is homosynaptic; it results, as does the behavior, from a change in activity in the same pathway that is excited by the stimulus that elicits the reflex. At the cellular level, the homosynaptic depression that underlies short-term habituation results from a decrease in the number of transmitter quanta released per action potential from the presynaptic terminals of the sensory neurons (Castellucci and

Kandel, 1974), and this is the result of a reduced Ca^{2+} influx (Klein and Kandel, 1980).

During homosynaptic depression, the reduction in transmitter release produced by a single stimulus is already evident in response to the second stimulus and can persist for 10–15 min. This suggests that the presynaptic molecular events responsible for the decrease in transmitter release are set in motion by a single stimulus and have been completed by the time the second stimulus is given. To explain how this decrease in transmitter release might occur, a modeling study by Gingrich and Byrne (1985) predicted that the pool of releasable transmitter quanta might be depleted by habituation. This hypothesis was tested directly by Bailey and Chen (1988c), using the electron microscope to visualize the presynaptic terminals of sensory neurons that had been altered by short-term habituation. They found that short-term habituation did not alter the number of sensory neuron presynaptic terminals, the number of transmitter release sites (active zones) within the presynaptic terminals, or the size of active zones. Nor did it alter the total number of synaptic vesicles in a presynaptic terminal. Rather, there was a dramatic reduction in the number of vesicles that were docked at release sites within the active zones, and thus there were fewer packets of transmitter ready to be released. Subsequent experiments further indicated that, in addition to the reduction in the number of synaptic vesicles docked at the active zone, habituation might also interfere with a mechanism directly coupled to the release process (Eliot et al., 1994b; Armitage and Siegelbaum, 1998). Combined, these studies suggested that habituation leads to the selective depletion of synaptic vesicles from the active zone and a consequent failure to mobilize overlying vesicles in the presynaptic terminal. To overcome habituation, therefore, a dishabituating stimulus would first have to mobilize vesicles into sensory neuron active zones (Hochner et al., 1986).

4.02.3.4 Redistribution of Synaptic Components and Early Microstructural Modifications

Recent imaging studies have revealed that even the early phase of hippocampal LTP can also be accompanied by concomitant pre- and postsynaptic alterations in the structure of the synapse. Tens of minutes after the induction of LTP, there is an outgrowth of new pre- and postsynaptic processes (Engert and Bonhoeffer, 1999; Maletic-Savatic et al., 1999; Ninonenko et al., 2003), and even earlier (minutes), there are increases in spine size (Matsuzaki at al., 2004), clusters of postsynaptic glutamate receptors (Shi et al., 1999), and clusters of presynaptic vesicle-associated proteins and sites where the pre- and postsynaptic clusters colocalize (Antonova et al., 2001). Any of these early structural changes could also be a 'tag' that must be stabilized by protein synthesis for more enduring plasticity (see section 4.02.4.4).

Similar to the clustering of synaptic proteins during LTP, intermediate-term facilitation in *Aplysia* is accompanied by the enrichment of empty sensory neuron varicosities with synaptic vesicles, leading to the rapid presynaptic activation of silent synapses (Kim et al., 2003). However, these intermediate-term changes do not persist for 24 h unless they are stabilized by additional molecular events (including the machinery for translational activation) recruited during the long-term process. The early (hours) stages of LTF are also accompanied by clustering of postsynaptic proteins including the *Aplysia* homologs of NMDA and AMPA receptors (Li et al., 2004). It is not yet known whether intermediate-term facilitation is accompanied by similar postsynaptic changes, but it seems likely that it is. However, presynaptic microstructural changes can occur during even earlier phases of learning-related synaptic plasticity in *Aplysia:* homosynaptic potentiation induced by moderate tetanic stimulation of the presynaptic neuron is accompanied by rapid (less than 10 min) aggregation of the vesicle-associated protein synaptophysin into new clusters or puncta (Jin et al., 2003), as occurs during early-phase LTP in hippocampal neurons and intermediate-term facilitation by 5-HT in *Aplysia.*

The rapid increases in clusters or puncta of presynaptic (synaptophysin) and postsynaptic (GluR1) proteins at the onset of LTP in hippocampal neurons are dependent on NMDA receptor activation and actin polymerization (Antonova et al., 2001). Maintenance of the increases for 30 min does not require protein synthesis, but maintenance for 3 h does (Antonova et al., 2001, 2005). Time-lapse imaging of synaptophysin–green fluorescent protein (GFP) revealed that the puncta are formed by aggregation of material from a more diffuse background level, as is also thought to occur for GluR1 (Shi et al., 1999). That aggregation may involve two types of molecules that can regulate actin: RhoA and VASP. For example, the rapid increases in puncta of both pre- and postsynaptic proteins are blocked by two inhibitors of RhoA, toxin B and Y27632, and immunocytochemical studies have shown that VASP is located at synapses and is phosphorylated and activated both presynaptically and

postsynaptically during potentiation (Wang et al., 2005). Thus, the redistribution of synaptic proteins appears to involve similar molecular pathways (regulation of actin by RhoA and perhaps also VASP) on both sides of the synapse.

Activity-dependent remodeling of the actin network is also involved in the formation of new varicosities and the enrichment of presynaptic proteins during the early stages of LTF in *Aplysia* (Hatada et al., 2000; Udo et al., 2005). In that case, actin is regulated by a different Rho GTPase, Cdc42. In addition, homosynaptic potentiation in *Aplysia* is blocked by presynaptic (but not postsynaptic) injection of phalloidin, which binds actin (Jin et al., 2003), suggesting that actin could also be involved in the rapid increase in puncta of synaptophysin during the potentiation.

Collectively, these results suggest that even the early phases of learning-related synaptic plasticity can already engage a coordinated sequence of pre- and postsynaptic functional and structural changes that may ultimately lead to the formation of new synapses, as occurs during synapse formation in development (Sanes and Lichtman, 1999; Cohen-Cory, 2002). Like synapse formation during development, these processes probably involve a variety of transsynaptic messengers. Recent evidence suggests that nitric oxide (NO) is one of several messengers involved in both the functional and structural changes during the early phases of hippocampal LTP.

4.02.4 Cellular and Molecular Mechanisms Underlying Long-Term Forms of Memory Storage

As mentioned above, the inhibition of transcription or translation does not affect short-term memory but blocks the formation of long-term memory in a variety of model systems, suggesting that the stabilization of memory traces depends on *de novo* gene expression (Kandel, 2001).

4.02.4.1 Gating Signals at the Synapse: A Balance between the Activities of Protein Kinases and Phosphatases

Synaptic stimulation of *Aplysia* sensory neurons leads to a local increase in cAMP and the activation of PKA by causing the catalytic subunits of this enzyme to dissociate from the regulatory subunits. The catalytic subunits can then phosphorylate different substrates in the synaptic terminals, such as potassium channels and proteins involved in exocytosis, leading to enhanced transmitter release during short-term memory. When synaptic stimulation reaches a given threshold or is repeated a number of times, it causes a persistent increase in the level of cAMP and leads to longer-lasting forms of synaptic plasticity. At the molecular level, this more robust pattern of stimulation causes the catalytic subunit of PKA to recruit p42 MAPK. Both then move to the nucleus, where they phosphorylate nuclear targets including other kinases that, in turn, can phosphorylate transcription factors and activate gene expression required for the induction of long-term memory (Bacskai et al., 1993; Martin et al., 1997b; Purcell et al., 2003).

In rodents, inhibition of PKA and MAPK does not affect E-LTP at Schaffer collateral synapses, but these kinases are required for L-LTP (Frey et al., 1993; English and Sweatt, 1996, 1997; Abel et al., 1997). The role of PKA seems to be different in hippocampal neurons than during LTF formation in *Aplysia* sensory neurons. In the hippocampus, PKA does not translocate to the nucleus and plays only a synaptic role: It can phosphorylate different targets, such as the GluR1 subunit of AMPAR (Lee et al., 2000), and it favors the induction of LTP by counteracting the activity of protein phosphatases (Abel et al., 1997; Winder et al., 1998). Finally, it also tags the synapse enabling the consolidation of the long-term process (Barco et al., 2002). In contrast, the role of MAPK appears to be more conserved, and its activation and translocation to the nucleus are also required, at least for forskolin- or brain-derived neurotrophic factor (BDNF)-mediated L-LTP (Martin et al., 1997b; Patterson et al., 2001).

In addition to protein kinases, synaptic protein phosphatases also play a key role in regulating the initiation of long-term synaptic changes. Various protein phosphatases, such as PP1 and calcineurin, oppose the local activity of PKA and act as inhibitory constraints on memory formation. Thus, an increase in calcineurin activity causes defects in long-term memory and L-LTP (Mansuy et al., 1998; Winder et al., 1998), whereas a reduction has the opposite effect (Malleret et al., 2001). Similarly, a reduction in PP1 activity also improves memory in mice (Genoux et al., 2002). Recent experiments in cultured *Aplysia* neurons indicate that calcineurin may also act in this organism as a memory suppressor for sensitization (Sharma et al., 2003a). Therefore, in both systems a

balance between phosphatase and kinase activities at a given synapse gates the synaptic signals that eventually reach the nucleus and can regulate both memory storage and retrieval (Abel et al., 1998).

4.02.4.2 Gating Signals at the Nucleus: Triggering *de Novo* Gene Expression

One of the features that fundamentally distinguish the storage of long-term memory from short-term cellular changes is the requirement for the activation of gene expression. Recently, Thompson et al. (2004) have found that, in the *Aplysia* sensory-motor neuron culture preparation, 5-HT stimulation that produces LTF triggers the nuclear translocation of importins, proteins involved in carrying cargos through nuclear pore complexes. Similarly, in hippocampal neurons, NMDA activation or LTP induction, but not depolarization, leads to translocation of importin (Thompson et al., 2004). The future identification of the molecular cargoes of importin and its signaling role in the nucleus are likely to increase our understanding of how transcription-dependent memory is regulated.

Studies in *Aplysia* revealed the participation of the cAMP/PKA-signaling pathway and the transcription factor, cAMP response element binding protein (CREB), in transcriptional activation by synaptic stimulation. During LTF in *Aplysia* sensory neurons, PKA activates gene expression via an *Aplysia* CREB1 (ApCREB1). In 1990, Dash et al. first demonstrated a role for CREB in LTF by microinjecting CRE oligonucleotides into sensory neurons cocultured with motor neurons (Dash et al. 1990). These decoy oligonucleotides inhibit the function of ApCREB1 by directly binding to this protein, thereby preventing its binding to CRE sites in regulatory regions that actvate expression of cAMP-responsive genes. Whereas injection of the CRE oligonucleotide had no effect on STF, it selectively blocked LTF. Studies by a number of laboratories have now revealed that different members of the CREB family of transcription factors participate in the molecular switch that regulates LTF formation (Bartsch et al., 1995, 1998; Lonze and Ginty, 2002; Barco et al., 2003). Both the CREB activator ApCREB1 and the repressor ApCREB2 contribute to this process. The formation of LTF requires the activation of ApCREB1 by PKA and the concomitant downregulation of ApCREB2 by MAPK (Guan et al., 2003). Injection of anti-ApCREB2 antibodies into *Aplysia* sensory neurons causes a single pulse of 5-HT, which normally induces STF lasting minutes, to evoke LTF that lasts several days (Bartsch et al., 1995). Conversely, injection of pApCREB1 phosphorylated by PKA can by itself trigger facilitation lasting 24 h, and this facilitation can be stabilized by a single pulse of 5-HT (Bartsch et al., 1998; Casadio et al., 1999).

These studies revealed that the transition from STF to LTF requires the simultaneous removal of transcriptional repressors and activation of transcriptional activators. Transcriptional repressors and activators can interact with each other both physically and functionally. Guan et al. (2002) used chromatin immunoprecipitation techniques to examine directly the role of CREB-mediated responses in long-term synaptic integration in the nucleus of *Aplysia* sensory neurons. They found that both facilitatory and inhibitory modulatory transmitters alter promoter occupancy by activator or repressor CREB isoforms and subsequently affect nucleosome structure bidirectionally through acetylation and deacetylation of histone residues in chromatin.

The complete set of genes regulated by a transcription factor in a specific cell type is still not known. In *Aplysia* sensory neurons, the activity of ApCREB1 leads to the expression of several immediate-response genes, such as ubiquitin hydrolase, that stabilizes STF (Hegde et al., 1997) and the transcription factor CCAAT-box-enhanced binding-protein (C/EPB), whose induction has been shown to be critical for LTF (Alberini et al., 1994). This induced transcription factor (in concert with other constitutively expressed molecules such as ApAF [Bartsch et al., 2000]) activate a second wave of downstream genes that can ultimately lead to the growth of new synaptic connections. These genes represent only a few of the family of gene products generated by CREB activity.

The participation of the cAMP/CREB pathway appears to be a general feature of long-term memory formation throughout the animal kingdom. The first genetic screenings designed to identify learning mutants in *Drosophila* revealed two interesting mutants, *dunce* and *rutabaga,* with specific defects in memory formation (Dudai et al., 1976; Duerr and Quinn, 1982) that were subsequently shown to affect genes in the cAMP signaling pathway (Byers et al., 1981; Waddell and Quinn, 2001). Experiments in transgenic flies have confirmed that the balance between CREB activator and repressor isoforms is critical for long-term behavioral memory. Thus, overexpression of an inhibitory form of CREB (dCREB-2b) blocked long-term olfactory memory but did not alter short-term memory (Yin et al., 1994; Perazzona et al., 2004). Indeed, most of the upstream signaling cascade leading to CREB activation

appears to be conserved through evolution, and many aspects of the role of CREB in synaptic plasticity described in invertebrates have also been observed in the mammalian brain. However, the role of CREB in explicit forms of memory appears to be more complex than in implicit forms of memory in invertebrates (for reviews, see Lonze and Ginty, 2002; Barco et al., 2003).

In mammals, CREB has been shown to regulate the expression of more than 100 genes, but it is still not clear how many of these putative downstream genes are actually regulated during learning and required for memory storage (Mayr and Montminy, 2001; Lonze and Ginty, 2002). The current list of target genes is heterogeneous and includes genes with very diverse functions, from regulation of transcription and metabolism to genes affecting cell structure or signaling. Many CREB targets, such as c-fos, EGR-1, or C/EBP, are themselves transcription factors, whose induction may trigger a second wave of gene expression. The availability of the complete mouse and human genome, the availability of the *Aplysia* neuronal transcriptome (Moroz et al., 2006), the development of new bioinformatics tools for their analysis, and the recent application of new unbiased, genome-wide screening approaches has begun to reveal the gene profiles regulated by CREB under different physiological conditions (Conkright et al., 2003; Euskirchen et al., 2004; Impey et al., 2004; Barco et al., 2005; Zhang et al., 2005). Although we have focused on CREB-dependent gene expression because of its conserved role in memory formation through evolution, other transcription factors, such as ApAF and C/EBP in *Aplysia* and SRF, C/EBP, c-fos, EGR-1, or NF-$\kappa\beta$ in mice (Tischmeyer and Grimm, 1999; Albensi and Mattson, 2000; Izquierdo and Cammarota, 2004; Ramanan et al., 2005) are also likely to contribute to the transcriptional regulation that accompanies long-lasting forms of synaptic plasticity.

The epigenetic marking of chromatin, by histone modifications, chromatin methylation, and the activity of retrotransposons, may have long-term consequences on transcriptional regulation of specific gene *loci* involved in long-term synaptic changes, and thus adds a new layer of complexity to our view of how nuclear function and synaptic activity affect one another (Guan et al., 2002; Hsieh and Gage, 2005; Levenson and Sweatt, 2005). The contribution of histone tail acetylation, a modification that favors transcription and is associated with active *loci*, was first revealed for LTF formation by Guan et al. (2002) in *Aplysia*. In addition to finding that facilitatory and inhibitory stimuli alter, bidirectionally, the acetylation stage and structure of promoters driven by the expression of genes involved in the maintenance of LTF, such as C/EBP, this study also demonstrated that enhancing histone acetylation with deacetylase (HDAC) inhibitors facilitates the induction of LTF. HDAC inhibitors have now been shown to enhance L-LTP in the Schaffer collateral pathway of mammals and memory formation in hippocampus-dependent tasks (Alarcon et al., 2004; Korzus et al., 2004; Yeh et al., 2004; Levenson et al., 2005). Conversely, mice with reduced histone acetyltransferase activity have deficits in both long-lasting forms of memory and LTP (Bourtchouladze et al., 2003; Alarcon et al., 2004; Korzus et al., 2004; Wood et al., 2005). These results indicate that critical chromatin remodeling occurs during the formation of long-term memory, and that these nuclear changes are required for the stable maintenance of memory storage.

4.02.4.3 Local Protein Synthesis

In addition to transcription in the nucleus and protein synthesis in the cell body, long-term memory also requires a second site of local protein synthesis at the synapse. A number of distinct mRNAs have been localized in the axons of *Aplysia* and in the dendrites of rodent hippocampal neurons (for review, see Steward and Schuman, 2001, 2003). The molecular mechanisms that target these mRNAs to the synapse are largely unknown, but some are carried by the kinesin motors, the key anterograde transport machinery (Puthanveettil and Kandel, 2006). Some of these mRNAs are thought to involve the recognition of *cis*-acting elements in their 3′ untranslated region by specific RNA-binding proteins that interact with the cytoskeleton. Once transported to the dendritic compartments, these mRNAs are translated only after docking at active synaptic sites, a process frequently referred to as synaptic or local protein synthesis. Recent studies suggest that regulation of local protein synthesis plays a major role in the control of synaptic strength at the sensory-to-motor-neuron connection in *Aplysia* and during L-LTP in the hippocampus. For example, Casadio et al. (1999) found that long-term, synapse-specific facilitation induced by 5-HT requires local protein synthesis for the stable maintenance of learning-induced synaptic growth. In the hippocampus, the induction of LTP in the Schaffer collateral pathway is accompanied by the transport of polysomes from dendritic shafts to active spines of CA1 neurons, suggesting a critical role for local protein synthesis in the morphological changes associated with LTP

(Ostroff et al., 2002), and local inhibition of protein synthesis blocks L-LTP in the Schaffer collateral pathway (Bradshaw et al., 2003; Cracco et al., 2005). The control of translation at the synapse is likely to be complex and involve several different mechanisms, including different types of mRNA transport and docking, cytoplasmic poly-adenylation, mTOR (which is the target of the selective protein synthesis inhibitor rapamycin; Cammalleri et al., 2003; Purcell et al., 2003), and the phosphorylation of different translation factors (see recent review by Sutton and Schuman, 2005). Many of the molecules contributing to the regulation of this process are required for both LTF in *Aplysia* and L-LTP in the hippocampus, including BDNF (which promotes local protein synthesis; Aakalu et al., 2001; Purcell et al., 2003), mTOR, and the cytoplasmic polyadenylation element binding protein (CPEB), which activates dormant mRNAs (Huang et al., 2002; Si et al., 2003a). The role of local protein synthesis in the capture and stabilization of synapse-specific forms of long-term plasticity is discussed in the following section.

4.02.4.4 Moving Back to the Synapse: Capture of Activity-Induced Gene Products

Following the sending of a retrograde signal to the nucleus and the subsequent transcriptional activation, newly synthesized gene products, both mRNAs and proteins, have to be delivered by kinesin-mediated fast axonal transport (Puthanveettil and Kandel, 2006) specifically to the synapses whose activation originally triggered the wave of gene expression. To explain how this specificity can be achieved in a biologically economical way given the massive number of synapses in a single neuron, Martin et al. (1997a) and Frey and Morris (1997) proposed the synaptic capture hypothesis. This hypothesis, also referred to as synaptic tagging, proposes that the products of gene expression are delivered throughout the cell but are only functionally incorporated in those specific synapses that have been tagged by previous synaptic activity. The 'synaptic tag' model has now been supported by a number of studies in both the rodent hippocampus (Frey and Morris, 1997, 1998; Barco et al., 2002; Dudek and Fields, 2002) and *Aplysia* (Martin et al., 1997a; Casadio et al., 1999).

Studies of synaptic capture at the synapses between the sensory and motor neurons of the gill-withdrawal reflex in *Aplysia* have demonstrated that the production of CRE-driven gene products in the nucleus is not sufficient to achieve synapse-specific LTF. One also needs a PKA-mediated covalent signal to mark the stimulated synapses, and consequent local protein synthesis to stabilize that mark (Martin et al., 1997a; Casadio et al., 1999). Thus, injection into the cell body of phosphorylated CREB-1 gives rise to LTF at all the synapses of the sensory neuron, but this facilitation is not maintained beyond 24–48 h unless one of the synapses is also marked by triggering the short-term process with a single pulse of 5-HT (Casadio et al., 1999). Once marked, that synapse and only that synapse shows maintained facilitation and growth.

Experiments in the rat hippocampus by Frey and Morris have demonstrated, in turn, that once transcription-dependent LTP has been induced at one pathway, the long-term process can be 'captured' at a second pathway receiving a single train that would normally produce only E-LTP. The stimulus for the short-term process causes a transient potentiation and, in addition, marks the synaptic terminals, enabling the capture of the newly expressed gene products. The properties of synaptic capture observed for intracompartmental capture in hippocampal CA1 neurons are similar to those described in the bifurcated sensory neurons of *Aplysia* (Martin et al., 1997a). However, in mammals, where there are two dendritic compartments – apical and basal – the tag appears to be restricted to specific dendritic compartments, and additional mechanisms are required to capture across compartments (Alarcon et al., 2006). Most of the molecular details underlying these processes are still unknown, but experiments with a line of transgenic mice expressing a constitutively active CREB protein have demonstrated that PKA activity is part of the tagging signal, and that the synaptic capture of CRE-driven transcription may be sufficient to support L-LTP (Barco et al., 2002). More recent experiments in these mutants and in BDNF-deficient mice support a role for presynaptically released BDNF in the tagging of the synapse for subsequent capture of L-LTP (Barco et al., 2005). Local synthesis of proteins, which we have discussed in the previous section, has also been proposed to be involved in synaptic capture of long-term forms in both *Aplysia* and rodents (Martin et al., 1997a; Barco et al., 2002). Martin et al. (1997a) investigated the role of local protein synthesis in an *Aplysia* culture system in which a single bifurcated sensory neuron was plated in contact with two spatially separated gill motor neurons. In this system, repeated application of 5-HT to one synapse produces a CREB-mediated, synapse-specific LTF that can be blocked by the local application

of inhibitors of translation, suggesting that local protein synthesis at the synapse is also required as part of the retrograde signaling cascade for the initiation of synapse-specific LTF.

4.02.4.5 The Stable Strengthening of Synaptic Connections: Synaptic Growth, Silent Synapses, and Self-Maintenance Mechanisms

Although a number of molecular components that underlie the functional changes associated with the storage of long-term memory have been characterized, little is known about how these are regulated by and coupled to the signaling pathways that give rise to the synaptic structural changes (Bailey et al., 2004).

Activity-induced remodeling of preexisting synapses and the growth of new synapses have been found to accompany various forms of long-term memory, a phenomenon particularly well documented in *Aplysia* sensory neurons (Bailey and Kandel, 1993). Long-term sensitization has been extensively studied in this respect because it is associated with a robust growth of new synaptic connections between the sensory neurons and their postsynaptic target cells (Bailey and Chen, 1983, 1988a,b, 1989). Studies of long-term sensitization have revealed that it is accompanied by two forms of learning-related structural plasticity: (1) the remodeling of preexisting synapses, resulting in an increase in the number, size, and vesicle content of presynaptic transmitter release sites (active zones) (Bailey and Chen, 1983), and (2) a growth process that appears similar to synaptogenesis during development and leads to a pronounced increase in the total number of presynaptic varicosities per sensory neuron (Bailey and Chen, 1988a). Sensory neurons from long-term sensitized animals exhibit a twofold increase in the total number of synaptic varicosities, as well as an enlargement in the size of each neuron's axonal arbor. The increase in the size and synaptic vesicle complement of sensory neuron active zones was found to be relatively transient, whereas the changes in varicosity and active zone number were much more stable and persisted for at least 3 weeks after training, similar to the duration of the behavioral change (Bailey and Chen, 1989). These findings demonstrated, for the first time, that learning-induced structural changes could be detected at the level of identified synaptic connections known to be critically involved in behavioral modification and suggested that the growth of new sensory neuron synapses is likely to represent the final and perhaps most stable phase of long-term memory storage in *Aplysia*.

More recently, Kim et al. (2003) have examined the contribution of each class of presynaptic structural change – remodeling of preexisting synapses and the growth of new synapses – to the different time-dependent phases of LTF. They monitored both functional and structural synaptic changes continuously using time-lapse confocal imaging of presynaptic varicosities of sensory neurons labeled with three different fluorescent markers: the whole-cell marker *Alexa-594* and two presynaptic marker proteins, *synaptophysin-eGFP* to monitor changes in the distribution of synaptic vesicles within individual varicosities and *synapto-PHluorin* to monitor active transmitter release sites (Miesenbock et al., 1998). Repeated pulses of 5-HT induced two temporally, morphologically, and molecularly distinct classes of presynaptic changes: (1) relatively rapid activation of silent presynaptic terminals through the filling of preexisting empty varicosities with synaptic vesicles, which requires translation but not transcription, and (2) generation of new synaptic varicosities, which occurs more slowly and requires both transcription and translation. In addition to its role in LTF, the rapid (hours) activation of silent presynaptic terminals may also contribute to the intermediate phase of synaptic plasticity and memory storage (Ghirardi et al., 1995; Mauelshagen et al., 1996; Sutton et al., 2001). These findings, the first to be made on individually identified presynaptic varicosities, suggest that long-term changes in synaptic effectiveness in *Aplysia* may involve the differential regulation of two fundamentally disparate forms of presynaptic compartment: (1) nascent (empty) silent varicosities that can be rapidly and reversibly remodeled into active transmitter release sites and (2) mature, more stable and functionally competent varicosities that may undergo a process of fission to form new stable synaptic contacts (Bailey et al., 2005).

Activation of silent synapses also plays a major role in LTP in mammals. In this case, the term *silent synapse* refers to excitatory glutamatergic synapses whose postsynaptic membrane contains NMDARs but no AMPARs (Malinow et al., 2000; Malinow and Malenka, 2002). The lack of AMPAR-mediated signaling renders these synapses inactive, or 'silent,' under normal conditions. Synaptic stimulation activates these silent synapses through the insertion of AMPARs into the postsynaptic membrane, a phenomenon sometimes referred to as AMPA-fication. Calcium/CamKII plays a critical role in this process.

Once this kinase is activated by high-frequency stimulation, it phosphorylates AMPARs or associated proteins, triggering their insertion into the postsynaptic membrane. The synapse is then no longer silent, and postsynaptic responses are, by consequence, enhanced. Conversely, synapses can be made to be silent, for example, after LTD induction, by removing AMPARs from the postsynaptic membrane (Malinow and Malenka, 2002).

In addition to changes in synaptic function, activity-induced growth and/or remodeling of synaptic connections are also important in the storage of explicit memory. However, their specific role is not as clear as in *Aplysia,* because the functional contribution of individual synapses to memory processes in the large and complex neuronal circuits of the mammalian brain is not yet well defined (see reviews by Lamprecht and LeDoux, 2004; Hayashi and Majewska, 2005; Segal, 2005). The generation and enlargement of dendritic spines has been associated with the production of LTP and synaptic activity in organotypic hippocampal slices (Matsuzaki et al., 2004; Nagerl et al., 2004), or acute slices of neonatal animals (Zhou et al., 2004), whereas these structural changes are much more subtle in the adult brain (Lang et al., 2004). In adults there is only a modest production of new spines (Zuo et al., 2005), and learning-related plasticity seems to rely more on subcellular changes than on anatomical changes. Thus, neuronal activity regulates the diffusion of molecules across the neck of dendritic spines (Bloodgood and Sabatini, 2005) and the transport of polysomes from dendritic shafts to active spines (Ostroff et al., 2002), as well as the trafficking of neurotransmitter receptors (Malinow and Malenka, 2002).

Biological molecules have a relatively short half-life (hours to days) compared with the duration of memory (days, weeks, even years). How then, in the absence of frank anatomical changes, can the altered molecular composition of a synapse be maintained for such a long time? Most answers to this elusive question rely on some type of self-sustained alteration that can somehow modulate synaptic strength. For example, Malinow and colleagues have proposed that two regulatory pathways control the insertion and removal of AMPA receptors at the synapse: The maintenance pathway is always on and controls the constant turnover of receptor subunits, whereas the constructive pathway is only turned on during LTP induction (Malinow et al., 2000; Malinow and Malenka, 2002). The activation of the constructive pathway and insertion of new AMPARs would cause the growth and/or maturation of postsynaptic densities, enabling the formation of new memories, whereas the maintenance pathway would be responsible for their stabilization (Hayashi et al., 2000; Lisman and Zhabotinsky, 2001). Another interesting model for long-term memory storage was suggested by Crick more than 20 years ago (Crick, 1984). Crick proposed that autocatalytic kinases might provide the molecular mechanism for long-lasting, self-maintained changes in synaptic function. John Lisman further developed this idea based on the autocatalytic properties of the calcium/CamKII (Lisman and Zhabotinsky, 2001).

More recently, Kandel and Si have proposed a model based on the prion-like properties of the *Aplysia* neuronal CPEB (Si et al., 2003b). *Aplysia* CPEB has two conformational states: one is inactive or acts as a repressor, and the other is active. In a naive synapse, the basal level of CPEB expression is low, and its state is inactive or repressive. However, if a given threshold is reached, CPEB switches to the prion-like state, which activates the translation of dormant mRNAs through the elongation of their poly-A tail (Si et al., 2003a). Once the prion state is established at an activated synapse, dormant mRNAs, made in the cell body and distributed cell-wide, would be translated only at the activated synapses. Because the activated CPEB can be self-perpetuating, it could contribute to a self-sustaining, synapse-specific long-term molecular change. Interestingly, a structurally similar neuronal isoform of CPEB, CPEB-3, has been found in mouse hippocampal neurons, where it is induced by the neurotransmitter dopamine (Theis et al., 2003).

These molecular mechanisms are not mutually exclusive: The synaptic translation of CamKII mRNAs can be regulated by CPEB, and the synthesis and traffic of new AMPAR subunits may require CamKII activity as well as enhanced protein synthesis (Burgin et al., 1990; Ouyang et al., 1999; Huang et al., 2002) .

4.02.5 Concluding Remarks

Cell biological and molecular studies of both implicit and explicit memory processes have revealed two major forms of storage mechanisms. The storage of long-term memory is associated with altered gene expression, as well as the synthesis of new mRNAs and proteins, and is often accompanied by changes in both the number and structure of synaptic connections. In contrast, short-term (up to about 1 h) memory and the early phases of long-term synaptic

storage in *Aplysia* and hippocampus involve covalent modification of preexisting proteins in either the presynaptic (*Aplysia*) or postsynaptic (hippocampus) neuron, leading to an alteration in the strength of preexisting synaptic connections.

The discovery of intermediate (2–3 h) forms of synaptic plasticity that involve elements of the short-term and long-term molecular mechanisms in both *Aplysia* and hippocampus have demonstrated that distinct phases that overlap these processes can be revealed by specific protocols. These new intermediate phases may also form a bridge to the morphological changes that occur during long-term plasticity: Recent imaging studies of living synapses in hippocampus and *Aplysia* have shown that even the early phases of synaptic plasticity are accompanied by microstructural alterations. These early structural changes may seed the formation of new functional synapses, which may then be further elaborated and stabilized by additional long-term training. This emerging view is likely to supplement the more established idea that early-phase plasticity exclusively involves either pre- or postsynaptic covalent modifications and suggests that these early phases of synaptic plasticity also may already involve microstructural alterations capable of contributing importantly to the transition between short-term and long-term memory storage.

Finally, as we have outlined in this chapter, one of the key unifying findings emerging from the molecular study of implicit and explicit memory processes is the unexpected realization that these distinct forms of memory, which differ not only in the neural systems involved but also in the nature of the information stored and in the role of attention in that storage, nevertheless share a common set of molecular mechanisms for their long-term representation. Thus, whereas animals and humans are capable of a wide variety of learning processes that use a number of different second messenger and signaling cascades, they may recruit the same restricted set of molecular logic for the storage of long-term memory.

4.03 Sensitization and Habituation: Invertebrate

D. Fioravante, E. G. Antzoulatos, and J. H. Byrne, The University of Texas Medical School at Houston, Houston, TX, USA

4.03.1 Introduction

Survival of animals is dependent on their capacity to adapt to their environment by modifying their behavior. The experience-induced modification of behavior is a manifestation of learning, whereas memory is the retention of a learned behavior over time. A conceptual scheme that has driven the investigation of learning for the largest part of the twentieth century rests on the distinction between associative and nonassociative forms of learning. Nonassociative learning is best exemplified by habituation and sensitization. Habituation is defined as the gradual waning of a behavioral response to a weak or moderate stimulus that is presented repeatedly. Following habituation, the response may be restored to its initial state either passively with time (i.e., spontaneous recovery), or with the presentation of a novel stimulus (i.e., dishabituation). Sensitization is defined as the enhancement of a behavioral response elicited by a weak stimulus following another, usually noxious stimulus. Sensitization can also develop in response to a moderate stimulus that is presented repeatedly at relatively short intervals.

Associative learning refers to the formation of an association either between two stimuli (i.e., classical conditioning), or between a behavior and a stimulus (i.e., operant conditioning). In classical conditioning, a novel or weak stimulus (conditioned stimulus; CS) is paired with a stimulus that generally elicits a reflexive response (unconditioned stimulus and response, respectively; US and UR). After sufficient training with contingent CS-US presentations (which may be a single trial), the CS comes to elicit a learned response (conditioned response; CR), which often resembles the UR (or some aspect of it). Operant conditioning is an experimental procedure in which the behavior of an animal may be followed by either a desirable or an aversive stimulus, arranged by the

experimenter. The desirable stimulus (e.g., food) will typically increase the future occurrence of this behavior (a process called positive reinforcement). An aversive stimulus (e.g., a noxious electric shock) will tend to decrease the future probability of this behavior (a process called punishment). A behavior can also be reinforced when it becomes contingent with the removal of an aversive stimulus from the animal's environment (i.e., negative reinforcement). Thus, through the processes of operant conditioning an animal learns the consequences of its behavior.

Humans and other animals are capable of displaying more complex forms of learning than the four types described above. However, these four types are likely to constitute the building blocks for more complex forms of learning. Thus, a major goal of neurobiologists is to explain the anatomical, biophysical, and molecular processes of the nervous system that underlie simple forms of learning and memory. Specifically, what parts of the nervous system are critical for learning? How is information about a learned event acquired and encoded in neuronal terms? How is information stored, and, once stored, how is it retrieved? Most neuroscientists believe that the answers to these questions lie in understanding the ways in which the properties of individual nerve cells in general, and synaptic connections, in particular, change when learning occurs. To that end, the investigation of neuronal mechanisms of learning and memory in invertebrates has been very fruitful over the past 40 years. This chapter will focus on mechanisms of habituation and sensitization in *Aplysia* and other invertebrates. A detailed discussion of mechanisms of associative learning in *Aplysia* and other invertebrates can be found in subsequent chapters (*See* Chapters 4.02, 4.04, 4.06, 4.07, 4.08, 4.09, 4.10).

4.03.2 Habituation and Sensitization in *Aplysia*

4.03.2.1 Aplysia Withdrawal Reflexes and Underlying Neural Circuits

One animal that is well suited for the examination of the molecular, cellular, morphological, and network mechanisms underlying neuronal plasticity and learning and memory is the marine mollusc *Aplysia*. This animal has a relatively simple nervous system with large, identifiable neurons that are accessible for detailed anatomical, biophysical, and biochemical studies. Neurons and neural circuits that mediate many behaviors in *Aplysia* have been identified. In several cases, these behaviors can be modified by learning. Moreover, specific loci within neural circuits at which modifications occur during learning have been identified and aspects of the cellular mechanisms underlying these modifications have been analyzed.

Two withdrawal reflexes of *Aplysia* have been used extensively to analyze the neuronal mechanisms contributing to nonassociative and associative learning (for reviews see Hawkins and Kandel, 1984; Carew and Sahley, 1986; Byrne, 1987; Byrne et al., 1991, 1993). The first behavior is the siphon–gill withdrawal reflex. Within the mantle cavity is the respiratory organ of the animal, the gill, and protruding from the mantle cavity is the siphon (**Figure 1**). The

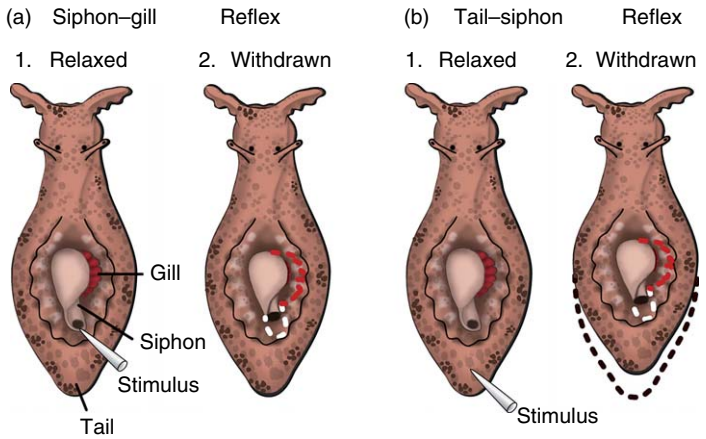

Figure 1 Siphon–gill and tail–siphon withdrawal reflexes of *Aplysia*. (a) Siphon–gill withdrawal. Dorsal view of *Aplysia* (1) Relaxed position. (2) A stimulus (e.g., a water jet, brief touch, or weak electric shock) applied to the siphon causes the siphon and the gill to withdraw into the mantle cavity. (b) Tail–siphon withdrawal reflex. (1) Relaxed position. (2) A stimulus applied to the tail elicits a reflex withdrawal of the tail and siphon.

siphon–gill withdrawal reflex is elicited when a tactile or electrical stimulus is delivered to the siphon and results in withdrawal of the siphon and gill (**Figure 1(a)**). A second behavior that has been examined extensively is the tail–siphon withdrawal reflex. Tactile or electrical stimulation of the tail elicits a coordinated set of defensive responses, two components of which are a reflex withdrawal of the tail and the siphon (**Figure 1(b)**).

A prerequisite for the analysis of the neural and molecular basis of learning is an understanding of the neural circuit that controls the behavior. The afferent limb of the siphon–gill withdrawal reflex consists of sensory neurons with somata in the abdominal ganglion. The siphon sensory neurons (SN) monosynaptically excite gill and siphon motor neurons (MN) that are also located in the abdominal ganglion (**Figure 2**). Activation of the gill and siphon motor neurons leads to contraction of the gill and siphon. Excitatory, inhibitory, and modulatory interneurons (IN) in the withdrawal circuit have also been identified, although only excitatory interneurons are illustrated in **Figure 2**. The afferent limb of the tail–siphon withdrawal reflex consists of a bilaterally symmetric cluster of sensory neurons that are located in the left and right pleural ganglia (Walters et al., 1983a). These sensory neurons make monosynaptic excitatory connections with motor neurons in the adjacent pedal ganglion, which produce withdrawal of the tail (**Figure 2**). In addition, the tail sensory neurons form synapses with various identified excitatory and inhibitory interneurons (Buonomano et al., 1992; Cleary and Byrne, 1993; Xu et al., 1994). Some of these interneurons activate motor neurons in the abdominal ganglion, which control reflex withdrawal of the siphon. Moreover, several additional neurons modulate the tail–siphon withdrawal reflex (Raymond and Byrne, 1994; Cleary et al., 1995) (**Figure 3(a1)**).

The sensory neurons for both the siphon–gill and tail–siphon withdrawal reflexes are similar and appear to be important plastic elements in the neural circuits. Changes in their membrane properties and the strength of their synaptic connections (synaptic efficacy) are associated with learning and memory. Moreover, the properties of these neurons are modulated by *in vitro* analogs of behavioral training.

4.03.2.2 Habituation

Habituation, perhaps the simplest form of nonassociative learning, refers to the gradual waning of the responses elicited by a repeatedly presented stimulus. Repeated presentation of a relatively weak stimulus will most probably lead to habituation, whereas repeated presentation of a relatively strong stimulus

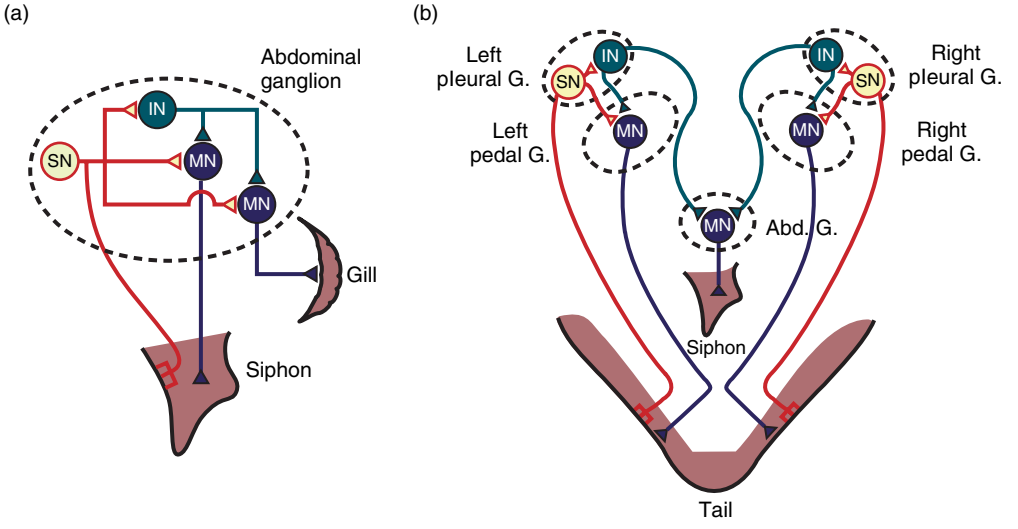

Figure 2 Simplified circuit diagrams of the siphon–gill (a) and tail–siphon (b) withdrawal reflexes. Stimuli activate the afferent terminals of mechanoreceptor sensory neurons (SN) whose somata are located in central ganglia. The sensory neurons make excitatory synaptic connections (triangles) with interneurons (IN) and motor neurons (MN). The excitatory interneurons provide a parallel pathway for excitation of the motor neurons. Action potentials elicited in the motor neurons, triggered by the combined input from the SNs and INs, propagate out peripheral nerves to activate muscle cells and produce the subsequent reflex withdrawal of the organs. Modulatory neurons (not shown here but see **Figure 3(a1)**), such as those containing serotonin (5-HT), regulate the properties of the circuit elements, and, consequently, the strength of the behavioral responses.

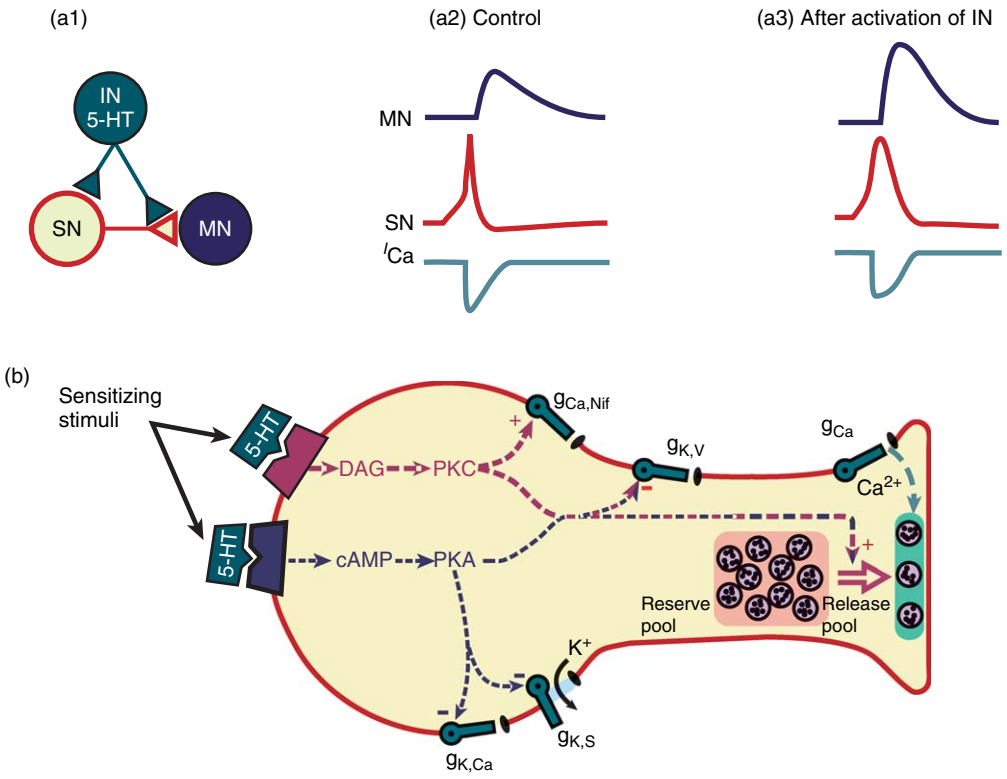

Figure 3 Model of heterosynaptic facilitation of the sensorimotor connection that contributes to short-term sensitization in *Aplysia*. (a1) Sensitizing stimuli activate facilitatory interneurons (IN) that release modulatory transmitters, one of which is 5-HT. The modulator leads to an alteration of the properties of the sensory neuron (SN). (a2, a3) An action potential in a SN after the sensitizing stimulus results in greater transmitter release and hence a larger postsynaptic potential in the motor neuron (MN) than an action potential prior to the sensitizing stimulus. For short-term sensitization the enhancement of transmitter release is due, at least in part, to broadening of the action potential and an enhanced flow of Ca^{2+} into the sensory neuron. (b) Molecular events in the sensory neuron. 5-HT released from the facilitatory interneuron (Part a1) binds to at least two distinct classes of receptors on the outer surface of the membrane of the sensory neuron, which leads to the transient activation of two intracellular second messengers: DAG and cAMP. These second messengers, acting though their respective protein kinases, affect multiple cellular processes, the combined effects of which lead to enhanced transmitter release when a subsequent action potential is fired in the sensory neuron. See section 4.03.2.3.1 for abbreviation definitions.

may lead to sensitization, which is discussed in the next section of the chapter. Habituation is generally distinguished from simple fatigue or sensory adaptation because responsiveness can be rapidly restored (dishabituated) by the presentation of a novel stimulus to the animal. The parametric features of habituation have been previously described in detail by Thompson and Spencer (1966).

Habituation shares some features with more complex forms of learning. First, habituation has a temporal gradient. Similar to most forms of learning, each trial has only a transient effect, which necessitates the presentation of multiple trials. Second, the interval at which training trials are presented is critical. Massing many trials together may lead to faster, albeit only short-lived habituation. In contrast, spacing trials too far apart may lead to little or no habituation. Therefore, an optimal intertrial interval exists, which is determined by the stimulus features and the response system. Third, the effects of habituation training are reversible. As mentioned above, they can be reversed spontaneously with the passage of time (spontaneous recovery), or they may be reversed by the presentation of a novel stimulus (dishabituation). Fourth, habituation learning is stimulus-specific. Although habituation can generalize to novel stimuli, this generalization is limited and depends on the degree of physical similarity between the trained and novel stimuli. Habituation is an indispensable form of learning. It is probably the earliest manifestation of the ability of all animals to store and retrieve the memory of a stimulus, as well as the

ability to filter out stimuli that are inconsequential. The latter is a necessary element of selective attention, which places behavior under the dynamic control of stimuli that carry important behavioral contingencies (more on attention can be found in subsequent chapters; *See* Chapters 1.13, 2.02).

A major step in the understanding of neural mechanisms of habituation was made in the early 1970s (Pinsker et al., 1970; Carew and Kandel, 1973). In a group of three seminal articles, it was reported that the siphon–gill withdrawal reflex of *Aplysia* can display habituation, that habituation was accompanied by a decrease in the spike activity of gill motor neurons in response to tactile stimulation of the siphon, and that an activity-induced decrease in the efficacy of sensorimotor synapses could be responsible for the reduced responsiveness of motor neurons and for behavioral habituation (Castellucci et al., 1970; Kupfermann et al., 1970; Pinsker et al., 1970). Starting with those early reports, behavioral habituation of withdrawal reflexes became tightly linked to homosynaptic depression of sensorimotor synapses. Since then, the vast majority of research studies that aimed at understanding the mechanisms of habituation focused on understanding the mechanisms of synaptic depression, which, similar to habituation, can appear in both short- and long-term forms.

4.03.2.2.1 Short-term depression of Aplysia sensorimotor synapses

Quantal analysis of sensorimotor synapses suggested that short-term homosynaptic depression involves primarily a decrease in presynaptic transmitter release (Castellucci and Kandel, 1974). The presynaptic nature of synaptic depression was also supported by a more recent report that repeated application of exogenous glutamate to the postsynaptic neuron did not result in depression, that blockade of postsynaptic glutamate receptors did not block depression, and that synaptic depression did not correlate with changes in the amplitude of miniature excitatory postsynaptic potentials (mEPSPs) (Armitage and Siegelbaum, 1998). To account for the depressive effect of repeated activity of sensory neurons on transmitter release, an early model of depression relied on cumulative inactivation of calcium channels and decline in the calcium entering the presynaptic terminal and triggering release (Klein et al., 1980).

Extensive parametric analysis of the kinetics of depression and recovery from depression as a function of the stimulation frequency revealed that the mechanisms must be more complex than just a decrease in calcium influx or a depletion of presynaptic vesicles (Byrne, 1982). A quantitative model of transmission at the sensorimotor synapse suggested that the inactivation kinetics of presynaptic calcium channels cannot account for the kinetics of depression; neither does simple depletion of releasable vesicles (Gingrich and Byrne, 1985). Rather, the model suggested the existence of dynamic interactions between use-dependent depletion of readily releasable vesicles and calcium-dependent mobilization of stored vesicles to supply the releasable ones. This model of synaptic depression was supported by morphological studies of the sensorimotor synapse, which indicated that the fraction of readily releasable vesicles decreased with activity, parallel to synaptic depression (Bailey and Chen, 1988b).

A subsequent study of spontaneous release from cultured sensory neurons revealed that synaptic depression was accompanied by a decrease in the frequency of mEPSPs (Eliot et al., 1994). However, the change in mini EPSP frequency did not parallel the synaptic depression in magnitude or in duration. This finding argued against the depletion of presynaptic terminals with releasable vesicles as the sole mechanism of depression, and suggested that depression may be due to a change in excitation–secretion coupling as well. However, this decrease in excitation–secretion coupling does not appear to be due to the decrease in calcium influx that had been previously suggested (Klein et al., 1980): Calcium imaging of cultured sensory neurons revealed that the calcium transients are unaffected by repetitive activity (Armitage and Siegelbaum, 1998).

Based on theoretical and statistical analyses of transmission at the sensorimotor synapse, another model of synaptic depression put forth the activity-dependent inactivation of individual release sites, proposing the transient switching off of presynaptic release machinery following an action potential (Royer et al., 2000). A similar model of synaptic depression arising from inactivation of release sites was suggested by Gover et al. (2002). Finally, the comparison of transmitter release from cultured sensory neurons stimulated by hypertonic solutions versus electrical activity revealed that both types of stimuli draw transmitter from the same presynaptic pool, and suggested that depression is mediated by both depletion of releasable transmitter and a change in excitation–secretion coupling (Zhao and Klein, 2002). Thus, the most recently proposed model of depression of sensorimotor synapses relies again on activity-dependent depletion of releasable vesicles,

acknowledging though that there must be at least one other process that contributes as well.

Despite their differences, the studies outlined in this section have two common elements. First, they all supported the presynaptic nature of depression. Second, they all employed repetitive stimulation of the synapse at intervals at least as long as 1 s. However, when the sensorimotor synapse is stimulated at 10 Hz (100-ms interval), but not at 1 Hz, depression of evoked excitatory postsynaptic potentials (EPSPs) partly results from desensitization of the postsynaptic receptors (Antzoulatos et al., 2003). Therefore, both the kinetics of synaptic depression (Byrne, 1982; Eliot et al., 1994) and the mechanisms underlying it depend on the stimulation regime.

Another form of short-term depression of *Aplysia* sensorimotor synapses can be elicited by brief exposure to the neuropeptide Phe-Met-Arg-Phe-NH_2 (FMRFa). Because activation of a third type of synapse, a modulatory one, and release of a neuromodulator are required, this form of plasticity is termed heterosynaptic. In contrast, depression arising exclusively from intrinsic activity is termed homosynaptic depression. FMRFa-immunoreactive inhibitory interneurons have been identified that innervate tail and siphon sensory neurons (Mackey et al., 1987; Small et al., 1992; Xu et al., 1994). These interneurons are activated by shock to nerves that innervate the tail, and stimulation of these neurons inhibits sensorimotor synapses. However, the extent to which activation of these FMRFa-immunoreactive neurons contributes to habituation has not been determined.

Applying FMRFa to sensory neurons leads to a hyperpolarization of the membrane potential, a decrease in the duration of the action potential, and inhibition of synaptic transmission via the modulation of potassium conductances (Abrams et al., 1984; Ocorr and Byrne, 1985; Belardetti et al., 1987; Critz et al., 1991; Pieroni and Byrne, 1992). Moreover, FMRFa directly affects presynaptic Ca^{2+} currents (Blumenfeld et al., 1990; Edmonds et al., 1990) and the release machinery itself, as indicated by a decrease in the frequency of mEPSPs (Dale and Kandel, 1990). The second messenger mediating the actions of FMRFa seems to be arachidonic acid (AA) produced by phospholipid metabolism (Piomelli et al., 1987) and its downstream metabolite 12-hydroperoxyeicosatetraenoic acid (12-HPETE) (Buttner et al., 1989). Recently, FMRFa was found to inhibit one member of the MAP kinase family, extracellular signal-regulated protein kinase (ERK), but activate another, p38 mitogen-activated protein kinase (p38 MAPK) (Guan et al., 2003; Fioravante et al., 2006). The latter probably activates a phospholipase A2 molecule, which in turn can release AA from phospholipids (Piomelli, 1991). FMRFa also engages protein phosphatases in regulating the outward potassium currents (Ichinose and Byrne, 1991), in particular protein phosphatase 1 (PP1). In other systems, p38 MAPK can activate PP1 (Westermarck et al., 2001), raising the interesting possibility that FMRFa exercises its actions on sensory neuron conductances through a p38 MAPK-PP1 pathway.

4.03.2.2.2 Long-term depression of Aplysia sensorimotor synapses

Repetitive stimulation of *Aplysia* withdrawal reflexes can lead to both short- and long-term habituation (Pinsker et al., 1970; Carew and Kandel, 1973; Stopfer et al., 1996). Short- and long-term habituation share aspects of a common mechanism, synaptic depression. However, whereas short-term synaptic depression arises primarily from transient changes in release, long-term depression has been attributed to persistent structural changes in sensory neurons (Bailey and Chen, 1988a). Extensive morphological analyses of sensory neurons from habituated animals have revealed that the number of synaptic contacts is reduced compared to controls. Moreover, the structure of presynaptic terminals is affected, with fewer synaptic vesicles and reduced size of active zones (the sites of transmitter release).

In addition, activation of sensory neurons at 2 Hz for 15 min induces prolonged (at least 80 min) homosynaptic depression (long-term depression; LTD) of isolated *Aplysia* sensorimotor synapses in cell culture (Lin and Glanzman, 1996). This form of depression relies on activation of postsynaptic *N*-methyl-D-aspartate (NMDA)-like receptors and is sensitive to postsynaptic Ca^{2+}, because infusion of the calcium chelator BAPTA into the postsynaptic motor neuron blocks induction of LTD, but not short-term synaptic depression. Similarly, prolonged habituation of the siphon-elicited gill withdrawal reflex in reduced preparations was recently shown to depend on activity of postsynaptic glutamate receptors both of the NMDA and non-NMDA type (Ezzeddine and Glanzman, 2003).

A more extensively studied form of long-term synaptic depression in *Aplysia* is elicited by repeated application of the neuropeptide FMRFa (Montarolo

et al., 1988; Guan et al., 2003). FMRFa-induced LTD requires transcription, translation (Montarolo et al., 1988; Bailey et al., 1992), but also gene silencing (Guan et al., 2002). Inducing events in FMRFa-mediated LTD include activation of p38 MAPK and recruitment of the transcription repressor CREB2 (cAMP response element binding protein) to the promoter region of genes such as *c/ebp* (Guan et al., 2003; Fioravante et al., 2006).

Little is known about the mechanisms underlying consolidation of LTD. Two genes that are regulated by FMRFa and could be important in the consolidation of LTD are sensorin (Sun et al., 2001) and *Aplysia* cell adhesion molecule (Schacher et al., 2000), even though the requirement of their regulation for LTD has not been demonstrated. Finally, expression of heterosynaptic LTD is accompanied by morphological changes, including loss of presynaptic varicosities and retraction of neurites (Schacher and Montarolo, 1991).

4.03.2.3 Sensitization

Sensitization refers to the augmentation of the behavioral response elicited by a test stimulus. Sensitization to a test stimulus can be induced in one of two ways. First, it can be induced by presentation of another, usually strong stimulus. An example of such sensitization is pseudoconditioning, where an increase in responsiveness to the CS in a classical conditioning procedure may not be due to associative learning (as in classical conditioning), but instead due to the sensitization induced by the strong US. Second, sensitization can be induced by the mere repetition of the test stimulus. As mentioned above, the repetition of a weak stimulus will lead to habituation of the behavioral response, whereas repetition of a moderate to strong stimulus may lead to sensitization. This form of sensitization can sometimes appear as a transient rise in response magnitude before habituation eventually ensues.

Both forms of sensitization have been studied in *Aplysia*, with major emphasis on the former one described above. Similar to habituation, sensitization was also attributed early on to plasticity of the sensorimotor synapse (see next section). Although habituation was attributed to homosynaptic depression of the synapse, sensitization was attributed to heterosynaptic facilitation, induced by the diffuse release of neuromodulators, such as serotonin. Also similar to habituation, sensitization can appear both in short- and long-term forms, which have been extensively studied in their neuronal analogs, short and long-term synaptic facilitation.

4.03.2.3.1 *Short-term sensitization*

In *Aplysia*, sensitization of withdrawal reflexes can be induced by electric shocks to the tail or the lateral body wall of the animal (Carew et al., 1971). Peripheral electric shock has been shown to modulate transmission at the sensorimotor synapse through heterosynaptic facilitation (Carew et al., 1971; Walters et al., 1983a,b).

Several lines of evidence suggest that serotonin (5-HT) is the neurotransmitter involved in heterosynaptic facilitation. First, 5-HT is present in *Aplysia* hemolymph, and its concentration increases in sensitized animals (Levenson et al., 1999). Recent studies also indicated that 5-HT concentration increases in several regions of the *Aplysia* CNS in response to nerve stimulation (Marinesco and Carew, 2002). Second, serotonergic cells are present (Hawkins, 1989; Nolen and Carew, 1994) and serotonergic fibers are in close proximity to sensory neurons (SNs) (Zhang et al., 1991; Marinesco and Carew, 2002; Zhang et al., 2003). Third, depletion of endogenous 5-HT by addition of a neurotoxin (5,7-DHT) blocks the ability of tail stimuli to sensitize the gill-withdrawal reflex (Glanzman et al., 1989). Along the same lines, application of the 5-HT receptor antagonist cyproheptadine blocks facilitation induced by nerve stimulation (Mercer et al., 1991). Finally, exogenously applied 5-HT mimics the actions of tail stimulation both in facilitating the strength of synaptic connections and in increasing the strength of reflex responses (Brunelli et al., 1976; Walters et al., 1983a, b; Abrams et al., 1984; Zhang et al., 1997), and nerve shock-induced 5-HT release correlates with synaptic plasticity (Marinesco et al., 2006).

The conclusions drawn from studies conducted in the 1970s and 1980s led to the formulation of a model for short-term sensitization, according to which sensitizing stimuli activate serotonergic facilitatory interneurons, releasing 5-HT and activating a serial cascade of events in the sensory neurons. The binding of 5-HT to one class of receptors on the outer surface of the membrane of the sensory neurons leads to the activation of adenylyl cyclase, which in turn, leads to an elevation of the intracellular level of the second messenger adenosine-3′,5′-monophosphate (cyclic AMP, cAMP) in sensory neurons. When cAMP binds to the regulatory subunit of cAMP-dependent protein kinase (protein kinase A, PKA), the catalytic subunit is freed and can now add phosphate groups to specific substrate proteins and, hence, alter their functional

properties (Bernier et al., 1982; Ocorr and Byrne, 1985; Pollock et al., 1985; Ocorr and Byrne, 1986; Ocorr et al., 1986; Sweatt et al., 1989). One effect of activated PKA is phosphorylation of a class of membrane channels (S-K^+ channels, named for their ability to be modulated by serotonin) and reduction of the S-K^+ conductance ($G_{K,S}$) (Klein and Kandel, 1980; Klein et al., 1982; Siegelbaum et al., 1982). Consequently, a test stimulus triggers a greater number of action potentials in the sensory neuron after sensitization. Each of these spikes is broader, leading to increased Ca^{2+} influx and enhanced transmitter release. As a result, the follower motor neuron is more intensely activated, and the behavioral response is enhanced (i.e., sensitized). Thus, it was previously believed that serotonin (5-HT) exerted all of its actions in the sensory neurons via the cAMP-mediated reduction of $G_{K,S}$.

Later studies, however, indicated that the effects of 5-HT are more complex than originally suggested. Not only $G_{K,S}$ is modulated by 5-HT, but also at least three other conductances: 5-HT increases a dihydropyridine-sensitive Ca^{2+} current ($G_{Ca,Nif}$) (Braha et al., 1990; Edmonds et al., 1990), decreases a component of the Ca^{2+}-activated K^+ current ($G_{K,Ca}$) (Walsh and Byrne, 1989), and modulates a voltage-dependent K^+ current ($G_{K,V}$) (Baxter and Byrne, 1989, 1990a; Goldsmith and Abrams, 1992; Hochner and Kandel, 1992; Sugita et al., 1994; White et al., 1994). The effects of channel modulation appear to be synergistic, favoring increased sensory neuron excitability or transmitter release. Spike broadening, which has a major impact on transmitter release, is probably due to modulation of $G_{K,V}$ rather than $G_{K,S}$, whereas $G_{K,S}$ and $G_{K,Ca}$ appear to be critical for regulating membrane excitability, with modest effects on spike duration (Baxter and Byrne, 1990a, b). The 5-HT-induced increase in $G_{Ca,Nif}$ does not appear to contribute to enhanced transmitter release, as this conductance is not directly responsible for triggering exocytosis of synaptic vesicles, although it may contribute to accumulation of presynaptic calcium during intense activity (Edmonds et al., 1990).

Two of the three 5-HT-induced effects on K^+ conductances (modulation of $G_{K,S}$ and $G_{K,Ca}$) are mediated exclusively by PKA. The effects of 5-HT on $G_{K,V}$ appear to be caused by activation of two second messenger pathways, only one of which is the cAMP pathway mentioned above (Hochner and Kandel, 1992). Serotonin also appears to act through another class of receptors to increase the level of the second messenger diacylglycerol (DAG). DAG activates protein kinase C (PKC), leading to its translocation (Sossin, 2007). PKC, like PKA, is involved in the spike-duration-dependent process of facilitation (Sugita et al., 1992, 1994). In addition, a nifedipine-sensitive Ca^{2+} conductance ($G_{Ca,Nif}$) and the delayed K^+ conductance ($G_{K,V}$) are regulated by PKC. The modulation of $G_{K,V}$ contributes importantly to the increase in duration of the action potential (**Figure 3(a3)**). Because of its small magnitude, the modulation of $G_{Ca,Nif}$ appears to play a minor role in the facilitatory process.

The role of ionic conductances in modulation of synaptic transmission is relatively well understood. Less well understood is a second process that has a profound effect on synaptic transmission, but which is independent of spike duration (spike-duration independent process; SDI). The existence of the second process was first postulated based on a mathematical model of a sensory neuron (Gingrich and Byrne, 1985, 1987). Experimental studies have provided support for the SDI process (Hochner et al., 1986; Braha et al., 1990; Pieroni and Byrne, 1992; Klein, 1993, 1994). Although the mechanism is poorly understood, the SDI process is likely to include mobilization of vesicles into a readily releasable pool. This process appears to be particularly important when the sensory neuron is depressed by previous low frequency (ISI = 10 s) stimulation (Braha et al., 1990; Ghirardi et al., 1992; Pieroni and Byrne, 1992; Klein, 1993; Sugita et al., 1997), making the SDI process an attractive candidate for dishabituation mechanisms and for maintaining synaptic strength during high levels of release (see below). The relative contribution of PKA and PKC to facilitation of previously depressed synapses varies as a function of the extent of preexisting depression. In nondepressed synapses, 5-HT produces short-term facilitation that can be blocked completely by inhibitors of PKA but is not affected by H7, an inhibitor of PKC. In contrast, as synapses become more depressed, the inhibitor of PKC becomes progressively more effective in blocking 5-HT-induced short-term facilitation (Braha et al., 1990; Ghirardi et al., 1992; Sugita et al., 1997).

Nevertheless, it has only recently become clear that, apart from dishabituation, sensitization may also involve facilitation of depressed synapses, because a moderate stimulus does not trigger a single spike in the sensory neuron, but a burst of spikes (Phares et al., 2003). By the end of this burst, the motor neuron responses depress substantially, regardless of the state of the first response. Enhancement of these depressed

responses by sensitization is likely to involve the SDI process.

Progress has been made in understanding the second-messenger cascades involved in the SDI process and identified synaptic terminal proteins as downstream targets. These targets include synapsin and SNAP-25, highly conserved synaptic proteins that appear to regulate homosynaptic depression and short-term heterosynaptic facilitation. Synapsin is localized in presynaptic nerve terminals, where it interacts with synaptic vesicles, actin and spectrin (Jovanovic et al., 1996; Matsubara et al., 1996; Hosaka et al., 1999; Zimmer et al., 2000). Because the interaction of synapsin with actin and synaptic vesicles is regulated by phosphorylation, synapsin is believed to reversibly tether synaptic vesicles in a reserve pool, thereby regulating vesicle availability and mobilization (Hilfiker et al., 1998, 1999). The *Aplysia* isoform of synapsin (apSyn) contains the same domain arrangement as other vertebrate and invertebrate synapsins (Angers et al., 2002). Several potential regulatory sites have been identified throughout the sequence of apSyn. In addition to the PKA/CAMK I consensus phosphorylation site in the A-domain, two potential MAPK sites and several PKC sites are detected. In ganglia and in cultured cells, synapsin localizes in presynaptic varicosities and forms distinct puncta, presumably due to the aggregation of protein and its interaction with vesicle membranes (Angers et al., 2002).

ApSyn is phosphorylated following application of 5-HT, which results in short-term facilitation of the sensorimotor synapse. This phosphorylation requires PKA and MAPK. Also, 5-HT results in a reduction in the number of apSyn puncta, which represents the dissociation of the protein from synaptic vesicles (and probably the cytoskeleton) upon phosphorylation. The reduction of apSyn puncta after 5-HT is dynamic and reversible, and it requires PKA and MAPK activity (Angers et al., 2002). Finally, recent results from apSyn overexpression experiments indicated that synapsin regulates basal synaptic strength, homosynaptic depression and 5-HT-induced recovery from depression (Fioravante et al., 2007).

Based on the results described above, the following model has been proposed (Angers et al., 2002): At rest, most vesicles are clustered in a filamentous protein network forming the reserve pool, and 5-HT can modulate the function of apSyn by altering its phosphorylation state via PKA and MAPK. Upon phosphorylation, apSyn molecules dissociate from the vesicles and the cytoskeleton, allowing vesicles to be mobilized to release sites when they become depleted.

Another highly conserved synaptic protein, SNAP-25, has recently been implicated in the regulation of short-term facilitation, especially in previously depressed synapses. In these synapses, PKC, rather than PKA, predominantly mediates 5-HT-induced dedepression (Ghirardi et al., 1992; Dumitriu et al., 2006) through phosphorylation of SNAP-25 (Houeland et al., 2007) and probably other, yet unidentified synaptic targets.

4.03.2.3.2 Long-term sensitization

Whereas short-term sensitization can be induced by a single brief stimulus, the induction of long-term sensitization, whose memory can persist for days to weeks, requires a more extensive training regime (e.g., repeating the sensitizing stimuli over a 1.5-h period). Compared with short-term sensitization, less is known about the cellular mechanisms underlying long-term sensitization. One simplifying hypothesis is that the mechanisms underlying the expression of long-term sensitization are the same as those of short-term sensitization, but extended in time. Some evidence supports this hypothesis. For example, similar to short-term sensitization, K^+ conductances and excitability of sensory neurons are also modified by long-term sensitization (Scholz and Byrne, 1987; Cleary et al., 1998).

Biophysical properties of neurons mediating the *Aplysia* withdrawal reflexes have been examined following long-term sensitization induced by a single 1.5-h-long training session (1-day protocol), or by four such sessions repeated at 24-h intervals (4-day protocol). Twenty-four hours following the 1-day protocol of long-term sensitization training, three biophysical properties of tail sensory neurons are altered: Neuronal excitability, the after-depolarization following long current pulses, and the after-depolarization following short current pulses (Cleary et al., 1998). In addition to the biophysical properties of sensory neurons, 1-day training affects two properties of motor neurons: The resting membrane potential is increased and the spike threshold is decreased (Cleary et al., 1998). Long-term sensitization also correlates with facilitation of the sensorimotor synapses, both after 1-day training and after 4-day training (Frost et al., 1985; Cleary et al., 1998; Wainwright et al., 2004; Antzoulatos and Byrne, 2007). Surprisingly, although short-term sensitization is associated with spike broadening in sensory neurons (see above), long-term sensitization is associated with spike narrowing in sensory neurons (Antzoulatos and Byrne, 2007). The functional effects of the spike narrowing are not clear,

but narrowing of the spike may be related to a decrease in spike propagation failures that occurs in response to high-frequency peripheral stimulation after long-term sensitization.

Another branch of the research on long-term sensitization has focused on the morphological effects of sensitization training on sensory neurons. One-day training for long-term sensitization does not induce gross structural changes in sensory neuron morphology, even though it does induce long-term changes in excitability and synaptic strength (Cleary et al., 1998). In contrast to 1-day training, 4-day training is more effective at inducing outgrowth when compared to untrained controls (Bailey and Chen, 1983; Wainwright et al., 2002;, 2004). This outgrowth includes an increase in the total arborization length of sensory neuron branches, in the number of sensory neuron branch points and varicosities, and in the number of synaptic contacts between sensory and motor neurons (Wainwright et al., 2002, 2004).

Biochemical correlates of long-term sensitization have also been examined. Most of these studies have focused on the induction phase, identifying changes in levels of the second messenger cAMP and regulation of several proteins (Barzilai et al., 1989; Eskin et al., 1989; Muller and Carew, 1998; Zwartjes et al., 1998). Progress has been made in identifying biochemical changes related to the consolidation or expression of long-term sensitization. Recently, long-term training was observed to produce enhanced uptake of glutamate (Levenson et al., 2000), the putative transmitter of sensory neurons (Antzoulatos and Byrne, 2004). This increase in uptake occurred in sensory neurons and appeared to be caused by an increased number of glutamate transporters. Although the functional role of this enhanced uptake is presently unclear, it indicates that clearance of glutamate from the cleft may be an important factor in the regulation of synaptic efficacy (Chin et al., 2002b). A change in glutamate uptake could potentially exert a significant effect on synaptic efficacy by regulating the amount of transmitter available for release, the rate of clearance from the cleft, and thereby the duration of the EPSP and the degree of receptor desensitization (Antzoulatos et al., 2003).

A substantial amount of data indicates that the induction of both short- and long-term sensitization partly share common cellular pathways (**Figure 4**). For example, both forms of sensitization activate the cAMP/PKA cascade. In the long-term form, however, activation is prolonged and sufficient to induce gene transcription and new protein synthesis (Castellucci et al., 1989; Levenson et al., 1999). This finding is consistent with the relatively long duration of the training period required for inducing long-term sensitization and the lasting duration of the effects. cAMP presumably exerts its major effects by activation of PKA (Schacher et al., 1988; Scholz and Byrne, 1988; O'Leary et al., 1995; Muller and Carew, 1998). Activated PKA translocates to the nucleus,

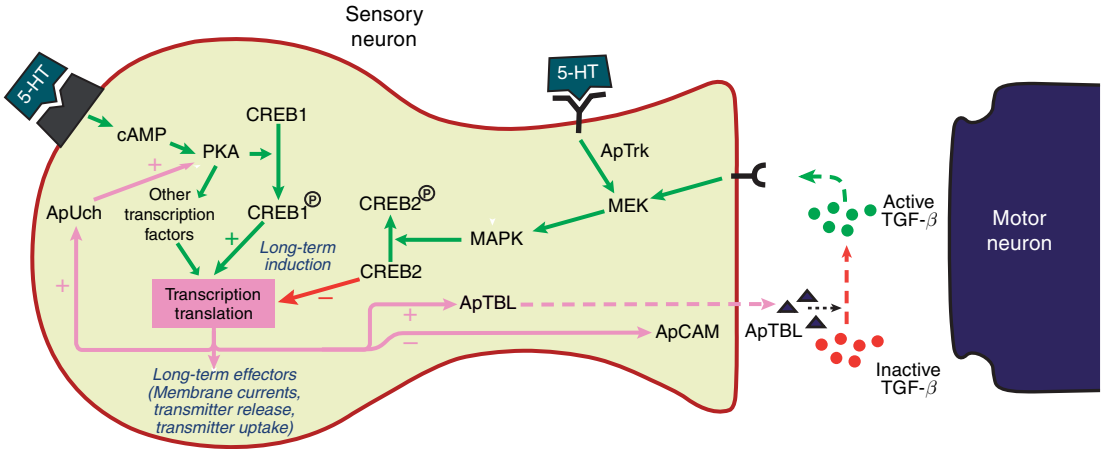

Figure 4 Simplified scheme of the mechanisms in sensory neurons that contribute to long-term sensitization. Sensitization training leads to release of 5-HT, which activates the cAMP/PKA cascade and the ERK MAPK cascade. PKA phosphorylates and activates CREB1, whereas ERK phosphorylates and inhibits CREB2. CREB1 acts as an initiator of gene transcription and CREB2 acts as a repressor of gene transcription. The combined effects of activation of CREB1 and inhibition of CREB2 lead to regulation of the synthesis of at least ten proteins, only three of which (apTBL, apUCH, apCAM) are shown. ApTBL is believed to activate latent forms of TGF-β, which can then bind to receptors on the sensory neuron and further activate MAPK. See section 4.03.2.3.2 for abbreviation definitions.

where it phosphorylates and activates the transcription factor CREB1. Activated CREB1, which is necessary for long-term facilitation (LTF), binds to the promoter region of responsive genes, and induces their expression (Dash et al., 1990, 1991; Bartsch et al., 1998; Guan et al., 2002). A prolonged increase in cAMP also leads to the induction and subsequent expression of a gene encoding the protein ubiquitin C-terminal hydrolase (Ap-Uch). This neuron-specific enzyme enhances the degradation of certain proteins including the regulatory subunits of PKA (Hegde et al., 1997). With fewer regulatory subunits of PKA to bind to catalytic subunits, the catalytic subunits are persistently active and may contribute to long-term facilitation of transmitter release (Muller and Carew, 1998).

In addition to the cAMP/PKA cascade, sensitization training and prolonged 5-HT application also activate MAPK (Sacktor and Schwartz, 1990; Sossin and Schwartz, 1992, 1993; Sossin et al., 1994; Sossin and Schwartz, 1994; Martin et al., 1997a; Sharma et al., 2003; Sharma and Carew, 2004). Prolonged application of 5-HT results in persistent phosphorylation (and subsequent activation) of MAPK though activation of a tyrosine receptor kinase-like molecule (ApTrk) (Ormond et al., 2004), cAMP (Martin et al., 1997b; Michael et al., 1998) (but see Dyer et al., 2003), and/or the neuropeptide sensorin (Hu et al., 2004b). Activated MAPK translocates to the nucleus (Martin et al., 1997b) where it may regulate gene transcription, possibly through inhibition of the transcription factor CREB2 (Bartsch et al., 1995). Since under basal conditions CREB2 acts as a repressor of gene transcription, its inhibition may lead to derepression and net gene expression in concert with CREB1 (**Figure 4**). The involvement of additional transcription factors such as ApAF (*Aplysia* activating factor) (Bartsch et al., 2000; Lee et al., 2006) and ApLLP (*Aplysia* LAPS18-like protein) (Kim et al., 2003a, 2006) in learning-induced gene expression is currently being investigated.

Recently, it has become clear that the role of transcription factors in long-term memory formation is not limited to the induction phase but may also extend to the consolidation phase. For example, prolonged treatment with 5-HT leads to the binding of CREB1 to the promoter of its own gene and induces CREB1 synthesis (Mohamed et al., 2005). The newly synthesized CREB1 appears to be necessary for LTF (Liu et al., 2008). This observation agrees well with earlier findings that the requirement for gene expression is not limited to the induction phase. The necessity of prolonged transcription and translation for LTF observed at 24 h persists for at least 7–9 h after induction (Alberini et al., 1994; O'Leary et al., 1995). These results suggest that CREB1 can regulate its own level of expression, giving rise to a CREB1 positive feedback loop that is necessary for memory consolidation.

In addition to CREB1, several other proteins are regulated during LTF. One of the newly synthesized proteins, intermediate filament protein (IFP) (Noel et al., 1993), is thought to contribute to the new growth observed after prolonged treatment with 5-HT. Increased synthesis of calmodulin (CaM) (Zwartjes et al., 1998) also occurs, but the functional significance of this effect has not been determined. The neuropeptide sensorin is also upregulated by 5-HT and is thought to contribute to the formation and stabilization of new synapses (Hu et al., 2004a,b).

Aplysia tolloid/BMP-like protein (apTBL-1) (Liu et al., 1997) is also synthesized in response to increases in cAMP. Tolloid and the related molecule BMP-1 appear to function as secreted Zn^{2+} proteases. A signal sequence at the amino terminal indicates that apTBL-1 is secreted to the extracellular space where one of its actions may be to activate members of the TGF-β family of growth factors (**Figure 4**). Indeed, in sensory neurons, TGF-β mimics the effects of 5-HT in that it produces long-term increases in synaptic strength and excitability of the sensory neurons (Zhang et al., 1997; Farr et al., 1999). Interestingly, TGF-β activates the MEK/MAPK pathway in the sensory neurons and induces MAPK translocation to the nucleus (Chin et al., 2002a, 2006), where it phosphorylates CREB1 (Chin et al., 2006). This activation could yield another round of protein synthesis to further consolidate long-term sensitization.

LTF involves not only increased synthesis but also downregulation of proteins such as the regulatory subunit of PKA (discussed earlier in this section) and a homolog of neuronal cell adhesion molecule (NCAM). Downregulation of NCAM alters the interaction of the neuron with other cells and allows the restructuring of the axon arbor (Mayford et al., 1992; Bailey et al., 1997). The sensory neuron could then form additional connections with the same postsynaptic target or make new connections with other cells.

4.03.2.3.3 Other temporal domains for the memory of sensitization

Operationally, memory has frequently been divided into two temporal domains, short-term and long-term. It has become increasingly clear from studies of a number of memory systems that this distinction

is overly restrictive. For example, in *Aplysia*, Carew and his colleagues (Sutton et al., 2001) and Kandel and his colleagues (Ghirardi et al., 1995) discovered an intermediate phase of memory that has distinctive temporal characteristics and a unique molecular signature. The intermediate-phase memory (ITM) for sensitization is expressed approximately 30 min to 3 h after the beginning of training. It declines completely prior to the onset of long-term memory. Like long-term sensitization, its induction requires protein synthesis, but unlike long-term memory, it does not require mRNA synthesis. The expression of the intermediate-phase memory requires the persistent activation of PKA (Muller and Carew, 1998; Sutton and Carew, 2000; Sutton et al., 2001).

An intermediate-term facilitation (ITF) of the sensorimotor synapse, which is produced by application of five pulses of 5-HT (an analog of sensitization training), corresponds to the ITM as it displays similar temporal dynamics and requires protein synthesis but not RNA synthesis (Ghirardi et al., 1995; Sutton and Carew, 2000). This latter feature of ITF distinguishes it from short-term facilitation, which requires neither protein nor RNA synthesis, and long-term facilitation, which requires both (see above). Depending on the induction protocol, ITF may require intermediate-term activation of PKA or PKC (Sossin et al., 1994; Sutton and Carew, 2000; Pepio et al., 2002; Lim and Sossin, 2006). These kinases can be activated for hours following prolonged treatment with 5-HT (Muller and Carew, 1998; Sutton and Carew, 2000). Finally, activation of previously silent release sites has also been implicated in ITF and could be a mechanism for memory consolidation (Kim et al., 2003b).

In addition to the intermediate-phase memory, it is likely that *Aplysia* has different phases of long-term memory. For example, at 24 h after sensitization training there is increased synthesis of a number of proteins, some of which are different from those whose synthesis is increased during and immediately after training (Noel et al., 1993). These results suggest that the memory for sensitization that persists for more than 24 h may be dependent on the synthesis of proteins occurring at 24 h and may have a different molecular signature than the 24-h memory.

Based on the experimental results reviewed above, a synthesis of the sensitization mechanisms in *Aplysia* can now be attempted. A brief sensitizing experience can affect the animal transiently (i.e., short-term sensitization), through an increase in the excitability of sensory neurons and in the efficacy of sensory neuron synapses. Short-term facilitation is achieved through spike-broadening-mediated and spike-duration-independent increases in transmitter release. These modifications, lasting up to several minutes, are mediated by phosphorylation of K^+ channels and other effector molecules, such as synapsin. More prolonged training, which typically involves multiple, appropriately timed stages of sensitization, can lead to modifications lasting 24 h or more. A single day of sensitization training leads to persistent increases in the efficacy of sensory neuron synapses and in the excitability of sensory neurons. Long-term facilitation after a single day of training does not involve gross structural changes of sensory neurons or changes in the number of synaptic varicosities. With 4 days of training, long-term sensitization is still accompanied by synaptic facilitation, but changes in sensory neuron excitability are not as prominent as they are after short-term training or after a single session of long-term training. After 4 days of training, long-term synaptic facilitation is achieved through an increase in the number of synaptic contacts. Collectively, these results indicate that facilitation of sensory neuron synapses is a ubiquitous feature of sensitization. However, the mechanisms that support the facilitation vary over time and with the extent of training. The conversion of one type of long-term expression mechanism to another is interesting, as it presumably reflects the engagement of a distinct set of genes that are part of an overall program for the expression of particularly enduring forms of long-term memory.

4.03.3 Habituation and Sensitization in Other Invertebrates

4.03.3.1 Gastropod Molluscs

4.03.3.1.1 Tritonia

To escape a noxious stimulus, the opisthobranch *Tritonia diomedea* initiates stereotypical oscillatory swimming. This escape swim can be dissected into several components, including number of cycles per swim, latency to swim onset, and swim cycle period. The various swim components can exhibit habituation, dishabituation, and/or sensitization (Frost et al., 1996). In particular, the escape swim undergoes habituation and dishabituation of the number of cycles per swim (Mongeluzi and Frost, 2000). Swimming probability can also decrease as a result of habituation (Brown,

1998). This habituation is accompanied by sensitization of the latency to swim onset (Frost et al., 1998).

The neural circuit underlying swim consists of sensory neurons, precentral pattern generating (CPG) neurons, and motor neurons. This circuit can be studied in the isolated perfused brain of *Tritonia*, where electrical stimulation of a nerve can elicit fictive swimming patterns (Dorsett et al., 1973). Habituation of fictive swimming correlates with a decrease in the cycle number and cycle period of swim motor programs (Frost et al., 1996; Brown, 1997) and appears to involve plasticity at multiple loci, including decrement at the first afferent synapse. Sensitization appears to involve enhanced excitability and synaptic strength in one of the CPG interneurons. Modulation of interneurons can be mediated by 5-HT, which has diverse effects on multiple loci of the circuit (Sakurai et al., 2006).

4.03.3.1.2 *Land snail* (Helix)

Land snails withdraw in response to weak tactile stimulation. The withdrawal behavior is mediated by a neuronal circuit involving four groups of nerve cells: Sensory neurons, motor neurons, modulatory neurons, and command neurons (Balaban, 2002). This withdrawal can be habituated or sensitized, depending on the intensity of stimulation. Habituation of the withdrawal behavior emerges from depletion of neurotransmitter at sensory cell synapses as well as heterosynaptic inhibition mediated by FMRFa-containing neurons (Balaban et al., 1991). Sensitization appears to be mediated by serotonergic modulatory cells whose spiking frequency increases following noxious stimulation (Balaban, 2002). These serotonergic cells are electrically coupled so that they get recruited and fire synchronously in response to strong excitatory input. One gene that is upregulated by external noxious input is the *Helix* Command Specific #2 (HCS2) (Balaban et al., 2001). The *HCS2* gene encodes a precursor protein whose processed products may function as neuromodulators or neurotransmitters mediating the withdrawal reactions of the snail (Korshunova et al., 2006). Application of neurotransmitters and second messengers known to be involved in withdrawal behavior result in upregulation of *HCS2* gene (Balaban, 2002).

The mechanisms underlying habituation and sensitization in the *Helix* can be further investigated by reconstructing behaviorally relevant synapses in culture. Using this approach, mechanosensory neuron-withdrawal interneuron synapses were found to display several forms of short-term synaptic plasticity such as facilitation, augmentation, and posttetanic potentiation (Fiumara et al., 2005).

4.03.3.2 Arthropods

4.03.3.2.1 *Crayfish* (Procambarus clarkii)

A crayfish escapes from noxious stimuli by flipping its tail. A key component of the tail-flip circuit is a pair of large neurons called the lateral giants (LGs), which run the length of the animal's nerve cord. The LGs are the decision and command cells for the tail-flip. The crayfish tail-flip response exhibits habituation (Wine et al., 1975) and sensitization (Krasne and Glanzman, 1986). Plastic changes induced during learning involve modulation of the strength of synaptic input driving the LGs (Edwards et al., 1999). A diminution of transmitter release with repeated activation of afferents is thought to underlie habituation (Krasne and Roberts, 1967; Zucker, 1972). An inhibitory pathway was also identified that can tonically inhibit the LGs (Krasne and Wine, 1975; Vu and Krasne, 1992, 1993; Vu et al., 1993). This putatively GABAergic (Vu and Krasne, 1993) (but see Heitler et al., 2001) inhibitory pathway also plays a major role in habituation (Krasne and Teshiba, 1995). In addition to the regulation of synaptic strength, habituation also results in decreased excitability of LGs (Araki and Nagayama, 2005). Bath application of the endogenous neuromodulators 5-HT and octopamine decrease the rate of LG habituation to repetitive sensory stimulation (Araki et al., 2005). Octopamine is also thought to at least partly mediate sensitization, because it mimics the sensitizing effects of strong stimulation on the tail-flip (Glanzman and Krasne, 1986; Krasne and Glanzman, 1986).

4.03.3.2.2 *Honeybee* (Apis mellifera)

Honeybees, like other insects, are superb at learning. For example, classical conditioning of feeding behavior can be produced by pairing a visual or olfactory stimulus with sugar solution to the antennae. Numerous studies described the molecular mechanisms underlying memory formation, which involve upregulation of the cAMP pathway and activation of PKA resulting in CREB-mediated transcription of downstream genes (Menzel, 2001) (*See* Chapter 4.06). Nonassociative learning has also been studied in the honeybee, albeit to a lesser extent. Habituation of the proboscis extension reflex can be elicited by repeatedly touching one antenna with a droplet of sugar water (Braun and Bicker, 1992) and lasts for at least 10 min (Bicker and Hahnlein, 1994). Following habituation, the proboscis

extension response can be restored spontaneously with time (spontaneous recovery) (Bicker and Hahnlein, 1994) or by stimulating the contralateral antenna (dishabituation) (Braun and Bicker, 1992). Application of tyramine, a metabolic precursor of the endogenous neuromodulator octopamine, accelerates the rate of habituation of the reflex (Braun and Bicker, 1992). Recently, activation of PKA was implicated in habituation of the reflex, but not dishabituation or spontaneous recovery, suggesting that the cellular mechanisms mediating habituation, dishabituation, and spontaneous recovery are distinct (Muller and Hildebrandt, 2002). With repeated training sessions over 2 days, long-term memory for habituation lasting for 24 h can be demonstrated (Bicker and Hahnlein, 1994). Finally, sensitization of the antenna reflex can be produced as a result of presenting gustatory stimuli to the antennae (Mauelshagen, 1993; Menzel et al., 1999).

4.03.3.2.3 Drosophila melanogaster

Because the neural circuitry in the fruit fly is both complex and inaccessible, the fly might seem to be an unpromising subject for studying the neural basis of learning. However, the ease with which genetic studies are performed compensates for the difficulty in performing electrophysiological studies (DeZazzo and Tully, 1995). A multitude of behaviors have been used as a model system to study nonassociative learning in *Drosophila*, including proboscis extension (Duerr and Quinn, 1982), thoracic bristle-elicited cleaning reflex (Corfas and Dudai, 1989), landing response (Rees and Spatz, 1989; Asztalos et al., 1993), jump-and-flight escape response (Engel and Wu, 1996), and odor-elicited startle response (Cho et al., 2004). Habituation has been demonstrated in all of these behaviors and molecular pathways underlying this form of learning have been identified and include the cAMP/PKA pathway (dunce and rutabaga mutants) (Duerr and Quinn, 1982; Corfas and Dudai, 1989; Engel and Wu, 1996; Cho et al., 2004), protein phosphatase 1 (Asztalos et al., 1993), and cGMP-dependent protein kinase (PKG) (Engel et al., 2000). In flies carrying the rutabaga mutation, which leads to diminished cAMP synthesis, habituation of the cleaning reflex is abnormally short-lived but dishabituation is unaffected (Corfas and Dudai, 1989). Moreover, in flies carrying the dunce mutation, which results in elevated cAMP levels, habituation rates of the jump-and-flight reflex are moderately increased but spontaneous recovery and dishabituation are not affected (Engel and Wu, 1996). These results reinforce the idea that the processes underlying habituation, dishabituation, and spontaneous recovery are distinct (also see the section titled 'Honeybee (*Apis mellifera*)'). Finally, in the dunce and rutabaga flies, sensitization of the proboscis-extension reflex dissipates more rapidly compared to wild-type controls (Duerr and Quinn, 1982).

4.03.3.3 Annelids

4.03.3.3.1 Leech

In the leech *Hirudo medicinalis*, nonassociative learning has been studied in several well characterized behaviors: Movements in response to light and water currents (Ratner, 1972), bending (Lockery and Kristan, 1991), shortening reflex to repeated light (Lockery et al., 1985) or tactile stimulation (Belardetti et al., 1982; Boulis and Sahley, 1988; Sahley et al., 1994), and swimming (Catarsi et al., 1993; Zaccardi et al., 2001).

In the shortening reflex of the leech, the neuronal changes underlying habituation and sensitization occur in the pathway from mechanosensory neurons to electrically coupled neurons, the S cells (Bagnoli and Magni, 1975; Sahley et al., 1994). Habituation of this reflex can reach asymptotic levels after 20 training trials and correlates with decreased S-cell excitability (Burrell et al., 2001). The reflex can be restored following application of a single noxious stimulus (dishabituation) (Boulis and Sahley, 1988). The potentiation of the shortening reflex observed during sensitization requires the S neurons, as their ablation disrupts sensitization (Sahley et al., 1994). This potentiation is mediated by 5-HT through an increase of cAMP (Belardetti et al., 1982), which also increases S-cell excitability (Burrell et al., 2001). Depletion of 5-HT disrupts sensitization (Sahley et al., 1994). Interestingly, ablation of the S cells only partly disrupts dishabituation, indicating that separate processes contribute to dishabituation and sensitization (Ehrlich et al., 1992; Sahley et al., 1994).

An additional mechanism that could potentially contribute to habituation of the shortening reflex involves depression of the synapses of touch (T) sensory neurons onto their follower target neurons. This synaptic depression has been associated with an increase in the amplitude of the T-cell after-hyperpolarizing potential (AHP) that follows their discharge (Brunelli et al., 1997; Scuri et al., 2002). The lasting increase in AHP amplitude, following low-frequency stimulation of T cells, has been attributed, in turn, to increased activity of the electrogenic Na^+ pump, and requires activation of phospholipase A2 and the downstream arachidonic acid metabolites (Scuri et al., 2005).

4.03.3.4 Nematoda

4.03.3.4.1 Caenorhabditis elegans

C. elegans is a valuable model system for cellular and molecular studies of learning. Its principal advantages are threefold. First, its nervous system is extremely simple. It has a total of 302 neurons, the anatomical connectivity of which has been described at the electron microscopy level. Second, the developmental lineage of each neuron is completely specified. Third, its entire genome has been sequenced, making it highly amenable to a number of genetic and molecular manipulations. *C. elegans* responds to a vibratory stimulus applied to the medium in which they locomote by swimming backwards. This reaction, known as the tap withdrawal reflex, exhibits habituation, dishabituation, sensitization, and long-term (24-h) retention of habituation training (Rankin et al., 1990). Laser ablation studies have been used to elucidate the neural circuitry supporting the tap withdrawal reflex and to identify likely sites of plasticity within the network. Plastic changes during habituation appear to occur at the chemical synapses between presynaptic sensory neurons and postsynaptic command interneurons (Wicks and Rankin, 1997). Analysis of several *C. elegans* mutants has revealed that synapses at the locus of plasticity in the network may be glutamatergic (Rose and Rankin, 2001). Mutation of the gene coding for the brain-specific inorganic phosphate transporter *eat-4* results in more rapid habituation compared to wild-type worms and slower recovery (Rankin and Wicks, 2000). The protein coded by *eat-4* is involved in the regulation of glutamatergic transmission and is homologous to the mammalian vesicular glutamate transporter VGLUT1 (Bellocchio et al., 2000). *Eat-4* worms also do not display dishabituation, suggesting that neurotransmitter regulation plays a role in habituation and dishabituation (Rankin and Wicks, 2000). Moreover, worms that carry a mutation in glr-1, an excitatory glutamate receptor expressed in postsynaptic command interneurons, do not display long-term memory for habituation (Rose et al., 2003). In general, the study of behavioral genetics in the worm has provided significant insights into the ways in which genes regulate behavior (Rankin, 2002).

4.03.4 Emerging Principles

As a result of research on several invertebrate model systems, some general principles have emerged. A list of these principles might include the following: (1) short-term and long-term forms of learning and memory require changes in existing neural circuits, (2) these changes may involve multiple cellular mechanisms within single neurons, (3) second messenger systems play a role in mediating cellular changes, (4) changes in the properties of membrane channels are commonly correlated with learning and memory, (5) changes in intrinsic excitability (*See* Chapter 4.40) and synaptic efficacy are correlated with short- and long-term memory, and (6) long-term memory requires new protein synthesis and growth, whereas short-term memory does not.

4.04 Molecular Mechanisms of Habituation in *C. elegans*

M. P. Butterfield and C. H. Rankin, University of British Columbia, Vancouver, BC, Canada

4.04.1 Introduction to Habituation

The most basic form of learning is nonassociative learning, which involves alterations in response to a single (sometimes repeated) stimulus. Habituation, dishabituation, and sensitization are the three main forms of nonassociative learning. Habituation is the simplest form of nonassociative learning and has been defined as a decrease in response to repeated or long-lasting stimulation (Groves and Thompson, 1970). This form of learning has been found in all organisms studied, from protozoa to humans. If a strong, novel stimulus is presented after the organism has been habituated to the initial stimuli, the organism will immediately recover its habituated response. This phenomenon is known as dishabituation and has been used to distinguish habituation from sensory adaptation or fatigue. Although a great deal is known about the characteristics of habituation, very little is known about the molecular mechanisms that underlie it.

Habituation allows an organism to ignore irrelevant stimuli; thus it is the basis for selective attention. If organisms did not habituate, then they would give equal attention to all stimuli in the environment and could not attend to stimuli important for survival. Further, the behavioral rules that govern habituation described by Groves and Thompson (1970) are followed in all species and systems studied. For these reasons, the mechanisms underlying this simple form of learning are likely to be highly conserved throughout evolution. To accurately study such a simple form of learning, it becomes increasingly important to reduce any other factors that could confound such study. Because of this, organisms that exhibit very simple behaviors and that can easily be studied at the cellular and genetic levels provide good model systems to discover the molecular mechanisms involved in habituation.

4.04.2 *Caenorhabditis elegans* as a Model System

Caenorhabditis elegans is a very powerful and useful model system in which to study molecular mechanisms of simple forms of learning and memory. Rankin et al. (1990) first showed that *C. elegans* are capable of a variety of simple behaviors including habituation, dishabituation, and long-term memory lasting for at least 24 h. This nematode has a small nervous system that is

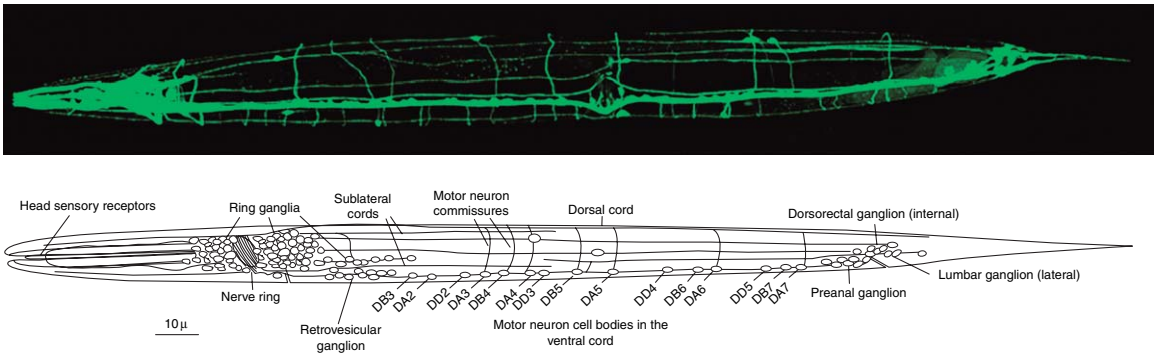

Figure 1 The nervous system of *C. elegans*. Top: *C. elegans* nervous system labeled with a pan-neuronal GFP (photo courtesy of W. Materi and D. Pilgrim). Worm is 1 mm in length. Bottom: Anatomical drawing of the nervous system of *C. elegans*. Drawing courtesy of Richard Durbin.

composed of only 302 neurons, which allows for the unique ability to map behaviors to specific identified neurons and sites of plasticity (**Figure 1**). The connectivity of the nervous system has been resolved at the electron microscope level and has produced a complete wiring diagram indicating 5000 chemical synapses and 3000 electrical synapses (White et al., 1986). Further, the entire cell lineage has been investigated and determined. Combining this knowledge, researchers have been able ablate single identified neurons and investigate the behavioral outcome (Chalfie et al., 1985). Also, since the cuticle of this nematode is transparent, the use of laser ablation of single, identified neurons has made circuit analysis possible, and the use of genetic markers such as green fluorescent protein (GFP) has allowed the analysis of changes in expression patterns of specific gene products *in vivo* (Chalfie et al., 1994). The worm's genome has been mapped and sequenced, which has led to the identification of numerous genes and gene products (Wood, 1988; Riddle et al., 1997). Also, the genetics of *C. elegans* is easy to manipulate. The use of both forward and backward genetic screens and, more recently, RNA interference techniques has led to the identification of a large number of genes that play a role in mediating various behaviors. Another major advantage of this model system is that it is relatively simple to manipulate gene expression spatially or temporally, allowing for the investigation of the roles of specific genes in targeted tissues and/or at specified time points.

4.04.3 Olfactory Habituation

The presentation of an olfactory stimulus can lead to a chemotaxic response, which is the migration toward or away from that stimulus. *C. elegans* will perform both of these behaviors; it is attracted to various ions, amines, and some volatile substances (ketones, esters, etc.), and it is repelled by acidic pH, D-tryptophan, and various volatile substances (benzaldehyde, octanol, etc.; Bargmann and Mori, 1997). Continuous or repeated presentation of such compounds can result in a decrement of the chemotaxic response (Colbert and Bargmann, 1995). Bernhard and Van der Kooy (2000) showed that this decrease in behavioral response could be mediated by two forms of olfactory plasticity: adaptation and habituation. Although adaptation can be considered a form of plasticity, it is not considered to be a form of learning because the response decrement is mediated by sensory fatigue, and the response will return to baseline levels only after sufficient time is allowed for the sensory system to recover. On the other hand, habituation to olfactory stimuli is considered a learning process because, although a similar response decrement occurs as with adaptation, when a novel or noxious stimulus is administered, dishabituation will occur.

Using solubilized Na^+ (an attractant ion), Wen et al. (1997) showed that olfactory habituation can occur in *C. elegans*. They showed that, when exposed to an attractant (75 $mmol^{-1}$ $NaCH_3COO$) for a prolonged time, the chemotaxic response to migrate toward that attractant diminished. But when worms were exposed to a much higher concentration of $NaCH_3COO$ (300 $mmol^{-1}$) for a brief period of time and then given the same behavioral assay, the habituated response returned to near baseline levels, indicating that dishabituation had occurred and that this behavioral decrement was habituation and not adaptation.

To investigate the differences between the processes of habituation and adaptation, Bernhard and Van der Kooy (2000) varied preexposure

concentrations of the volatile odorant diacetyl (DA) within a single paradigm. They found that preexposing and testing worms in high concentrations of DA induced a nonreversible decrement in chemotaxic response despite the introduction of a strong, novel stimulus. When preexposed to an intermediate concentration of DA, no decrement of response was observed. Interestingly, at very low concentrations of preexposure and testing, worms exhibited a decrement in response that could be dishabituated. Taken together, these data suggest that the processes of olfactory plasticity can be dissociated from habituation by the concentration of DA used, with adaptation requiring high concentrations of DA and habituation requiring low concentrations of DA.

Although a number of genes important for adaptation have been identified, little is known about the genetics of olfactory habituation. Wen et al. (1997) showed that mutant worms, *lrn-1* and *lrn-2,* had deficits in classical conditioning associative learning paradigms but showed no deficits in nonassociative habituation. However, more recently, Morrison and van der Kooy (2001) showed that a mutation in an alpha-amino-3-hydroxyl-5-methyl-4-isoxazolepropionate (AMPA)-type glutamate receptor subunit, *glr-1,* impaired both olfactory associative learning and habituation. These data suggest that the mechanisms involved in associative learning and habituation may be dissociable at the level of the *lrn-1* and *lrn-2* genes but share a common pathway that involves the *glr-1* gene.

4.04.4 Mechanosensory Habituation

4.04.4.1 Mechanosensation in *C. elegans*

Mechanosensation, which is the transduction of mechanical force into intracellular signals, allows organisms to sense touch, vibration, and other tactile stimuli. In *C. elegans,* mechanosensation has been studied in two major ways: first, touch to the body from gentle stimulation with a small hair and, second, vibration felt through the surrounding environment resulting from the administration of a mechanical tap delivered to the side of a Petri dish (Garcia-Anoveros and Corey, 1997). Most of the research on habituation has been done using the tap stimulus. The advantage of using the tap stimulus as opposed to the body touch when studying mechanosensory behavior is that the strength of stimulation can be controlled using a machine, whereas there is uncontrollable variation when delivering touch using a handheld device. In response to a tap stimulus, a worm will respond by swimming backward (a reversal), which has been termed the tap-withdrawal response.

4.04.4.2 Habituation

Using the tap-withdrawal response, Rankin et al. (1990) were the first to show that *C. elegans* is capable of nonassociative learning. When they administered a tap stimulus to the side of the Petri plate holding the worm, they observed that the distance that the worms reversed in response to the tap decreased when the stimulus was repeated at regular intervals. The response returned to baseline levels (spontaneous recovery) a few minutes following the last tap stimulus. To ensure that this response decrement was habituation and not sensory fatigue, they followed habituation training with a brief electrical shock in order to dishabituate the worms. Following shock, their response to tap increased significantly above the habituated level, indicating that the electrical shock had induced dishabituation, and the original response decrement observed was habituation and not adaptation or fatigue.

4.04.4.3 Behavioral Analyses of Short-Term Habituation

Thompson and Spencer (1966) and Groves and Thompson (1970) laid out the behavioral characteristics of habituation. These same criteria are used today to define habituation, and so far, all species studied show these same characteristics. Having a behavior well characterized is an asset when trying to determine underlying cellular mechanisms. It is important for researchers to make constant comparisons between behavior and the hypothesized cellular mechanisms in order to develop a greater understanding of the factors that govern habituation.

In their descriptions of habituation, Thompson and Spencer (1966) and Groves and Thompson (1970) missed one aspect of habituation that is common in all systems studied and can be used to find clues about possible molecular mechanisms of habituation. These early papers stated that habituation is sensitive to frequency, with high-frequency stimuli producing more rapid habituation than low-frequency stimuli, and that habituation recovers spontaneously. Both of these are correct; however, in all species studied, frequency also affects the rate of spontaneous recovery, with high-frequency

stimulation leading to more rapid spontaneous recovery than low-frequency stimulation (Rankin and Broster, 1992; **Figure 2**(**a**)). Rankin and Broster (1992) showed that in *C. elegans* this relationship of spontaneous recovery to frequency of stimulation held, regardless of the number of stimuli delivered (as long as decrement had reached asymptotic levels) and regardless of the level of habituation reached (when levels of habituation were matched between worms habituated with high and low frequencies, rate of recovery was still dependent on frequency of the habituation). This is important for two reasons. The first is that this difference is the opposite of what would be predicted by fatigue or adaptation in that, in both of those cases, the more complete the decrement the longer the recovery. With high frequency the decrement is rapid and often complete, but recovery is very rapid, while with low frequency the decrement is not complete and yet recovery takes much longer than for high-frequency stimulation. Thus, the sensitivity of spontaneous recovery to the frequency of stimulation is a second way, in addition to dishabituation, to distinguish whether a behavioral decrement is the result of habituation, or the result of sensory adaptation or motor fatigue. The second reason that the sensitivity of recovery to frequency of stimulation is important is the deductions one can draw from this about molecular

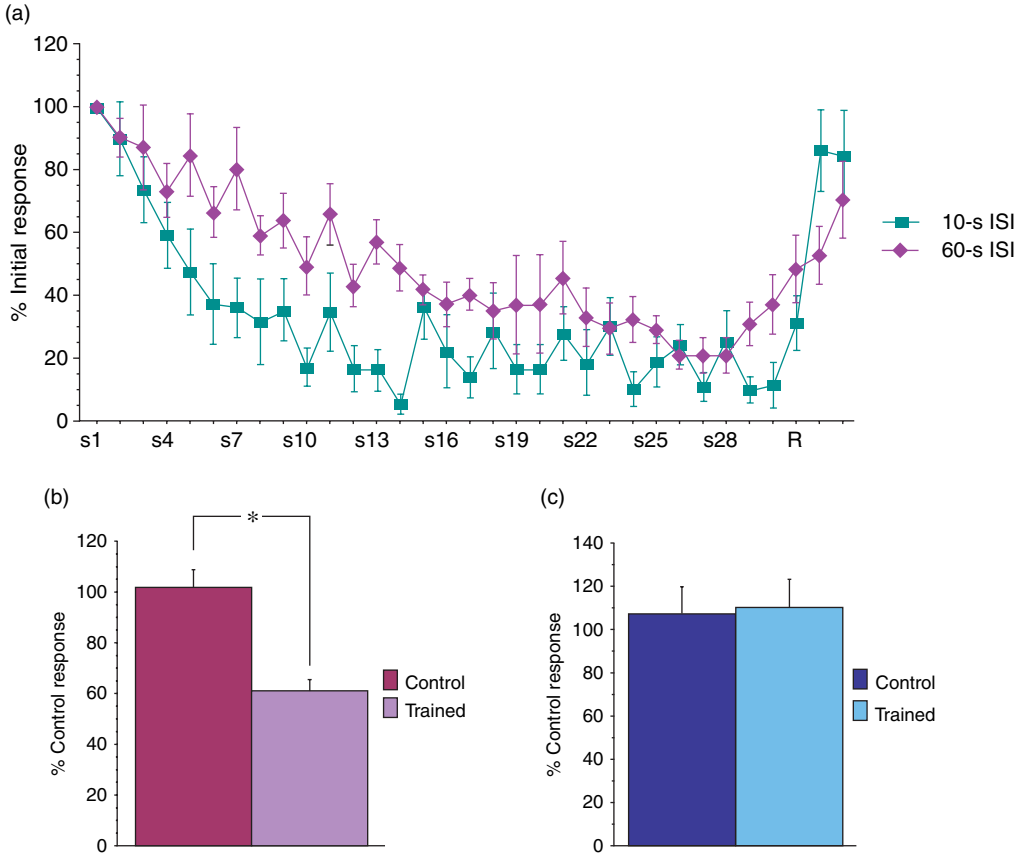

Figure 2 (a) Reversal responses of wild-type worms shown as the mean percent initial response across 30 tap stimuli with three recovery taps at 30 s, 5 min, and 10 min after habituation training. The 10-s interstimulus interval (ISI) group shows more rapid habituation and a lower asymptotic level when compared to the 60-s ISI group. The 10-s ISI group also shows faster and more rapid recovery following habituation training than the 60-s ISI group. (b) Mean percentage of control response magnitude for long-term memory for five test stimuli 24 h following habituation training given at a 60-s ISI. The significantly lower level of responding in the trained group compared to the control group indicates the retention of memory for habituation training. (c) Mean percentage of control response magnitude for long-term memory for five test taps 24 h following habituation training given at a 10-s ISI. The lack of memory observed when training is given at a 10-s ISI suggests either that 60-s ISI training selectively recruits molecular mechanisms needed to induce the formation of long-term memory for habituation training, or that 10-s ISI training recruits molecular mechanisms that block the formation of long-term memory (Butterfield and Rankin, unpublished results, 2006).

mechanisms of habituation. If an animal that has habituated to stimuli at a high frequency (i.e., short interstimulus intervals, ISIs) recovers rapidly, while an animal habituated to the same level to a low frequency recovers more slowly, this indicates that the two habituated animals are not the same, and some different processes have been activated in the neurons of the two animals to regulate recovery differently. From this observation Rankin and Broster (1992) hypothesized that habituation was not mediated by a single molecular mechanism, but that stimulation at different frequencies recruited different cellular mechanisms. The observation that long ISIs can be used to produce long-term memory for habituation, while short ISIs cannot, provides further support for this hypothesis (Beck and Rankin, 1997; **Figures 2**(**b**) and **2**(**c**)). Broster and Rankin (1994) hypothesized that, if different ISIs recruited different molecular mechanisms, then studies of genes involved in habituation should lead, at the very least, to the discovery of genes that play a role in habituation to all frequencies, genes that play a role in habituation to high frequencies, and genes that play a role in habituation to low frequencies. We have recently found support for this hypothesis and identified two genes that are involved in short-term habituation. One specifically affects habituation at high frequencies; the other specifically affects habituation at low frequencies (Rankin, unpublished data, 2006).

4.04.5 Neural Circuit

4.04.5.1 Identifying Neurons Involved in Habituation

Once the behavior was well characterized, the next step in discovering the molecular mechanisms involved in habituation to tap stimuli was to identify the neural circuit responsible for this behavior. The neural circuit underlying the behaviors of backward swimming in response to head touch and forward swimming in response to tail touch was characterized by Chalfie et al. (1985). Wicks and Rankin (1995) investigated the neural circuit underlying the tap-withdrawal response by studying the effects of laser ablating cells in the head and tail touch circuits on the response to tap and found that the response to tap involves integration of sensory input from both the head and tail. The neural circuit for the response to tap consists of five mechanosensory cells, two bilaterally paired PLM neurons that transduce tail touch, and 2 bilaterally paired ALM neurons and a single AVM neuron that transduce head touch; these sensory neurons synapse onto four pairs of command interneurons that mediate forward (AVAs and AVDs) and backward movement (AVBs and PVCs; **Figure 3**(**a**)). Ablation of all sensory cells completely abolished the response to tap (Wicks and Rankin, 1995). Ablation of only the head touch neurons (ALMs and AVM) resulted in consistent forward swimming in response to tap (termed an acceleration) in contrast to the consistent reversal responses seen in intact worms. Similarly, backward swimming was always seen in response to tap in PLM ablated (PLM–) worms. These reversals were larger than the reversals of intact animals, suggesting that in the intact worms the effect of stimulation of the tail cells by the tap competes with the effect of stimulation of the head touch cells and moderates the response size. Interestingly, ablation of AVM only resulted in a decrease in reversal frequency and magnitude of reversals and an increase in acceleration (forward swimming) frequency. In a study of the response to tap across development, it was observed that, at younger stages, worms responded by both reversing and accelerating at equal frequencies, similar to what is observed in AVM– worms (Chiba and Rankin, 1990). Since AVM is not present at hatching and only becomes fully functional in young adults, Chiba and Rankin (1990) suggested that the shift in adult worms to predominantly reversing response to tap may be mediated by the development of AVM. All these results combined indicated that the response to tap was mediated by the integration of inputs from two competing neural circuits, one driving forward movement and one driving backward movement.

4.04.5.2 Roles of Identified Neurons in Habituation

To identify the sites of changes in the pathway(s) underlying habituation of the tap-withdrawal response, Wicks and Rankin (1996b) laser ablated specific touch cells and observed any changes in habituation rate or asymptotic level. Laser ablation of the PLM sensory neurons results in consistent backward movement in response to tap. When given the short-term habituation training at a 10-s and 60-s ISI, PLM– worms showed habituation at both ISIs. The initial slope of the PLM– group was smaller than that of the intact group (**Figures 3**(**b**) and **3**(**c**)). When Wicks and Rankin (1996b) investigated the role of the touch cells of the anterior mechanosensory field (AVM and ALM), they found

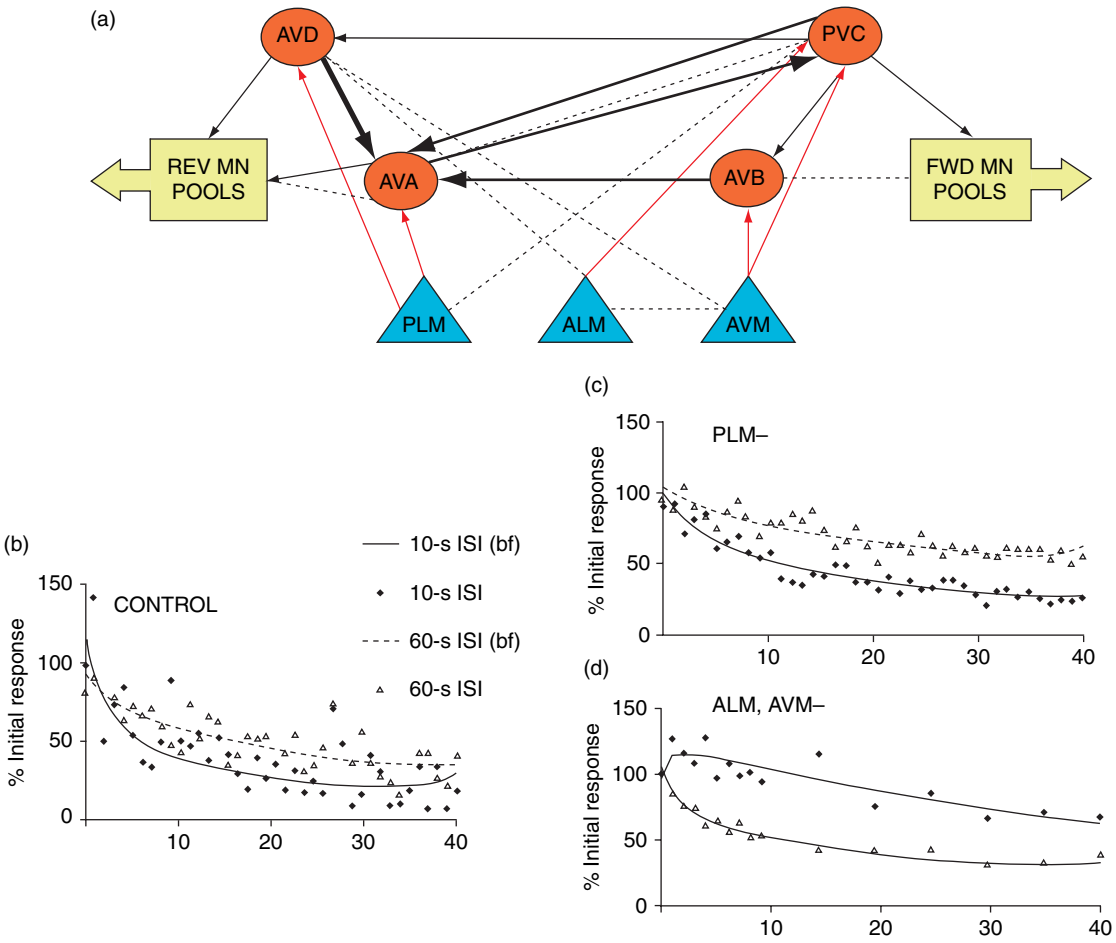

Figure 3 (a) Simplified neural circuit underlying tap withdrawal. The circuit consists of five mechanosensory neurons (*triangles*), eight command interneurons (*circles*), and two motor neuron pools (*squares*). All cells represent bilateral classes of cells except ALM, which is a single cell. The arrows and dotted lines represent chemical synapses and gap junctions, respectively. The number of synaptic contacts is proportional to the width of the arrows. The red-colored arrows indicate the synaptic connections that have been hypothesized to be the sites of plasticity that mediate habituation (Wicks and Rankin, 1997; Kitamura et al., 2001). (b, c) Scatter plot graphs fitted with best fit lines (bf) demonstrating the effect of ISI (10 s vs. 60 s) on the kinetics of habituation of the reversal response in intact animals (control) and PLM-ablated animals (PLM–). (d) Scatter plot graph showing the effects of ablation of ALM and AVM on the kinetics if habituation of acceleration responses. Wicks and Rankin (1996b) hypothesized that the responses of both the PLM– and AVM, ALM– groups combine to make up the behavior we see in the intact animal. Figure adapted from Wicks SR and Rankin CH (1996b). The integration of antagonistic reflexes revealed by laser ablation of identified neurons determines habituation kinetics of the *Caenorhabditis elegans* tap withdrawal response. *J. Comp. Physiol. A* 179: 675–685, with permission from Springer-Verlag.

results that were quite different from those of the PLM– group. Worms with ablations in the head sensory neurons accelerate forward in response to tap. They found that both ALM– and ALM, AVM– groups habituated slower at a 10-s ISI than at a 60-s ISI, and they showed an initial response facilitation prior to the decrement that was especially strong when habituated at a 10-s ISI (**Figure 3(d)**). Further, the ALM, AVM– group had a significantly higher asymptotic level at a 10-s ISI as opposed to the 60-s ISI. Finally, ablation of one of the pairs of command interneurons (PVCs), thought to modulate forward movement, resulted in worms that reversed 100% of the time; however, unlike the PLM– worms, the reversals seen in PVC– worms were not significantly different in magnitude from control worms. The results support the hypothesis of Chalfie et al. (1985) that the PLM cells make inhibitory chemical connections to the head touch circuit interneurons (AVD and AVA); these connections remain intact

following PVC ablation and continue to compete with the head sensory neuron stimulation. Taken together, the results of ablation of cells important in both the forward and backward motion pathways have shown that reversals and accelerations habituate at different rates; thus their relative contribution to the intact response varies over the course of habituation. For example, at a 10-s ISI the initial facilitation of the acceleration response competes more strongly with the reversals and the reversals seen in intact worms decrease in amplitude very quickly. This suggests that to understand the habituation of behavior it is not sufficient to study the mechanisms underlying the decrement in a single cell, but it may be necessary to understand the effect of repeated stimulation on all aspects of the neural circuits underlying the behavior.

4.04.5.3 Localizing the Site of Plasticity in the Neural Circuit

Two behaviors that share command interneurons and motor neuron pools with the tap-withdrawal response are thermal sensation and spontaneous reversing. All of these behaviors differ from tap at the level of sensory input. Wicks and Rankin (1997) hypothesized that, if the site of plasticity that mediates habituation is located at the sensory input level, then habituation to tap should not alter baseline levels of both the response to a heat probe and spontaneous reversing. On the other hand, if the site of plasticity is at the level of the interneurons and motor neurons, then these behaviors should be altered by habituation training in response to tap. Wicks and Rankin (1997) found that habituation to tap did not affect other behaviors, thus providing data to support the hypothesis that the site of plasticity lies in the touch cells and/or the synaptic connections they make onto the interneurons.

Investigation into habituation of anterior body touch has also led to increased knowledge of how habituation occurs in the neural circuit. Kitamura et al. (2001) performed gentle body touch using a hair at a 15-s ISI, using intact worms, and observed the expected kinetics of habituation with an initial, rapid decrement of reversal magnitude followed by an asymptotic level of that response. Through systematic ablations of combinations of neurons involved in the response to anterior body touch (ALM, AVM, AVD, and PVC), they found that laser ablation of both AVD interneurons resulted in significantly more rapid habituation than observed in intact animals. The ablation of any of the other interneurons had no effect on the rate of habituation, suggesting that the AVD interneurons play a critical role in the habituation to anterior body touch. Kitamura et al. (2001) also found that coablating the right ALM and the AVM neurons resulted in rapid habituation, suggesting that in these animals the chemical synapse that the left ALM makes with the right AVD and PVC interneurons is responsible for the behavior observed. Further investigation led to the conclusion that the chemical synapses between the left ALM sensory neurons and the PVC interneurons mediate the rapid habituation of the coablated worms. The fact that more rapid habituation can be attributed to at least two sites in the neural circuit suggests that each synapse in the circuit may have the potential to be the site of plasticity.

Taken together, the studies performed by both Wicks and Rankin (1995) and Kitamura et al. (2001) show that habituation to mechanosensory stimuli in intact animals involves the integration of a variety of inputs. However, the most likely site of plasticity appears to be situated at the level of the chemical synapses between the sensory neurons and their target interneurons.

4.04.6 Genetic Dissection of Short-Term Habituation

4.04.6.1 Role of Genes Involved in Glutamate Neurotransmission

A number of genes involved in glutamate neurotransmission are expressed in the touch cells and the command interneurons, suggesting that glutamatergic transmission plays a major role in the response to tap. Presynaptically, in the sensory neurons (ALM, AVM, and PLM) a homologue of a mammalian glutamate vesicular transporter, known as EAT-4, is expressed (Lee et al., 1999). Postsynaptically, in the command interneurons (AVA, AVB, AVD, and PVC) homologues of both the mammalian AMPA/Kainate-type and n-methyl-D-aspartate (NMDA) glutamatergic receptors, GLR-1 and NMR-1, respectively, are expressed (Hart et al., 1995; Maricq et al., 1995; Brockie et al., 2001). If glutamatergic transmission plays a critical role in habituation in *C. elegans,* then worms that lack, or have mutations in, one or more of these genes should have altered patterns of habituation.

Rankin and Wicks (2000) first examined *eat-4* mutants using the short-term habituation paradigm. Initially, they found that, when compared to

wild-type worms, there was no difference in the initial response to the tap stimulus. When given repeated stimulation, at both 10- and 60-s ISIs, *eat-4* worms habituated more rapidly and reached a lower asymptotic level than wild-type worms. Similarly, *eat-4* worms showed much slower spontaneous recovery following habituation training; however, the dependence on ISI was still present in both habituation and recovery kinetics (faster decrement and faster recovery from short ISI training as compared to long ISI training). This result suggests that the absence of EAT-4 disrupts one or more cellular mechanisms of habituation but leaves others (ISI dependent processes) intact. Interestingly, *eat-4* is also the first gene that has been shown to play a role in dishabituation. When given a dishabituating stimulus (an electric shock), the *eat-4* mutants did not show facilitation of the response above the habituated level, indicating that they did not dishabituate. Since *eat-4* worms still show ISI-dependent spontaneous recovery, the decrement seen in these worms is habituation and not fatigue or adaptation. Because we do not know the relationship between the molecular mechanisms of habituation and the molecular mechanisms of dishabituation, these results illustrate the importance of having more than a single way to distinguish habituation from fatigue. Using a transgenic rescue strain (DA1242) produced by Lee et al. (1999), Rankin and Wicks (2000) showed that wild-type habituation and dishabituation behaviors were also rescued. These studies with *eat-4* worms support the hypothesis that glutamatergic transmission plays an important role in habituation of the tap-withdrawal response and that the glutamate vesicular transporter is essential for dishabituation.

Because *eat-4* worms did not respond differently from wild-type in response to the initial tap stimuli but differed only after repeated stimuli, Rankin and Wicks (2000) concluded that EAT-4 (a glutamate vesicular transporter) is not required for glutamatergic transmission but, rather, is required for sustained synaptic activity. The hypothesis is that the touch sensory neurons of *eat-4* worms have fewer glutamate-filled vesicles than those of wild-type worms, and so they are quickly exhausted in response to repeated stimulation. The importance of neurotransmitter vesicles in habituation is supported by work in *Aplysia* that has shown that there are fewer synaptic vesicles in the active zones of sensory neurons from habituated animals than from the terminals of nonhabituated animals (Bailey and Chen, 1988). The regulation of the amount of glutamate in vesicles in the terminals of the sensory neurons and/or the regulation of vesicular release are the most likely mechanisms underlying the behavioral changes observed during habituation.

Since the deficits in presynaptic release of glutamate seen in *eat-4* worms alter the kinetics of habituation to tap, it was suggested that postsynaptic glutamate receptors should also play a significant role in the same behavior. Genes for four ionotropic glutamate receptors are expressed on the command interneurons: *glr-1, glr-2, nmr-1*, and *nmr-2* (Hart et al., 1995; Maricq et al., 1995; Brockie et al., 2001). *glr-1* and *glr-2* have been shown to form heteromeric receptors (Chang and Rongo, 2005), and *nmr-1* and *nmr-2* are thought to form heteromeric receptors as well. Studies to date have focused mainly on mutations in *glr-1* and *nmr-1*. When given habituation training, *glr-1* worms showed smaller initial responses to tap than wild-type animals but showed relatively normal short-term habituation to 10- and 60-s ISIs when compared to wild-type worms (Rose et al., 2002). *nmr-1* worms showed normal short-term habituation, indistinguishable from wild-type. The results thus far indicate that none of the glutamate receptor genes tested alone gives the same pattern as EAT-4–deficient worms, which suggests that habituation may be mediated postsynaptically by the activation of an, as yet, unidentified glutamate receptor or by the simultaneous activation of multiple glutamate receptors.

4.04.6.2 Other Identified Components of Habituation

Sanyal et al. (2004) showed that dopamine, which plays an important role in behavioral plasticity in many mammalian systems, also may play an important role in modulating *C. elegans* habituation. Sanyal et al. (2004) studied mutations in two genes involved in dopamine regulation and neurotransmission; *dop-1* mutants, which do not express a dopamine receptor on neurons involved in the mechanosensory circuit, show altered patterns of habituation compared to wild-type worms, as do *cat-2* mutants, which lack an enzyme that is required for dopamine synthesis. Sanyal et al. found that *dop-1* mutants and *cat-2* mutants had a more rapid decrement in reversal frequency (the number of worms that respond to each tap) than wild-type worms. However, when measuring reversal length (the dependent variable in all previous studies mentioned), there was no difference among all three groups. This result

suggests two alternative hypotheses: the first is that different mechanisms regulate the decrease in the probability of a reversal response and the size of the response; the second is that dopamine may not be involved in habituation to tap, but instead may modulate the integration of sensory stimuli from the head and tail touch circuits.

Xu et al. (2002) performed a forward genetic screen on habituation to tap and isolated *hab-1,* a mutant which habituated more slowly and responded at a higher asymptotic level than wild-type worms when tested at both 2- and 10-s ISIs. Further, the *hab-1* mutants responded like wild-type worms to the initial tap and also responded normally to a dishabituating stimulus. Unfortunately, the gene product of *hab-1* has yet to be identified. However, the observed pattern of slower habituation is opposite to the results seen with both *eat-4* and *dop-1,* suggesting that the gene product of *hab-1* may play an antagonistic role to the molecular mechanisms of glutamatergic and dopamine signaling that is hypothesized to underlie short-term habituation.

4.04.7 Analyses of Long-Term Habituation

4.04.7.1 Dependence on Protocol

Analysis of long-term memory for habituation to the tap-withdrawal response has led to increased knowledge and further understanding of the mechanisms that govern habituation behavior. Rankin et al. (1990) were the first to report long-term memory habituation to tap. Using a modified protocol from experiments with *Aplysia* (Carew et al., 1972), they were able to show that if worms were given distributed habituation training they were able to retain memory for that training for at least 24 h. To investigate the behavioral parameters that reliably produce long-term memory for habituation, Beck and Rankin (1997) examined ISI and type of training. They replicated the finding of Rankin et al. (1990) that long-term memory could be produced by distributed training, and they found that, if they used a massed training protocol where all stimuli were delivered without break periods instead of a distributed training protocol, long-term memory was not observed. In addition, they found that long-term memory could not be reliably produced from training at a 10-s ISI, whereas it was produced using a 60-s ISI. This result supports the hypothesis of Rankin and Broster (1992) that there may be specific cellular mechanisms, which are recruited by training with a 60-s ISI or inhibited by training with a 10-s ISI, to induce memory formation during habituation training (**Figures 2(b)** and **2(c)**). Taken together, these data show that long-term memory of habituation training is most reliably produced when stimuli are administered at longer ISIs in a distributed or spaced manner. This parallels observations made in studies that found that distributed training is superior to massed training for the induction of long-term memory in many species, including *Aplysia, Drosophila,* and humans (Ebbinghaus, 1885; Carew *et al.*, 1972; Tully and Quinn, 1985).

4.04.7.2 Molecular Correlates of Memory for Habituation Training

Since distributed training was essential for the induction of long-term memory for habituation training, it was hypothesized by Beck and Rankin (1995) that the mechanisms that are responsible for consolidation of the memory were most likely occurring during the interblock intervals. To assess this, Beck and Rankin (1995) used heat shock (32 °C) to block protein synthesis and disrupt these cellular mechanisms. The cellular response to heat shock that was first observed in *Drosophila* has been shown to be same in every organism studied (Schlesinger et al., 1982). The response is the termination of protein synthesis of all proteins other than a class of proteins called heat shock proteins, the production of which is significantly increased. To determine the timing of memory consolidation of habituation training, heat shock was delivered before, during, or after training. Beck and Rankin (1995) found that disruption of memory consolidation by heat shock occurred during but not before or after habituation training, which supported their hypothesis that some of mechanisms that mediate the induction of long-term memory are occurring during the interblock periods. As well, they found that neither the kinetics of habituation nor the initial response to tap was affected by heat shock treatment. These data suggest that repeated tap stimulation with intervals between blocks triggers molecular mechanisms that involve protein synthesis.

Since the research with *eat-4* mutants suggested that glutamatergic neurotransmission plays a pivotal role in short-term habituation, Rose et al. (2002) hypothesized it might also play a role in long-term habituation. To investigate this, Rose et al. (2002) used the *eat-4* mutants to test for the presence of long-term memory for habituation training using the distributed training protocol. Interestingly, even though *eat-4* mutants habituate faster and more

completely than wild-type worms, they did not retain memory for this training 24 h later. This suggests that the sustained glutamate release that is important in short-term habituation is also critical to the formation of long-term memory. Rose et al. used the *eat-4* rescue strain, DA1242, and found that DA1242 worms showed normal memory 24 h after training; this supports the hypothesis that presynaptic glutamate release is essential for the formation of long-term memory.

Because release of presynaptic glutamate appeared to be essential for the induction of long-term memory, Rose et al. (2002) hypothesized that postsynaptic glutamatergic receptors might be involved in aspects of long-term memory for habituation as well. To examine this hypothesis Rose et al. (2003) tested worms with mutations in *glr-1,* a homologue of mammalian AMPA/Kainate glutamate receptor subunit (GluR1) and worms with a mutation in *nmr-1,* a homologue of mammalian NMDA-type glutamate receptor subunit (NR1). They found that worms with a mutation in *nmr-1* showed normal long-term memory for habituation. In contrast, *glr-1* worms showed no long-term memory for habituation. To confirm the importance of glutamate receptors in the formation of long-term memory, wild-type worms were treated with DNQX, a competitive non-NMDA glutamate receptor antagonist, during training. Treatment with DNQX had no effect on short-term habituation, but it did block the formation of long-term memory (Rose et al., 2003). These data suggest that *glr-1* plays a critical role in the induction of long-term memory but is not an essential component for short-term habituation.

The role of glutamate receptors in synaptic plasticity and memory formation has been extensively studied in mammalian systems. The most prominent and well-characterized forms of synaptic plasticity that may underlie mammalian memory formation are long-term potentiation (LTP) and long-term depression (LTD). Both LTP and LTD involve changes in synaptic expression levels of GluR1-containing AMPA-type glutamate receptors and trafficking of the receptors to and from the postsynaptic membrane (Malinow and Malenka, 2002). To examine whether similar processes were involved in the induction of memory for habituation training Rose et al. (2003) tested whether habituation training affected the expression pattern of the GluR1 homologue, GLR-1. Using worms carrying chimeric receptors made up of GLR-1 tagged with GFP (GLR-1::GFP), they were able to visualize changes in punctate *glr-1* expression (Rongo and Kaplan, 1999) along the ventral nerve cord (an area that corresponds to important synaptic sites reported in electron microscopy studies; White et al., 1986). They found that, following distributed habituation training, the number of GLR-1::GFP puncta along the ventral nerve cord did not change, but the size of the puncta in trained worms was significantly smaller than in control worms (**Figures 4(a)** and **4(b)**). This result suggests that the distributed habituation training did not alter the number of synapses along the nerve cord but rather reduced the number of receptors expressed per synapse on the interneurons. Further, blocking protein synthesis by applying heat shock during training blocked the downregulation of GLR-1::GFP expression. These data suggest that, although *glr-1* does not appear to play an important role in short-term habituation, its regulation critically mediates long-term memory for habituation.

4.04.8 Summary

The evidence discussed has shown that *C. elegans* can habituate to both olfactory stimuli and mechanosensory stimuli. Little is known about olfactory habituation other than that it appears to require low doses of the chemical stimuli and is dependent on the *glr-1* gene. On the other hand, mechanosensory habituation has been studied at the level of behavior, neural components, and genes involved. Using the tap-withdrawal paradigm, the dependence upon ISI appears to mediate a large number of aspects of habituation, including the rate of habituation, the level of habituation, and spontaneous recovery from habituation. The neural circuit that mediates habituation to tap has been thoroughly investigated, and this has led to the hypothesis that the most likely sites of plasticity are the synaptic connections between the sensory neurons and the command interneurons. Thus far, the molecular components that affect habituation include presynaptic glutamate release and dopaminergic neurotransmission, and are independent of the activation of *glr-1.* However, distributed habituation training that induces long-term memory recruits other cellular processes. These processes have been shown to be protein synthesis dependent and rely heavily upon the alterations in the expression of *glr-1.*

Taken together, these data suggest that habituation is not a simple or singular process but, rather, is mediated by a complex set of events that incorporates a variety of molecular mechanisms. These events

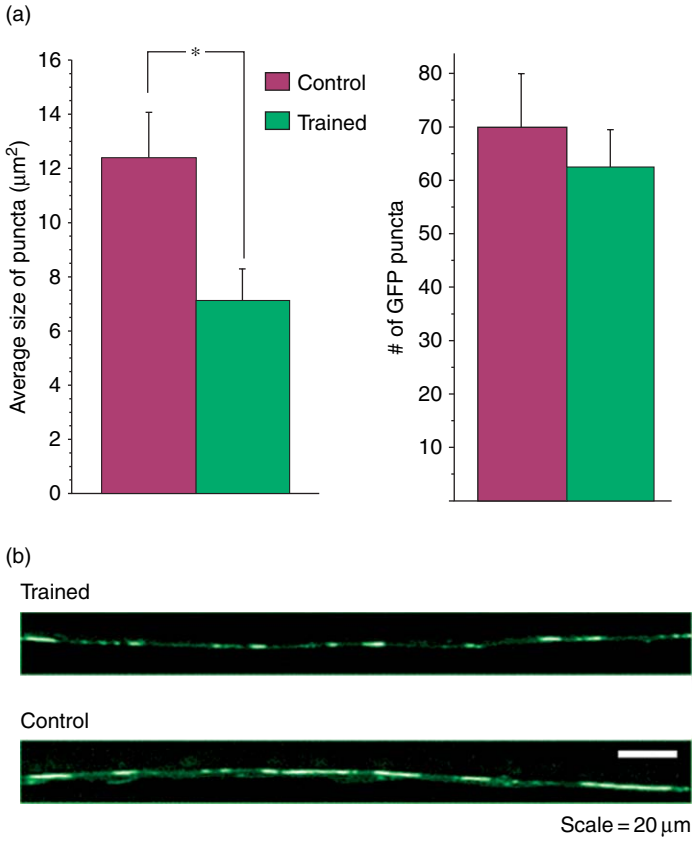

Figure 4 (a) Long-term memory for habituation training correlates with changes in GLR-1::GFP expression in the posterior ventral nerve cord 24 h after distributed habituation training. There were significantly smaller GFP puncta in the trained worms than in control worms; however, the number of puncta was not different between the two groups, suggesting that memory was reflected in a change in the average size of synapses and not a change in the number of synapses (Rose et al., 2003). (b) Confocal images of GLR-1::GFP expression in trained and control worms taken 24 h after distributed training.

integrate multiple neurotransmitters, multiple receptors, and multiple subcircuits, each mediating different aspects of habituation. Rather than there being a single mechanism of habituation, the data from *C. elegans* lead to the hypothesis that there are multiple mechanisms that can underlie this seemingly simple response decrement. Because of its well-studied genetics, physiology, and behavior, *C. elegans* is now, and will continue to be, a very powerful model system in which to elucidate the cellular events and processes that underlie key components involved in learning and memory.

4.05 Pain Sensitization

Y. Carrasquillo and R. W. Gereau IV, Washington University School of Medicine, St. Louis, MO, USA

4.05.1 Introduction

Over 10 years ago, Allan Basbaum published a review article entitled 'Memories of pain' (Basbaum, 1996). This article highlighted the role of central nervous system (CNS) plasticity in mediating pain sensitization, and since that time research into the molecular mechanisms mediating pain sensitization has exploded, leading to a new appreciation for the complexity of pain and its sensitization. Here we will introduce the neurobiology of pain and discuss the many mechanisms of sensitization in the pain neuraxis, as well as their relation to mechanisms of learning and memory.

4.05.1.1 Defining Pain: Acute Versus Chronic Pain

Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage (Merskey, 1979). Physiological pain serves a vital survival function as it alerts organisms to the presence of damaging or potentially damaging stimuli. The importance of the protective role of pain is exemplified by the detrimental outcomes of numerous pathological conditions that are characterized by the lack of pain sensation. A common group with significant morbidity due to the lack of pain perception is diabetics with peripheral neuropathy. In these patients, unnoticed repetitive injuries to the joints can lead to permanent joint deformity. Diabetic patients with peripheral neuropathy can also develop ulcers caused by undetected excessive pressure, by rubbing against the skin on the foot, or by stepping on a sharp object (Boulton, 2004). These ulcers can erode to the bone and lead to serious infections with resultant sepsis or need for amputations. Another rare, but yet very dramatic, example of the

protective role of pain is seen in patients with congenital insensitivity to pain. In these patients, pain and temperature insensitivity is manifested in childhood and results in the occurrence of painless fractures, ulcers, burns, and self-mutilation that can lead to death at a young age (Nagasako et al., 2003).

Under normal physiological conditions, pain results from trauma, inflammation, or nerve injury, thus acting as an early warning system that protects the body from further injury. Physiological pain usually subsides as the injury heals and can be frequently diagnosed and treated. Chronic pain, on the other hand, is considered a pathological condition with little or no beneficial function. It can last for a prolonged period of time, outlast the initial pathology, and it is often accompanied by maladaptive behaviors, irritability, depression, and disruption of work and social relationships (American Pain Foundation, 2002). Chronic pain may result from ongoing causes of pain with a known pathology such as in arthritis and cancer. Alternatively, chronic pain may be caused by either an unknown pathology or an associated injury, making their treatment even more challenging.

A major but also distinct component of pain is nociception, which is the sensory process by which a noxious stimulus, such as one induced by tissue damage, is transduced to neurophysiological signals that are then transmitted to the CNS. Nociception can occur without pain perception and pain perception can occur without nociception. An example of pain in the absence of nociception is seen in the phantom limb syndrome, when patients with amputated limbs report feeling pain in the missing limb.

4.05.1.2 Chronic Pain and Synaptic Plasticity

The understanding of the neural mechanisms underlying nociception and pain perception has significantly increased in the last 2 decades. A key finding for this advancement was the realization that responses of the sensory system to a given input are not fixed, but rather change, as a result of previous neuronal activity. This means that the responses of the sensory system are highly dependent on the neural memory of the system. This neuronal plasticity, also referred to as sensitization, has been observed and studied in different parts of the pain neuraxis such as peripheral nociceptors, spinal dorsal horn neurons, rostroventral medulla, anterior cingulate cortex, and amygdala.

Maladaptive and persistent neural changes in the sensory system can occur in response to trauma, inflammation, or nerve injury and are thought to underlie chronic pain. A classic example of sensitization is seen in the dorsal horn of the spinal cord (**Figure 1**). Following tissue injury, spinal cord dorsal horn neurons, which are the first CNS processing station for pain signal from the periphery, show a decreased threshold for action potential firing, increased responsiveness to a given stimulus, and receptive field enlargement (Woolf, 1983; Woolf and Wall, 1986; Cook et al., 1987). The increased responsiveness of

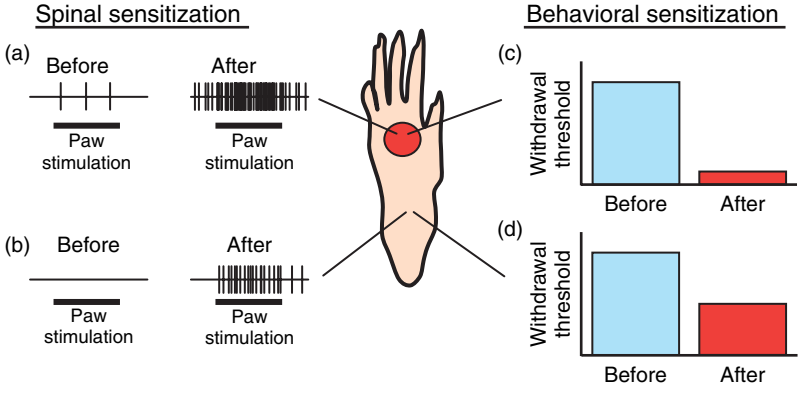

Figure 1 Diagrammatic representation of injury-induced spinal and behavioral sensitization. (a, b) Responses of a spinal cord dorsal horn neuron to paw stimulation before and after tissue injury. (a) Responses to stimulation in the injured area (red circle). After tissue injury, dorsal horn neurons exhibit increased responsiveness to a given stimulus. (b) Responses to stimulation in the noninjured area. Before tissue injury, the receptive field of the neuron did not include the stimulated area. After tissue injury, the neuron responds to stimulation in the noninjured area, demonstrating an enlargement of the receptive field (c, d) Paw withdrawal thresholds in response to mechanical stimulation before and after tissue injury. After tissue injury, withdrawal thresholds in response to mechanical stimulation of the injured (c) and noninjured areas (d) decrease.

dorsal horn neurons to a given stimulus correlates with the behavioral sensitization commonly observed after tissue injury (**Figure 1**). This pain sensitization is characterized by increased pain responses to normally noxious stimuli (hyperalgesia) and/or by pain responses to previously innocuous stimuli (allodynia). Hyperalgesia and allodynia after tissue injury can be experienced both in the injured area (primary hyperalgesia or allodynia) and in adjacent noninjured areas (secondary hyperalgesia or allodynia). Receptive field enlargement of dorsal horn neurons could therefore explain, at least in part, the phenomenon of secondary allodynia and hyperalgesia.

For years, researchers have been trying to identify neural processes that specifically mediate pathological but not physiological pain. The end goal is to develop novel and more efficient approaches for treating chronic pain conditions by decreasing maladaptive pain without affecting physiological pain, which is a vital adaptive response. Numerous studies have revealed striking similarities between the neural mechanisms underlying pain sensitization and those underlying learning and memory (Ji et al., 2003). These similarities have made the development of novel analgesic therapies even more difficult by adding yet another level of potential undesired side effects. At the same time, realization of this relationship has led to the development of a cognitive-behavioral approach to managing chronic pain that has been shown to be highly effective in helping to manage chronic pain. In this chapter, we will start by briefly discussing the advantages and limitations associated with the use of animal models for the study of pain and by summarizing basic concepts of the physiology of pain. We will then discuss the different forms of sensitization that have been reported in different areas of the pain neuraxis, including their anatomical and cellular substrates and their association with behavioral hypersensitivity that is induced by trauma, inflammation, or nerve injury. The chapter will end by comparing the neural mechanisms of pain with those of learning and memory and by discussing the implications for pain management.

4.05.2 Animal Models for the Study of Pain

The goal of pain research is to acquire new knowledge on the mechanisms, pathogenesis, diagnosis, and treatment of pain. The use of animal models of pain is essential to achieve this goal but, because of the negative nature of pain, there are a number of concerns as well as ethical, moral, and legal issues associated with the use of animals to study pain. Ethical guidelines for the investigation of experimental pain in animals have been established by the International Association for the Study of Pain (IASP) (Zimmermann, 1983). These guidelines primarily aim at ensuring that the animal is exposed to the minimal pain necessary for the purposes of the experiment. Whenever possible, experiments should be carried out in anesthetized animals utilizing transient stimuli and avoiding tissue damage. Many experiments to investigate the neural basis of pain can be pursued using these methods. However, to evaluate the mechanisms underlying persistent pain-related behaviors after tissue injury, the use of conscious animals and their exposure to tissue injury are imperative. To minimize discomfort and pain, the duration of all pain experiments should be as short as possible and the number of animals involved should be kept to a minimum. If possible, the investigator should expose the pain stimulus to himself to ensure that the experimental animal is not exposed to pain greater than humans could tolerate. Finally, to minimize discomfort, most experiments utilize techniques in which the animal has control over the intensity and duration of the pain stimulus by measuring the latency or threshold for withdrawal responses to the pain stimulus.

By definition, pain is a subjective perception of a given stimulus. Therefore, the main limitation of the use of animal models to study pain is that the investigator cannot determine with certainty the animal's perception. Animal models of pain are designed to mimic human pain conditions and employ characteristic animal behavioral responses to pain such as licking, withdrawal, and vocalization. Although not perfect, these methods allow the investigator to infer that the animal is experiencing pain. Changes in these stereotypical behaviors have long been used to measure the efficacy of experimental manipulations and pharmacological agents in reducing pain. Many of the drugs currently used to treat clinical pain have been shown to decrease nociceptive behavioral responses using animal models (Negus et al., 2006). Furthermore, neural mechanisms thought to underlie chronic pain have been observed both in human and in animal models of pain (Ji et al., 2003; Klein et al., 2004). It can therefore be concluded that animal models of pain are indeed useful for studying pathological pain.

4.05.3 Physiology of Pain

Pain processing starts with the conversion of noxious stimuli to neurophysiological signals (**Figure 2**). These neural signals are transmitted from the site of injury to the spinal cord and the brain where information about the intensity, quality, and location of the stimuli is processed. This processing is not unidirectional, however; descending pathways from the brain can significantly affect nociceptive transmission in the spinal cord, thus affecting pain perception. In this section, we will discuss the physiological basis of pain. The processes of transduction, transmission, modulation, and perception of pain will be discussed.

4.05.3.1 Pain Transduction

As in all sensory systems, the nociceptive system starts with the transduction of an external stimulus, in this case a noxious stimulus (thermal, mechanical, or chemical), to a neurophysiological signal. The transduction process occurs in nociceptor terminals that are located in the skin, muscles, and other end-organ tissues. Nociceptors are peripheral nerve endings of primary sensory neurons that selectively respond to noxious stimuli. The cell bodies of these primary sensory neurons are located in the dorsal root ganglia (DRG) and in the trigeminal ganglia. Dorsal root and trigeminal ganglion neurons are pseudo-unipolar cells. This means that these neurons have one axon that splits into two processes, with each process functioning as an axon. One of these processes conveys information from the periphery to the soma while the other one transmits information from the soma to neurons in the dorsal horn of the spinal cord or in the trigeminal nucleus caudalis of the brainstem. Two major classes of nociceptors have been described: Aδ- and C-nociceptors (Raja et al., 1999). Aδ-nociceptors are small-diameter, thinly myelinated fibers that conduct at 5–30 m/s and respond to either heat (thermal nociceptors) or intensive pressure (mechanical nociceptors), whereas C-nociceptors are small-diameter unmyelinated fibers that conduct slowly (<1 m/s) and respond to high-intensity mechanical, thermal, or chemical stimuli.

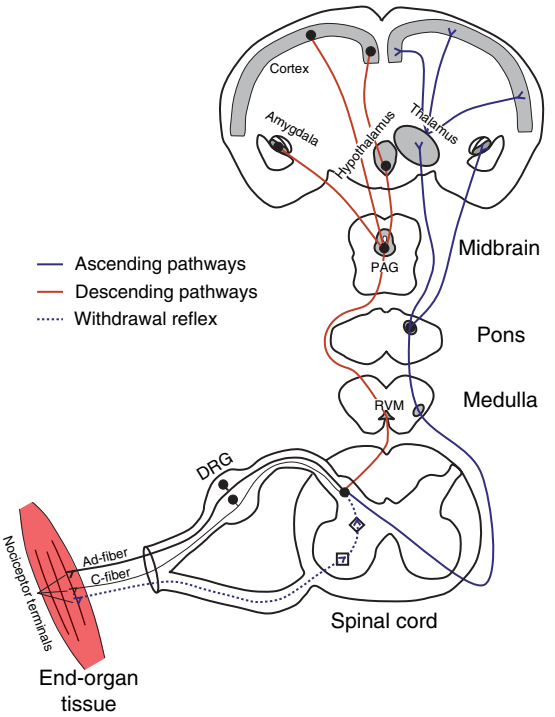

Figure 2 Illustration of anatomical pain pathways. Nociceptive information is transduced in nociceptor terminals located in the skin, muscle, and other end-organ tissues. Small-diameter unmyelinated C-fibers transmit the nociceptive information to neurons in the dorsal horn of the spinal cord, which in turn project to various brain regions via ascending pathways (solid blue line) that relay in the medulla, pons, and thalamus. Activation of motor neurons (□) by excitatory interneurons (◇) mediates the pain withdrawal reflex (dotted blue line). Descending pathways from the brain (red line), that relay in the periaqueductal gray matter (PAG) and rostroventromedial medulla (RVM), modulate nociceptive transmission in the dorsal horn. DRG, dorsal root ganglia.

The exact mechanism by which noxious stimuli are translated to neurophysiological signals in the peripheral nerve endings is not completely understood, but it is thought to involve the activation of proteins designed to convert noxious stimuli to depolarizing electric potentials. A family of receptors that has received increasing attention in recent years as major sensory transducers is the transient receptor potential (TRP) ion channel family. TRP channels are expressed in nociceptor terminals and transduce a wide range of thermal, mechanical, and chemical stimuli (Wang and Woolf, 2005; Story and Gereau, 2006). The TRPV1 receptor is activated by noxious heat ($\geq$43 °C), protons, or capsaicin (the pungent compound found in hot chili peppers); TRPV2 by noxious heat ($\geq$52 °C); TRPV4 by mechanical stimuli or protons; TRPM8 by cold ($\leq$23–28 °C), menthol, and icilin (a super cooling agent); and TRPA1 by noxious cold ($\leq$18 °C), icilin, mustard, cinnamon, or mechanical stimuli. Since TRP channels are activated within a range of noxious temperatures, and also by protons, chemicals, and intensive pressure, it has been hypothesized that these receptors have a prominent role in thermal, chemical, and mechanical nociception. Other receptors and ion channels such as the metabotropic glutamate receptors, the TREK-1 potassium channel, and the acid-sensing ion channels (ASIC) and dorsal root acid-sensing ion channels (DRASIC) have also been identified as potential sensory transducers in nociceptor terminals. The ultimate function of these channels is to provide a transduction current that depolarizes the nociceptor terminals and thereby initiate action potential firing in the nociceptor.

4.05.3.2 Pain Transmission

Nerve impulses generated in the periphery by noxious stimuli propagate via axons of DRG neurons to the dorsal horn of the spinal cord (**Figure 2**). The dorsal horn of the spinal cord is subdivided into six layers or laminae based on cytoarchitectural characteristics. C nociceptive afferents terminate mainly in laminae I and II, whereas Aδ afferents terminate mainly in laminae I and V (Basbaum and Jessell, 2000). Following DRG activation by peripheral noxious stimuli, neurotransmitters and peptides are released from DRG afferent terminals into the dorsal horn of the spinal cord. In the dorsal horn, these neurotransmitters and peptides act on postsynaptic receptors expressed by three types of dorsal horn neurons: excitatory interneurons, inhibitory interneurons, and projection neurons. Excitatory and inhibitory interneurons are part of the dorsal horn local circuitry; these neurons synapse on and modulate the firing of projection neurons, motor neurons, and other interneurons (**Figure 2**). Activation of motor neurons by excitatory interneurons mediates the classic pain withdrawal reflexes. Inhibitory interneurons can also exert presynaptic inhibition of nociceptive primary afferents, indirectly regulating the excitability of dorsal horn neurons by decreasing primary afferent input. Projection neurons, on the other hand, are the dorsal horn output neurons. These second-order neurons convey nociceptive information from the dorsal horn of the spinal cord to the thalamus, hypothalamus, and different brainstem structures via five major ascending pain pathways: the spinothalamic, spinohypothalamic, spinoparabrachial, spinoreticular, and spinomesencephalic tracts (Basbaum and Jessell, 2000; Almeida et al., 2004). These ascending pathways in turn project to various cortical and limbic structures such as the somatosensory cortex, cingulate cortex, insular cortex, prefrontal cortex, and amygdala (**Figure 2**). Sensory discriminative information about the localization, quality, and intensity of the noxious stimulus as well as the attentional, emotional, and cognitive components of pain are processed in these cortical and limbic structures (Almeida et al., 2004).

4.05.3.3 Pain Modulation

As discussed in the previous section, nociceptive transmission and synaptic efficacy in both primary afferent endings and dorsal horn neurons can be modulated by local circuits in the spinal cord. But this is not the only modulatory mechanism; the excitability of dorsal horn projection neurons and primary afferent endings can also be modulated by descending pathways from the brain that originate in the periaqueductal gray matter (PAG), project to the rostroventromedial medulla (RVM), and then terminate in the dorsal horn of the spinal cord (**Figure 2**).

Earlier studies focused on descending inhibition of spinal nociceptive processing, but now we know that descending modulatory pathways can be both inhibitory and facilitatory (Fields, 2000). Early in the 1990s, pioneering work by Howard Fields and colleagues identified three types of neurons in the RVM: on-cells, which facilitate nociceptive transmission; off-cells, which have a net inhibitory effect on nociceptive transmission; and neutral cells that show no nociception-related change in activity (Fields et al., 1983, 1991). *In vivo* electrophysiological recordings in the RVM revealed that on-cells discharge just prior to

withdrawal from a noxious stimulus, whereas off-cells pause during withdrawal from a noxious stimulus (Fields et al., 1983). Both types of cells are activated by electrical stimulation of the PAG and they both project directly to laminae I, II, and V of the dorsal horn, where nociceptive-specific neurons are located (Fields et al., 1995; Fields, 2000). Descending modulation of dorsal horn projection neurons and primary afferent endings seems to be mediated via activation or inhibition of excitatory and inhibitory local circuit interneurons in the dorsal horn. Physiologically, activation of descending inhibitory control upon peripheral noxious stimuli seems to provide a negative feedback mechanism that decreases nociceptive transmission at the level of the spinal cord, whereas activation of descending facilitatory pathways has been proposed to contribute to the development and maintenance of hyperalgesia and allodynia (Helmstetter and Tershner, 1994; Fields, 2000; Gebhart, 2004).

4.05.3.4 Pain Perception

The mechanisms of transduction, transmission, and modulation of noxious sensory stimuli described in the previous sections offer an explanation for how noxious sensory stimuli are translated to neurophysiological signals and how these signals are then propagated to and modulated by the CNS. However, these neural processes do not explain how certain stimuli are ultimately perceived as painful. The perception of pain is more than just direct processing of sensory stimuli. Clinical studies have demonstrated that the processes underlying pain perception comprise complex behavioral, psychological, and emotional factors (Turk, 2003; Lewandowski, 2004). Social and environmental factors influence the perception of pain, as do past experience and culture. Consequently, an apparently similar stimulus can generate enormous individual differences in pain perception. Several questions thus arise. How does pain perception occur? What are the neural mechanisms underlying how we perceive pain?

Projections from ascending nociceptive pathways to various cortical and limbic structures such as the cingulate cortex, insular cortex, prefrontal cortex, and amygdala have been described (Almeida et al., 2004) (**Figure 2**). Because of the long-standing role of these cortical and limbic structures in cognitive, emotional, and motivational processes, it has been proposed that their activation upon noxious stimuli is involved in mediating the negative emotional reactions to pain that can result in activity avoidance and escape behaviors (Coleman-Mesches and McGaugh, 1995; Johansen et al., 2001; Gao et al., 2004; Johansen and Fields, 2004; Lei et al., 2004; Tang et al., 2005). Much progress has been made in recent years in identifying brain regions and potential neural mechanisms underlying the cognitive and affective components of pain. This progress has been limited, however, by the methodological and conceptual difficulties associated with studying a subjective process such as pain perception, which becomes even more technically challenging when using animal models. The emergence of novel brain imaging techniques with better image quality and resolution has allowed researchers to perform studies that examine the neuroanatomical basis of different cognitive and emotional components of pain in humans.

4.05.4 Pain Sensitization

Under normal physiological conditions, pain acts as an early warning system to prevent injury. Many acute pain responses are simple reflexes (**Figure 2**). A classic example is the reflexive withdrawal experienced by individuals when they accidentally touch a hot surface. That immediate reflexive withdrawal from the heat source protects the body from burning. This physiological experience encompasses all of the pain components described in the previous section. First, the heat stimulus is translated to a neurophysiological signal in peripheral nerve endings, probably via the activation of one of the TRP ion channels. The nociceptive information is then transmitted to the dorsal horn of the spinal cord, where several processes take place:

1. Interneurons in the dorsal horn activate motor neurons in the ventral horn that mediate the withdrawal reflex.
2. Projection neurons send the nociceptive information to the somatosensory cortex, where information about the location, intensity, and quality of the stimulus is processed.
3. Projection neurons in the dorsal horn convey the nociceptive information to different cortical and limbic structures such as the anterior cingulate cortex, the insular cortex, and the amygdala, where pain awareness and associative learning occur.

The neural processes described in this example occur under normal physiological conditions, in uninjured tissue, when pain acts as a warning system to prevent

injury. When injury does occur, however, pain serves a slightly different but still physiologically adaptive role. After injury, hypersensitivity to both noxious and previously innocuous stimuli develops. Hypersensitivity after injury can be seen as a memory of the injury that engages a heightened protective system developed to prevent further injury, which could interfere with the healing process. A good example of this type of pain is the hypersensitivity experienced when a bone is broken. In this case, normally innocuous movements or stimuli such as light touch become painful. Movements that would otherwise be normal would interfere with the healing process of a broken bone; thus pain, in this case, serves a protective role to support the healing process.

After an injury, the responses of the sensory system to a given stimulus also increase. These increases can be seen at both the peripheral and central levels and are thought to underlie pain hypersensitivity. Heightened neuronal responses of the sensory system are commonly referred to as sensitization. Pain sensitization is characterized by a decreased threshold for action potential firing, increased responsiveness to a given stimulus, and receptive field enlargement. Different types of sensitization have been described in the peripheral and central nervous systems. Sensitization can occur as a consequence of an injury such as in the broken bone example; in this case, sensitization is an adaptive process and should subside as the injury heals. However, there are many instances in which sensitization can be maladaptive, outlasting the initial injury or with an unknown pathology. This pathological sensitization is thought to underlie chronic pain conditions. The properties, characteristics, and potential mechanisms of these various kinds of sensitization will be discussed in the following sections.

4.05.4.1 Peripheral Sensitization

Following tissue injury, multiple inflammatory mediators, such as substance P, prostaglandin E_2, bradykinin, nerve growth factor, tumor necrosis factor, and glutamate, are released by mast cells, macrophages, immune cells, and injured cells at the site of injury (Bhave and Gereau, 2004). Release of these inflammatory mediators initiates a cascade of events that leads to increased responsiveness of nociceptors, a phenomenon called peripheral sensitization (**Figure 3**).

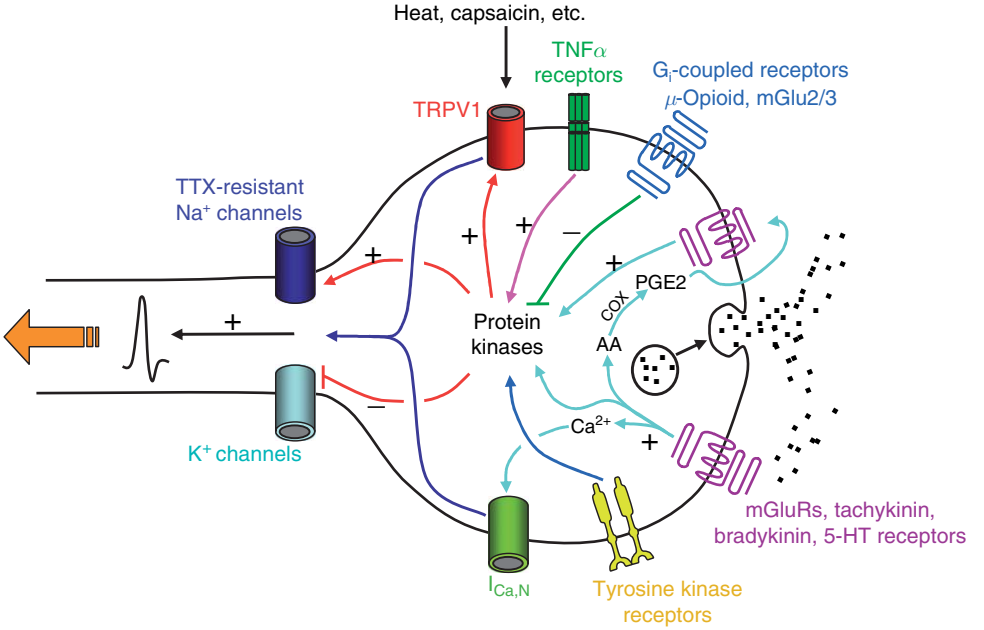

Figure 3 Potential mechanisms underlying peripheral sensitization. Following tissue injury, multiple inflammatory mediators are released at the site of injury and activate several membrane receptors. Subsequent activation of protein kinases and the phosphorylation of ion channels increase the excitability of dorsal root ganglia (DRG) neurons and thus contribute to peripheral sensitization. Sensitization of DRG responses is thought to underlie the reduced threshold that is commonly observed after tissue injury. 5-HT, serotonin; AA, arachidonic acid; Ca^{2+}, calcium; COX, cyclooxygenase; $I_{Ca,N}$, calcium-activated nonselective cation currents; K^+, potassium; mGluR, metabotropic glutamate receptor; PGE2, prostaglandin E2; TNFα, tumor necrosis factor alpha; TRPV1, transient receptor potential V1; TTX, tetrodotoxin.

Peripheral sensitization could result from a change in the cell-surface expression of ion channels that contribute to sensory transduction or action potential generation or from posttranslational modifications of ion channels that modulate the channel properties without necessarily affecting their cell-surface expression. Inflammatory mediators can directly activate ion channel proteins or indirectly activate intracellular pathways via the activation of G-protein-coupled receptors or receptor tyrosine kinases. Activation of intracellular pathways can result in acute modification of ion channels or in the activation of transcription factors, with a resultant increase in transcription and translation of new proteins. Transcriptional, translational, and posttranslational changes can therefore underlie the phenomenon of peripheral sensitization.

4.05.4.1.1 Acute modification of primary sensory neurons

Increased responsiveness of nociceptors to a given stimulus can be observed fairly quickly after tissue injury. Given that transcriptional and translational processes take longer to occur than the development of peripheral sensitization, it has been proposed that the initial stages of peripheral sensitization involve posttranslational modifications of ion channels or transducer molecules and not transcriptional or translational processes. On the other hand, maintenance of peripheral sensitization is thought to involve all three of these processes; that is, gene transcription, protein translation, and posttranslational modifications.

Posttranslational modifications such as phosphorylation can alter the biophysical properties of ion channels that are already inserted in the membrane at the time of injury. Many posttranslational modifications of this type are known to occur and to modulate the excitability of DRG neurons (Bhave and Gereau, 2004). An example of a posttranslational modification that occurs in DRG neurons and that sensitizes the responses of the neuron to a given stimulus is the phosphorylation of the sensory transducer ion channel TRPV1. Phosphorylation of TRPV1 by protein kinase A (PKA), protein kinase C (PKC), and calcium/calmodulin-dependent protein kinase II (CaMKII) results in sensitization of the channel's responses to capsaicin, heat, or pH and also in blockade of desensitization. These alterations in the biophysical properties of the channel could therefore contribute to the reduced threshold for noxious stimuli commonly observed after tissue injury *in vivo*. A caveat of most of the studies that have examined posttranslational modifications in DRG neurons is that the experiments have been conducted in *in vitro* preparations. It is still unknown whether these posttranslational modifications occur after tissue injury and if they contribute to pain hypersensitivity. The development of antibodies specific for modified proteins (i.e., phosphorylated TRPV1) would help answer this type of question.

As in many neurons in the CNS, it is also possible that after injury, posttranslational modifications of ion channels in DRG neurons promote the insertion of ion channels into the membrane. Increased availability of ion channels for activation would increase neuronal depolarizing responses to a given stimulus without necessarily altering the biophysical properties of the individual channels. Although not studied in DRG neurons thus far, trafficking of ion channels is a phenomenon that has received a lot of attention in recent years as one of the major mechanisms used by neurons to control synaptic responses. It is therefore very likely that ion channel trafficking in DRG neurons also underlies a component of peripheral sensitization.

In order for posttranslational modifications to occur, intracellular signaling molecules such as protein kinases need to be activated in DRG neurons in response to tissue injury (**Figure 3**). Activation of receptor tyrosine kinases and G-protein-coupled receptors by inflammatory mediators, such as nerve growth factor (NGF) or glutamate, trigger the activation of intracellular biochemical cascades that are initiated by the production or release of second messengers (Crawford et al., 1997; Bhave and Gereau, 2004). Examples of these second messengers are cyclic adenosine monophosphate (cAMP), diacylglycerol (DAG), inositol 1,4,5-triphosphate (IP_3), calcium (Ca^{2+}), and arachidonic acid (AA). Each of these second messengers either activates protein kinases that directly phosphorylate target proteins such as ion channels or produce other second messengers that can also directly bind to and modulate target proteins. AA is a second messenger system that has been extensively studied in DRG neurons (**Figure 3**). AA is released inside the cell in response to the activation of phospholipase A_2 or phospholipase C, which are enzymes that are activated by G-protein-coupled receptors. AA is oxidized by cyclooxygenases to produce prostaglandins and thromboxanes. Prostaglandins diffuse out of the cell and act on nearby prostanoid receptors. Activation of prostanoid receptors triggers biochemical cascades that mediate peripheral sensitization. The mechanism of action of nonsteroidal

anti-inflammatory drugs commonly used to treat inflammatory pain is to inhibit cyclooxygenase and subsequently reduce prostaglandin synthesis. It has been demonstrated that administration of these anti-inflammatory drugs prior to injury (i.e., before a surgical procedure) is more effective at decreasing inflammatory pain than administration after injury. Administration of these anti-inflammatory drugs prior to injury presumably prevents the development of peripheral sensitization.

4.05.4.1.2 Long-term modifications of primary sensory neurons

In addition to acutely modulating the biophysical properties of ion channels via posttranslational modifications, activation of intracellular signaling cascades after injury can also result in the activation of transcription factors that regulate gene expression and can subsequently result in the synthesis of new proteins such as ion channels, sensory transducers, and/or neuromodulators.

Changes in protein expression after injury can last for days, weeks, or even longer. For this reason, increases in protein expression have been proposed as one of the main mechanisms involved in the maintenance of persistent pain. For example, following persistent inflammation, there is an increase in mRNA levels of the tetrodotoxin (TTX)-resistant sodium channel Nav1.8 in small-diameter DRG neurons (Tanaka et al., 1998). This increase in mRNA levels is accompanied by an increase in the amplitude and density of TTX-resistant sodium currents, suggesting that Nav1.8 protein levels are also increased. Increased sodium currents could in turn increase the excitability of DRG neurons by decreasing the action potential threshold, thus producing the increased response to a fixed stimulus that typifies peripheral sensitization.

Translational changes independent of changes in transcription have also been observed in DRG neurons after inflammation and are thought to contribute to hypersensitivity (Ji et al., 2002b). Increased levels of the sensory transducer TRPV1 are observed at the protein level, but not at the mRNA level, in DRG neurons after persistent inflammation. These inflammation-induced increases in TRPV1 are dependent on NGF-induced activation of p38 mitogen-activated protein kinase (MAPK) and are thought to be mediated via downstream activation of a translational regulator such as eIF4E. In general, transcription and translational processes in DRG neurons after injury are thought to be initiated by the activation of the same receptors and second messenger pathways that mediate posttranslational modifications, but it is thought to require repeated stimulation and/or prolonged action of these second messenger systems.

As discussed in an earlier section of this chapter, nociceptive information is conveyed to the dorsal horn of the spinal cord via Aδ- and C-nociceptive fibers, whereas nonnoxious tactile information is transmitted to the dorsal horn by large-diameter Aβ-sensory fibers. Pain sensitization can be mediated by cellular and molecular changes that occur in peripheral nociceptive fibers that lead to increased responsiveness of nociceptors. Enhanced nociceptor responses in turn lead to increased release of neurotransmitters and neuromodulators from central DRG terminals, subsequently increasing dorsal horn excitability. In addition to these plastic phenomena, a phenotypic switch in Aβ-sensory fibers has also been observed after injury (Neumann et al., 1996). Increased excitability of dorsal horn neurons after injury is thought to be partly mediated by an elevation in the release of substance P by primary nociceptive afferents in the dorsal horn. Under normal conditions, substance P is exclusively expressed in nociceptive afferents; however, part of the phenotypic switch of Aβ-sensory fibers includes that they start synthesizing substance P, which is a peptide not normally expressed by these neurons. Thus, both *de novo* substance P protein synthesis in Aβ-sensory fibers and increases in the translation of this peptide in nociceptive fibers are thought to contribute to the maintenance of pain sensitization by increasing the excitability of dorsal horn neurons. Recruitment of Aβ-sensory fibers is also thought to mediate mechanical allodynia, which is pain to previously innocuous tactile stimulation (Neumann et al., 1996).

4.05.4.2 Sensitization in the Dorsal Horn of the Spinal Cord

Activity-dependent increases in excitability and synaptic transmission occur in the dorsal horn of the spinal cord in response to a short burst of repeated nociceptive input. This spinal sensitization is traditionally referred to as central sensitization to distinguish it from peripheral sensitization. Windup, spinal long-term potentiation (LTP), and classic central sensitization are three different forms of pain-induced sensitization that have been described in the dorsal horn and that are thought to underlie persistent pain. Although these three types of sensitization are considered three different phenomena, their

cellular and molecular mechanisms share many common properties. All these forms of sensitization are blocked or decreased by ablation of neurokinin 1 (NK1) receptor-expressing projection neurons in the dorsal horn, and they all depend on glutamatergic synaptic transmission. Some of these forms of sensitization are restricted to the activated synapse (homosynaptic), whereas others spread to adjacent synapses (heterosynaptic). The properties, characteristics, and potential mechanisms of windup, spinal LTP, and classic central sensitization will be discussed in the following sections.

4.05.4.2.1 Windup: Short-term sensitization of dorsal horn neurons

Normal healthy individuals report higher pain intensity ratings to electrical, mechanical, or thermal stimuli of constant intensity as the frequency of the stimulus delivered increases (Herrero et al., 2000). This change in reported pain is considered a behavioral correlate of windup, which is a progressive and frequency-dependent increase in the excitability of dorsal horn neurons that is evoked by a short train of repeated stimulation of nociceptive afferents. Windup can therefore be considered a cellular memory of nociceptor input and one form of sensitization of dorsal horn neurons. Experimentally, windup can be induced in the dorsal horn by stimulating nociceptive afferents at frequencies between 0.2 and 20 Hz, with the greatest degree of windup generated by 1- to 2-Hz stimulations (Herrero et al., 2000). Stimulations lower than 0.2 Hz fail to induce windup, whereas stimulations higher than 20 Hz induce habituation of the response, or winddown. A characteristic property of windup is that, unlike the other forms of central sensitization, it is only manifested during the course of the stimulus (Ji et al., 2003).

C-fiber stimulation generates slow excitatory synaptic potentials in the dorsal horn. Windup is thought to result from the temporal summation of these slow excitatory synaptic potentials (Herrero et al., 2000; Ji et al., 2003). The current view is that windup is mediated by cumulative depolarization of the neuron induced by the activation of alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors after repeated presynaptic stimulation. AMPA-mediated depolarization triggers the removal of the voltage-dependent Mg^{2+} block of *N*-methyl-D-aspartate (NMDA) receptors, resulting in further increase of temporal summation. In addition, activation of voltage-gated Ca^{2+} channels by neuronal depolarization has been proposed to generate plateau potentials that also contribute to the expression of windup (Herrero et al., 2000; Ji et al., 2003).

As discussed in previous sections, nociceptor stimulation results in presynaptic release of neurotransmitters and peptides in the dorsal horn of the spinal cord. Glutamate is the primary excitatory neurotransmitter that mediates synaptic transmission between peripheral afferents and the dorsal horn, and its release has been shown to be necessary for the development of windup. Presynaptic release of neuropeptides such as substance P and calcitonin gene-related peptide (CGRP) are also crucial for the expression of windup (Herrero et al., 2000). At the postsynaptic level, windup seems to depend on the activation of G-protein-coupled receptors and NMDA receptor activation, the latter being important for both the induction and the maintenance of windup (Herrero et al., 2000; Ji et al., 2003). Windup can be recorded in acute spinal cord slice preparations, demonstrating that spinal intersegmental and supraspinal modulation are not necessary for its development. At the same time, infusion of opioids or serotonin into the spinal cord inhibits the generation of windup, suggesting that inputs from supraspinal structures could potentially modulate windup (Herrero et al., 2000).

Under normal physiological conditions, windup is expressed as a homosynaptic form of sensitization; thus it can be induced by stimulation of C-fibers but not by A-fiber stimulation (Thompson et al., 1994; Ji et al., 2003). After inflammation, several plastic changes modulate the induction of windup (Thompson et al., 1994; Herrero et al., 2000) (**Figure 4**). Thus, stimulation of C-fibers that innervate the inflamed area produces enhanced windup, stimulation of afferent fibers that innervate uninflamed areas adjacent to the inflamed area or of Aβ-fibers that normally fails to induce windup can now induce windup, and a general reduction in the threshold for windup is observed. The physiological significance of windup is a matter of debate. The high-frequency synchronized stimulation used to induce windup does not naturally occur in nociceptor afferents in response to noxious stimulation; therefore, the physiological relevance of windup has been questioned. At the same time, because a windup-like phenomenon has been observed clinically, it is still possible that some form of windup occurs in response to repeated noxious stimulation of constant intensity, contributing to hypersensitivity.

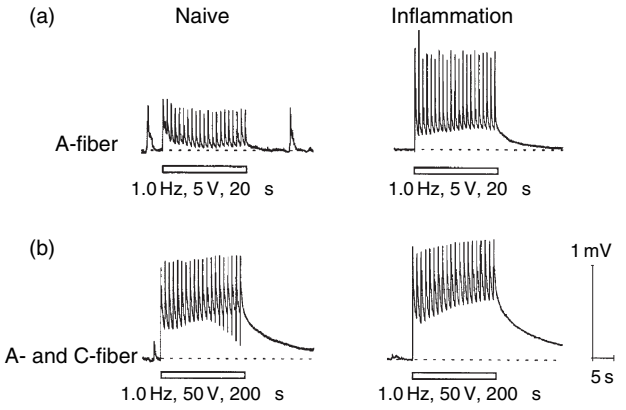

Figure 4 Effects of tissue injury on windup. Summated ventral root potentials (VRP) following low-frequency (1-Hz) repetitive stimulation of A-fibers or both A- and C-fibers recorded in spinal cords from naive or ultraviolet (UV)-injured animals. The horizontal bar indicates the stimulation period. (a) Stimulation of A-fibers (5 V, 20 μs) in naive animals failed to sustain a summated depolarization (left panel). An identical stimulation in spinal cords from UV-injured animals induced a robust and sustained depolarization (right panel) indicating that, after injury, windup can be induced by stimulation of A-fibers that fail to induce windup under normal conditions. (b) Stimulation of both A- and C-fibers (50 V, 200 μs) induced a robust and sustained depolarization in spinal cords from naive animals (left panel). An identical stimulation in spinal cords from UV-injured animals increased the amplitude of the sustained depolarization (right panel) indicating that, after injury, windup is enhanced. Adapted from Thompson SW, Dray A, and Urban L (1994) Injury-induced plasticity of spinal reflex activity: NK1 neurokinin receptor activation and enhanced A- and C-fiber mediated responses in the rat spinal cord in vitro. *J. Neurosci.* 14: 3672–3687.

4.05.4.2.2 Spinal long-term potentiation

Activity-dependent synaptic LTP and long-term depression (LTD) of excitatory postsynaptic potentials (EPSPs) can both be evoked in dorsal horn neurons following brief high-frequency repeated stimulation of presynaptic central DRG afferents (Randic et al., 1993). The development of LTP or LTD seems to depend on the postsynaptic membrane potential, with hyperpolarized potentials (−85 mV) favoring the development of LTD and more depolarized potentials (−70 mV) favoring the development of LTP. Both LTP and LTD are homosynaptic forms of sensitization; thus, potentiation or depression of EPSPs is normally restricted to the activated synapse and not other adjacent synapses. LTP or an LTP-like phenomenon can be induced in animals and in humans and has been strongly correlated with pain behavior. Synchronized high-frequency stimulation of peripheral afferents in intact animals or in acute spinal cord slice preparations can result in long-lasting increases in evoked postsynaptic responses of dorsal horn neurons (Randic et al., 1993; Sandkuhler and Liu, 1998). Similarly, in humans, high-frequency electrical stimulation of cutaneous afferents, using stimulation protocols that resemble the ones used to induce experimental LTP in animals, has been shown to induce long-term increases in reported pain sensitivity (Klein et al., 2004). The cellular and intracellular signaling mechanisms that underlie dorsal horn LTP and those that underlie injury-induced pain hypersensitivity are strikingly similar. For this reason, dorsal horn LTP has been commonly used as a cellular model of afferent-induced hyperalgesia.

LTP induction in the dorsal horn is dependent on a rise in free intracellular calcium in the postsynaptic cell as well as on postsynaptic activation of AMPA, NMDA, metabotropic glutamate receptors (mGluRs), and low-threshold T-type voltage-gated calcium channels. Activation of various intracellular signaling molecules such as PKA, PKC, extracellular signal-regulated protein kinase (ERK), Src tyrosine kinase (Src), and CaMKII in dorsal horn neurons is also necessary for the induction of LTP (Sandkuhler, 2000; Sandkuhler et al., 2000; Woolf and Salter, 2000; Ikeda et al., 2003). The activation of these intracellular molecules leads to posttranslational changes of target proteins such as ion channels, membrane receptors, and/or accessory subunits. Posttranslational modifications modulate the cell-surface expression and function of these proteins, ultimately increasing synaptic efficacy in the dorsal horn. Activation and posttranslational modifications of neuropeptide receptors such as NK1 and tachykinin receptors in the dorsal horn are also necessary for the induction of LTP (Sandkuhler et al., 2000). An interesting feature of dorsal horn LTP is that it can only be induced in a subpopulation of dorsal horn neurons.

LTP is preferentially induced in dorsal horn projection neurons that express the NK1 receptor but not in dorsal horn neurons that do not express this receptor (Ikeda et al., 2003). These findings, together with behavioral studies that show that ablation of NK1-expressing neurons in the dorsal horn attenuates the development of inflammation-induced hypersensitivity (Mantyh et al., 1997), suggest that NK1-expressing projection neurons are an important site of nociceptive plasticity in the dorsal horn.

Despite the cellular and molecular similarities between dorsal horn LTP and injury-induced pain hypersensitivity, the biological significance of dorsal horn LTP has long been questioned. High-frequency synchronized stimulation like the one used to induce experimental LTP does not resemble the low-frequency unsynchronized afferent barrage induced physiologically by natural noxious stimuli. In addition, although LTP has been shown to occur in the dorsal horn *in vivo* in response to natural noxious stimulation, this naturally occurring LTP can be induced in spinalized animals but not in intact animals. A recent study by Ikeda and colleagues put an end to this debate (Ikeda et al., 2006) (**Figure 5**). In their elegant study, Ikeda and colleagues showed that low-frequency stimulation (LFS) of C-fibers, at a frequency that resembles the afferent barrage that occurs during inflammation, induces a robust synaptic LTP of evoked EPSCs in NK1-expressing dorsal horn neurons that project to the periaqueductal grey (PAG). Ikeda et al. further demonstrated that LTP can be induced *in vivo*, in intact animals, by a natural low-frequency afferent barrage that is induced by peripheral inflammation. The mechanisms underlying the induction of LFS-induced LTP in the dorsal horn resemble those of injury-induced hyperalgesia (Ikeda et al., 2006), further supporting the idea that LTP of synaptic strength in the dorsal horn underlies inflammation-induced pain hypersensitivity.

4.05.4.2.3 Classic central sensitization

Following tissue injury and under pathological pain conditions, second-order nociceptive-specific neurons in the dorsal horn of the spinal cord show a decreased threshold for action potential firing, increased responsiveness to a given stimulus, and receptive field enlargement (Woolf, 1983; Woolf and Wall, 1986; Cook et al., 1987; Ji et al., 2003) (**Figure 1**). These electrophysiological changes are collectively referred to as central sensitization and, as peripheral sensitization, are thought to underlie the development of chronic pain. Unlike windup and dorsal horn LTP, central sensitization is considered a heterosynaptic form of sensitization, as these electrophysiological changes occur in both the activated synapse and also in adjacent synapses. Sensitization and recruitment of synapses adjacent to the activated synapses are thought to contribute to the receptive field enlargement that is characteristic of central sensitization and are thought to underlie the pain hypersensitivity that is experienced in noninjured areas following an associated tissue injury (secondary allodynia).

The molecular mechanisms underlying central sensitization and dorsal horn LTP are very similar. As is the case for dorsal horn LTP, central sensitization selectively occurs in NK1-expressing neurons in the dorsal horn and depends on the activation of AMPA, NMDA, and mGluRs. Multiple intracellular signaling pathways, such as ERK, PKA, PKC, CaMKII, and Src, are activated in dorsal horn neurons downstream of the activation of these receptors (Ji et al., 2003). Activation of an intracellular signaling pathway can exert both short-term and long-term neuronal modifications. Acute posttranslational modifications of ion channels are known to occur fairly quickly after the activation of intracellular molecules and are thought to mediate the early component of central sensitization, whereas sustained activation of intracellular molecules commonly results in their translocation to the nucleus, where they can activate different transcription factors. Transcription and translation of new proteins, in combination with sustained posttranslational modifications of ion channels, are thought to contribute to the maintenance of central sensitization.

The ERK signaling cascade is a good example of an intracellular signaling pathway that exerts both short-term and long-term neuronal modifications that contribute to central sensitization (**Figure 6**). ERK is activated in dorsal horn neurons shortly after tissue injury, downstream of the activation of a diversity of membrane receptors (Ji et al., 1999; Karim et al., 2001; Pezet et al., 2002; Adwanikar et al., 2004; Kawasaki et al., 2004; Slack et al., 2004; Kawasaki et al., 2006; Svensson et al., 2006). ERK directly phosphorylates the potassium channel Kv4.2, decreasing Kv4.2-mediated potassium currents, thereby increasing neuronal excitability (Hu and Gereau, 2003; Hu et al., 2003, 2006). ERK also regulates phosphorylation and the activity of the NR1 NMDA receptor subunit (Slack et al., 2004). In addition to these acute modifications of ion channels, ERK can also translocate to the nucleus, where it phosphorylates and activates the cAMP response element binding protein (CREB), which in turn promotes the transcription of immediate early genes such as c-fos

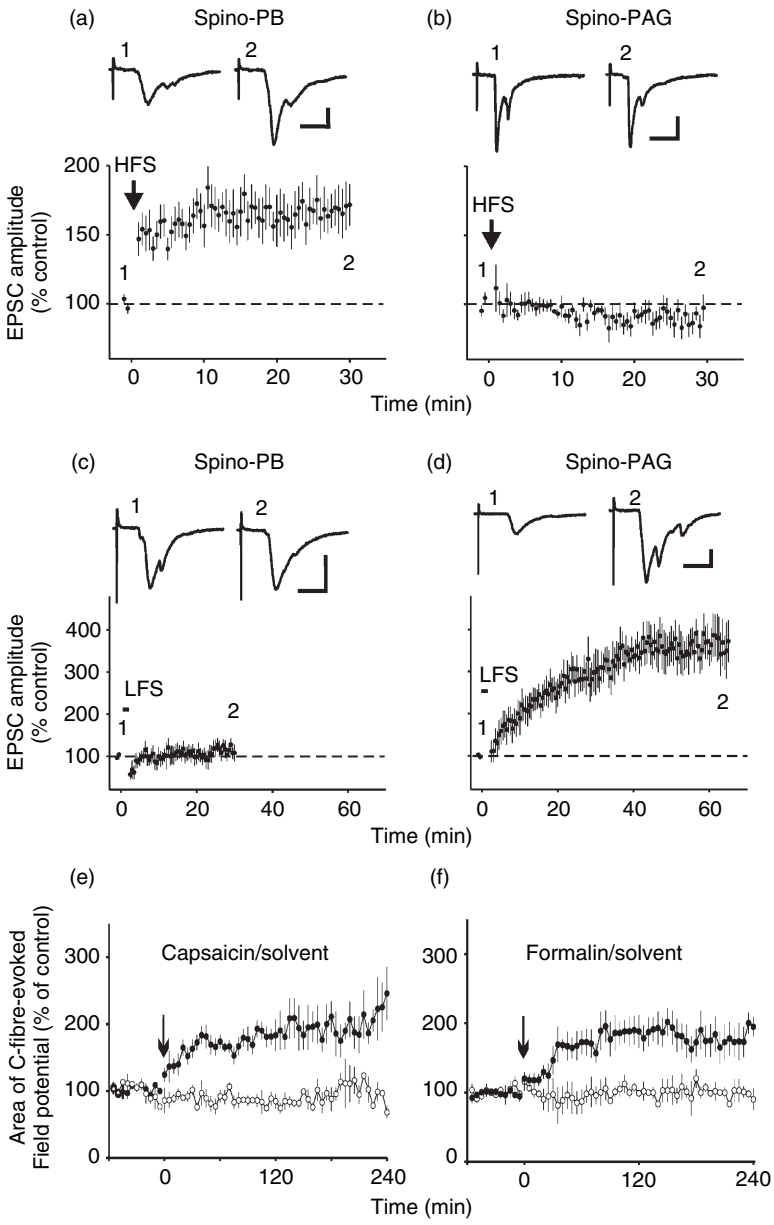

Figure 5 Spinal LTP can be induced by low-frequency afferent barrage evoked by electrical stimulation in vitro or inflammation of peripheral tissue in vivo. (a, b) High-frequency stimulation (HFS) of C-fibers selectively induced LTP in parabrachial (PB)-projecting but not in periaqueductal gray (PAG)-projecting lamina I neurons. (c, d) Low-frequency stimulation of C-fibers selectively induced LTP in PAG-projecting but not in PB-projecting lamina I neurons. Insets: Representative C-fiber-evoked excitatory postsynaptic currents (EPSCs) before and after C-fiber high frequency (a, b) or low-frequency (c, d) stimulation. Calibration bars: 20 ms/200 pA. (e, f) Inflammation induces LTP in the dorsal horn of the spinal cord *in vivo*. Extracellular recordings in the superficial dorsal horn following electrical stimulation of the sciatic nerve in vivo in anesthetized animals. Intraplantar injection (indicated by the arrow) of capsaicin (e) or formalin (f) induced spinal LTP *in vivo* (solid circles). Intraplantar injection of vehicle (open circles) failed to induce spinal LTP. Adapted from Ikeda H, Stark J, Fischer H, et al. (2006) Synaptic amplifier of inflammatory pain in the spinal dorsal horn. *Science* 312: 1659–1662.

and of other late-expressing genes such as prodynorphin and NK1 (Ji et al., 2002a; Kominato et al., 2003; Kawasaki et al., 2004; Song et al., 2005). Blockade of ERK activation in the dorsal horn decreases injury-induced hypersensitivity, NR1 phosphorylation, mGluR5-mediated increases in excitability, and CREB-mediated transcriptional regulation of c-fos, NK1, and prodynorphin.

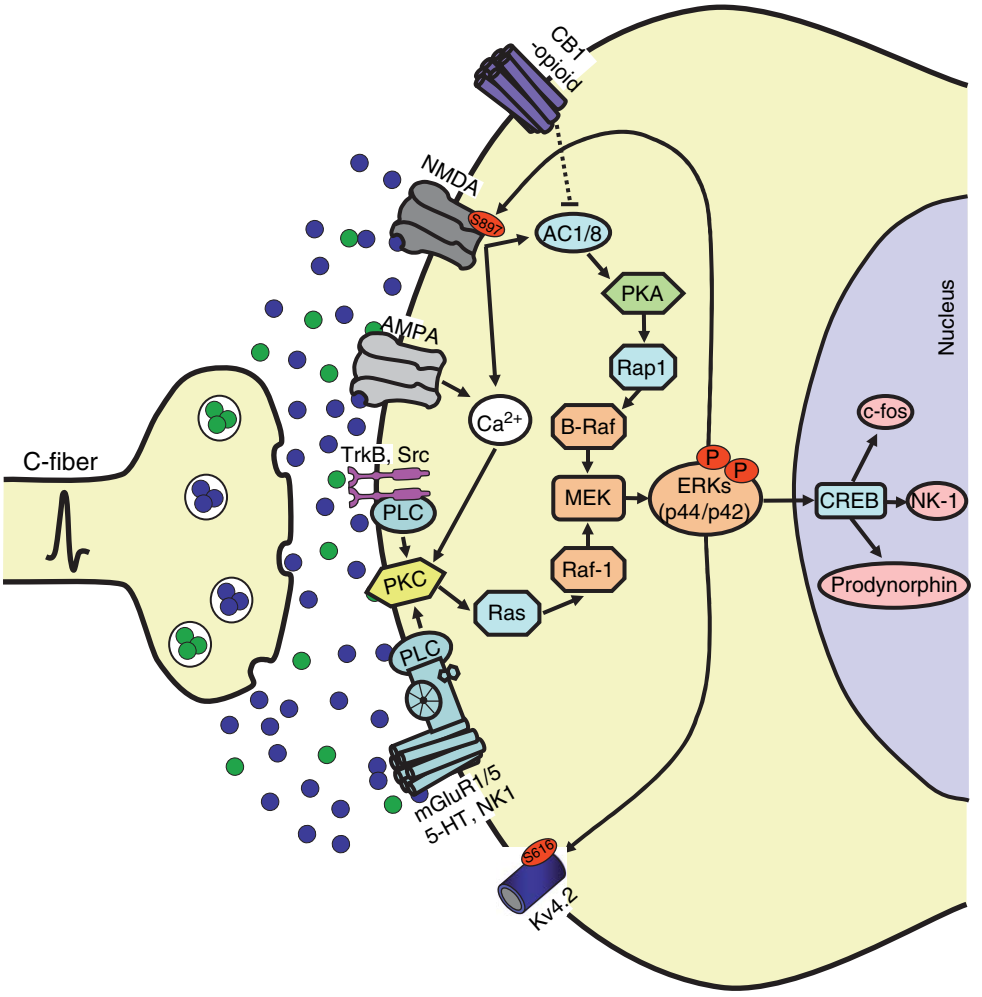

Figure 6 The extracellular signal-regulated protein kinase (ERK) signaling cascade in the dorsal horn contributes to central sensitization. Numerous cell-surface signals can activate the ERK signaling cascade in dorsal horn neurons in response to tissue injury. ERK directly phosphorylates the potassium channel Kv4.2 at Serine-616 (S616) and regulates phosphorylation of the NMDA receptor subunit NR1 at Serine-897 (S897). ERK can also translocate to the nucleus and activate CREB-dependent transcription of c-fos, NK1, and prodynorphin. 5-HT, 5-hydroxytryptamine (serotonin receptor); AC1/8, adenylyl cyclases 1 and 8; AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid receptor; B-Raf, B-Raf kinase; Ca^{2+}, calcium; CB1, cannabinoid receptor 1; CREB, cAMP-response element binding protein; MEK, mitogen-activated protein kinase/ERK; mGluR1/5, metabotropic glutamate receptors 1 and 5; NK1, neurokinin 1 receptor; NMDA, *N*-methyl-D-aspartate receptor; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; Raf1, Raf-1 kinase; Rap1, repressor activated protein 1; Ras, Ras GTPase; Src, Src tyrosine kinase; TrkB, tyrosine kinase receptor B.

In addition to the increased excitatory transmission observed in the dorsal horn during central sensitization, a decrease in inhibitory tone also contributes to the development and maintenance of central sensitization. Decreased synaptic efficacy in local inhibitory circuits seems to result from decreased gamma-aminobutyric acid (GABA) release, decreased receptor expression and function, and, although a controversial hypothesis, by a loss of inhibitory interneurons. Decreases in depolarization-induced GABA release are observed in the dorsal horn in a nerve injury model (Lever et al., 2003). Reduction in primary afferent-evoked inhibitory transmission and a decrease in the expression of GABA receptors and the GABA-synthesizing enzyme glutamic acid decarboxylase (GAD) are also observed after tissue or nerve injury (Castro-Lopes et al., 1995; Moore et al., 2002). In addition, intrathecal administration of GABA receptor antagonists has been shown to mimic central sensitization, further supporting

the hypothesis that decreased GABAergic tone contributes to the development of central sensitization (Sivilotti and Woolf, 1994). The dramatic loss of GABA and GAD immunostaining that is observed in the dorsal horn after nerve injury has led to the hypothesis that excitotoxic death of GABAergic neurons might contribute to decreased inhibitory tone after tissue injury. This is a controversial hypothesis, however, because stereological analysis of neuronal packing density and staining with apoptotic markers have failed to demonstrate a significant loss of neurons after tissue or nerve injury (Polgar et al., 2003, 2004, 2005). At the same time, the lack of changes in stereological studies is also debatable (Scholz et al., 2005). Despite this debate, it is well accepted that a decrease in GABAergic tone contributes to central sensitization; therefore, increasing GABAergic transmission in the dorsal horn could offer an alternative to alleviate pain. Preclinical studies in rodents have indeed demonstrated that transplanting neuronal cells bioengineered to synthesize GABA into the lumbar subarachnoid space decreases hypersensitivity in animal models of chronic neuropathic pain (Eaton et al., 2007).

4.05.4.3 Sensitization in Supraspinal Structures

Plastic changes in neuronal responses to noxious stimuli after tissue injury have also been observed and studied in supraspinal structures. Descending modulatory pathways are activated after tissue injury and can inhibit or facilitate the excitability of dorsal horn neurons. Descending inhibition or facilitation of pain transmission seems to depend on the nature of the stimulus, the environment in which the stimulus is applied, and the behavioral state of the animal. Supraspinal structures thus provide yet another level of modulation of pain processing. Pain-induced sensitization of the rostroventral medulla (RVM), the anterior cingulate cortex (ACC), and the amygdala has been described. The mechanisms of sensitization in these three supraspinal structures will be discussed in this section.

4.05.4.3.1 Rostroventral medulla

The RVM is a major source of descending modulation to the spinal dorsal horn. Realization that stimulation of the RVM could produce hyperalgesia led to the hypothesis that descending facilitation of nociceptive transmission could underlie injury-induced hypersensitivity (Zhuo and Gebhart, 1990). Many studies have followed up this observation and there is now substantial evidence that supports that sensitization of the RVM indeed contributes to the maintenance of injury-induced hypersensitivity (Porreca et al., 2002). Three types of neurons have been identified in the RVM. On-cells discharge just prior to withdrawal from a noxious stimulus, off-cells pause during withdrawal from a noxious stimulus, and neutral-cells show no nociception-related change in activity (Fields et al., 1983). Activation of on-cells has been proposed to facilitate nociceptive transmission in the dorsal horn. Consistent with this hypothesis, inflammation-induced persistent nociceptive input that is associated with hypersensitivity has been shown to increase the activity of on-cells in the RVM in an NMDA-dependent manner (Xu et al., 2007). Furthermore, chemical inactivation of the RVM or infusion of NMDA receptor antagonist into the RVM reduces injury-induced hypersensitivity (Urban et al., 1999; Wei and Pertovaara, 1999; Porreca et al., 2002). Interestingly, after inflammation, neutral-cells in the RVM that were initially unresponsive to noxious stimuli undergo a phenotypic switch, exhibiting response profiles that are characteristic of either on- or off-cells (Miki et al., 2002). Recruitment of neutral-cells might therefore contribute to RVM sensitization after inflammation. RVM sensitization has also been linked to the hypersensitivity that is commonly observed following opioid withdrawal. Opioid withdrawal-induced hypersensitivity is correlated with increased activity of on-cells in the RVM, and chemical inactivation of the RVM decreases opioid withdrawal-induced hypersensitivity (Bederson et al., 1990; Kaplan and Fields, 1991). Release of various neurotransmitters and neuropeptides such as glutamate, neurotensin, and cholecystokinin in the RVM have been shown to contribute to pain-induced RVM sensitization (Urban et al., 1996).

RVM modulation of injury-induced hypersensitivity seems to result, at least in part, from the activation of a spino-bulbo-spinal positive feedback loop (Suzuki et al., 2002). Following tissue injury, NK1-expressing projection neurons in the dorsal horn activate serotonergic neurons in the RVM, which in turn, via the activation of serotonergic descending facilitatory pathways, increase the excitability of dorsal horn neurons. Ablation of NK1-expressing dorsal horn neurons, which decreases injury-induced hypersensitivity, also decreases injury-induced activation of serotonergic RVM neurons. Furthermore, blockade of serotonin receptors in the dorsal horn reduces injury-induced

hypersensitivity, reproducing the effects of ablation of NK1-expressing dorsal horn neurons. *In vitro*, in an acute spinal cord slice preparation, serotonin application transforms silent synapses in the dorsal horn into functional ones, thus providing another potential mechanism for the RVM-mediated facilitation of nociceptive transmission in the dorsal horn (Li and Zhuo, 1998). In summary, activation of the spino-bulbo-spinal circuit in response to sustained nociceptive input generates a positive feedback loop that seems to perpetuate central sensitization, contributing in this way to the maintenance of injury-induced hypersensitivity.

4.05.4.3.2 Anterior cingulate cortex

Imaging studies in humans have repeatedly demonstrated increased neural activity in the ACC of healthy individuals as well as of chronic pain patients in response to noxious stimulation (Apkarian et al., 2005). Noxious stimulus-induced neuronal activity in the ACC positively correlates with the reported unpleasantness of the noxious stimuli (Rainville et al., 1997). For this reason, the ACC has been proposed to be a neural center that mediates the negative emotional component of pain. Consistent with this hypothesis, frontal lobotomies or cingulotomies in chronic pain patients have been shown to decrease the reported unpleasantness of pain without affecting nociception, or the sensory component of pain (Romanelli et al., 2004). Similarly, electrolytic lesions of the ACC have been shown to decrease injury-induced hypersensitivity in animal models of inflammatory and neuropathic pain (Donahue et al., 2001).

Zhuo and colleagues have extensively studied the cellular and molecular mechanisms that underlie ACC modulation of pain. They have shown that under normal physiological conditions, ACC neurons respond to peripheral noxious stimuli and can exhibit both LTP and LTD of synaptic transmission (Zhuo, 2005). Under chronic pain conditions, or after amputation of a digit, ACC neurons exhibit increased excitability, a long-lasting potentiation of noxious stimulus-induced synaptic responses, and lose the capability to undergo synaptic LTD (Wei et al., 1999; Wei and Zhuo, 2001; Gao et al., 2006) (**Figure 7**). Potentiation of synaptic responses to noxious stimuli and loss of LTD have therefore been proposed to mediate ACC modulation of nociception. Both ACC modulation of nociception and LTP are dependent on the activation of adenylyl cyclases 1 and 8 (AC1 and AC8) and on the expression levels of the NMDA receptor subunit NR2B (Wei et al., 2001, 2002; Wu et al., 2005). Thus, genetic elimination of AC1 and AC8 decreases injury-induced hypersensitivity and local activation of adenylyl cyclases in the ACC of these animals rescues the injury-induced hypersensitivity phenotype (Wei et al., 2002). On the other hand, genetic overexpression of NR2B in forebrain regions, including the ACC, increases inflammation-induced nociceptive behavior. Moreover, NR2B expression has been shown to be upregulated in the ACC after injury, and pharmacological blockade of these receptors in the ACC decreases injury-induced hypersensitivity. After tissue injury, activation of NMDA, AC1, and AC8 in the ACC results in long-lasting activation of the transcription factor CREB and in a subsequent increase in the transcription of immediate early genes such as c-fos (Wei et al., 2001, 2002). Transcriptional changes in the ACC are therefore thought to mediate pain-induced long-lasting sensitization of the ACC.

As mentioned, the ACC has been proposed to mediate an emotional component of pain. Multiple studies in animals support this hypothesis. ACC neurons have been shown to be activated during pain avoidance behaviors (Koyama et al., 2001). In addition, lesions of the ACC decrease both inflammation-induced conditioned place avoidance and noxious stimulus-induced escape-avoidance behavior after nerve injury (Johansen et al., 2001; Gao et al., 2004; LaGraize et al., 2004) (**Figure 8**). Furthermore, glutamatergic activation of the ACC during conditioning produces avoidance learning in the absence of peripheral noxious stimulation, suggesting that activation of the ACC is sufficient to induce pain unpleasantness (Johansen and Fields, 2004) (**Figure 8**). In support of this hypothesis, human neuroimaging studies have shown a reduction in ACC activity when the unpleasantness of pain is removed from the pain experience by performing hypnotic suggestions that affect pain unpleasantness without altering the perceived intensity of pain (Rainville et al., 1997).

4.05.4.3.3 Amygdala

The amygdala is part of the spino-ponto-amygdaloid pathway, a major ascending pronociceptive pathway that originates in lamina I of the spinal cord and medullary dorsal horn and relays in the parabrachial (PB) area to terminate in the central nucleus of the amygdala (CeA) (Bernard et al., 1989; Bernard and Besson, 1990; Jasmin et al., 1997). The amygdala also

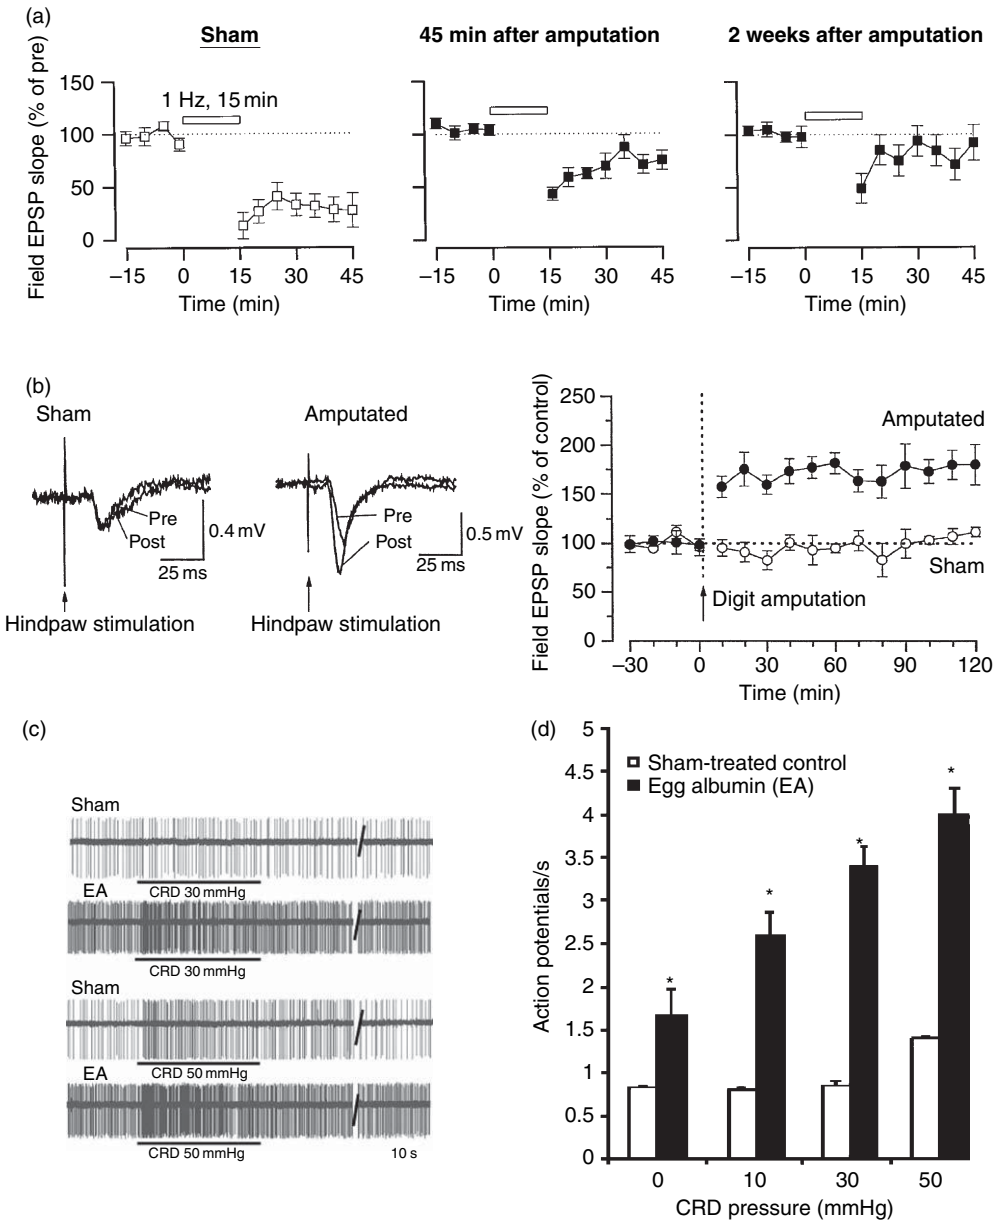

Figure 7 Injury induces loss of long-term depression (LTD), potentiation of synaptic transmission, and increased excitability in the anterior cingulate cortex (ACC). (a) Long-term potentiation (LTP) was recorded in ACC slices from sham animals or animals that had a single hindpaw digit amputated. Low-frequency stimulation, indicated by the horizontal bar, induced a robust LTD in the ACC of sham animals (left panel). An identical stimulation failed to induce LTD in the ACC of amputated animals 45 min (middle panel) and 2 weeks (right panel) after the amputation. (b) Amputation of a single hindpaw digit potentiates synaptic transmission in the ACC. Left panel shows representative traces of hindpaw-stimulation-evoked EPSPs in the ACC before (Pre) and after (Post) sham treatment or amputation. Right panel shows the time-course of hindpaw-stimulation-evoked EPSPs in the ACC. Amputation, but not sham treatment, induced a long-lasting potentiation of ACC responses to hindpaw stimulation. (c) Increased excitability in the ACC of viscerally hypersensitive rats. Representative single-unit recordings in the ACC in response to colorectal distention (CRD) in sham-treated and viscerally hypersensitive (EA) animals. Viscerally hypersensitive animals show increased background activity and CRD-evoked responses in the ACC when compared to sham-treated animals. (d) Frequency of firing in the ACC in response to CRD increases in a stimulus-intensity-dependent manner in viscerally hypersensitive animals (EA) when compared to sham-treated animals. Adapted from (a) Wei F, Li P, and Zhuo M (1999) Loss of synaptic depression in mammalian anterior cingulate cortex after amputation. *J. Neurosci.* 19: 9346–9354; (b) Wei F and Zhuo M (2001) Potentiation of sensory responses in the anterior cingulate cortex following digit amputation in the anaesthetised rat. *J. Physiol.* 532: 823–833; and (c, d) Gao J, Wu X, Owyang C, and Li Y (2006) Enhanced responses of the anterior cingulate cortex neurones to colonic distension in viscerally hypersensitive rats. *J. Physiol.* 570: 169–183.

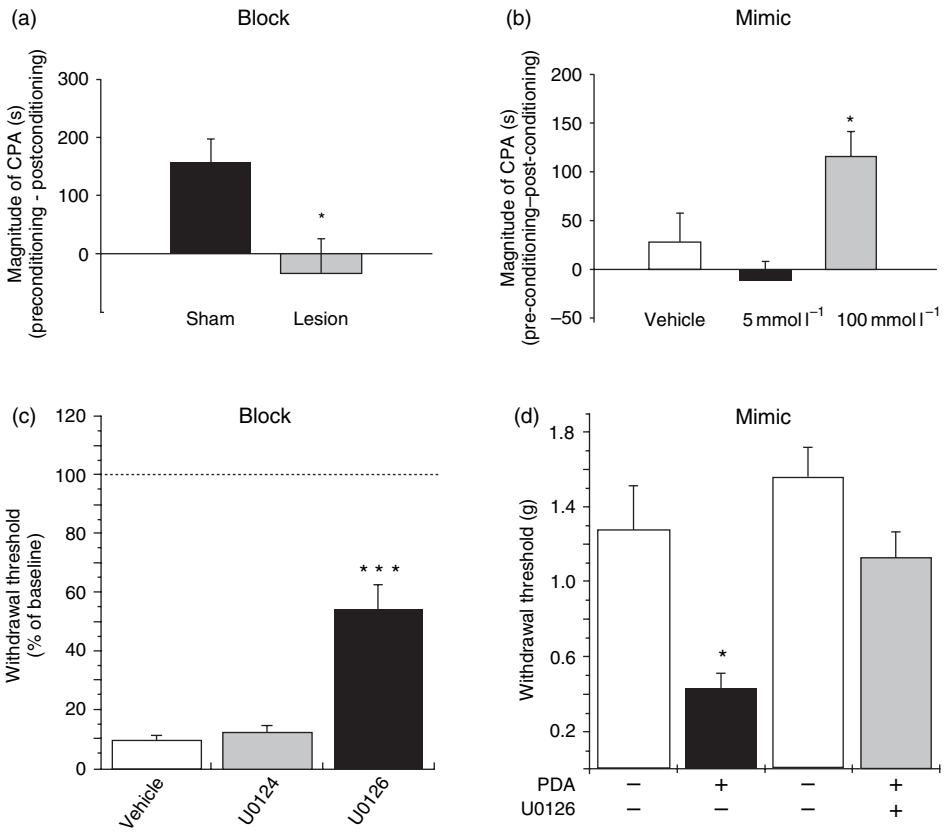

Figure 8 The anterior cingulate cortex (ACC) and the amygdala are important sites of modulation of inflammation-induced behavioral sensitization. (a) Inflammation-induced conditioned place avoidance (CPA) is blocked by lesions of the ACC. Animals with sham treatment show a higher magnitude of CPA scores than animals with ACC lesions. (b) Glutamatergic stimulation of the ACC mimics inflammation-induced conditioned place avoidance in the absence of inflammation. Animals were intra-ACC infused with vehicle, 5 mmol l^{-1} or 100 mmol l^{-1} of the glutamate agonist homocysteic acid (HCA). Infusion of HCA into the ACC induced a robust CPA in a dose-dependent manner. (c) Pharmacological blockade of ERK activation in the amygdala decreases inflammation-induced mechanical hypersensitivity. Animals were injected with 5% formalin into the hindpaw to induce inflammation. The MEK inhibitor U0126, the structural analog control compound U0124, or vehicle was infused into the amygdala and the effects of these treatments on mechanical thresholds were analyzed. Infusion of U0126 into the amygdala decreased inflammation-induced hypersensitivity when compared to vehicle- or U0124-treated animals. (d) Pharmacological activation of ERK in the amygdala mimics inflammation-induced mechanical hypersensitivity in the absence of inflammation. Mice received an intra-amygdala infusion of the phorbol ester PDA (120 pmol), which results in robust ERK activation, or a co-infusion of PDA (120 pmol) plus U0126 (1.5 nmol), and mechanical withdrawal thresholds were measured. Infusion of PDA into the amygdala decreased paw-withdrawal thresholds in response to mechanical stimulation when compared to baseline thresholds. PDA effects were blocked by co-infusion with U0126. Adapted from (a) Johansen JP, Fields HL, and Manning BH (2001) The affective component of pain in rodents: Direct evidence for a contribution of the anterior cingulate cortex. *Proc. Natl. Acad. Sci. USA* 98: 8077–8082; (b) Johansen JP and Fields HL (2004) Glutamatergic activation of anterior cingulate cortex produces an aversive teaching signal. *Nat. Neurosci.* 7: 398–403; and (c, d) Carrasquillo Y and Gereau RW IV (2007) Activation of the extracellular signal-regulated kinase in the amygdala modulates pain perception. *J. Neurosci.* 27: 1543–1551.

receives a direct projection from the spinal cord, with most of this tract originating in lamina V of the dorsal horn where nociceptive-specific neurons are located (Burstein and Potrebic, 1993). In addition to being part of ascending pain pathways, the amygdala has also been proposed to be part of a descending modulatory pain pathway (Hopkins and Holstege, 1978; Helmstetter et al., 1998; McGaraughty and Heinricher, 2002; Shane et al., 2003). Projections from the amygdala to the PAG have been identified using anatomical retrograde tracers (Hopkins and Holstege, 1978); these projections are thought to feed into the PAG-RVM-dorsal horn descending modulatory pain pathway (**Figure 2**).

In vivo electrophysiological recordings have mapped amygdala neurons that respond to peripheral

noxious stimuli (Bernard et al., 1992; Neugebauer and Li, 2002, 2003) (**Figure 9**). The majority of these neurons are located in the CeA, which is the target of the spino-ponto-amygdaloid ascending pain pathway (Bernard et al., 1989; Bernard and Besson, 1990; Jasmin et al., 1997). Under normal physiological conditions, CeA neurons have been shown to be preferentially excited or inhibited by cutaneous noxious stimuli or by noxious stimulation of deep tissue in a stimulus intensity-dependent manner, with receptive fields that included most areas of the body (four limbs, tail, trunk, face, cornea, tongue, and intraoral region). Moreover, in chronic pain conditions, CeA neurons have been shown to undergo neuroplastic changes, suggesting that plasticity in the amygdala might underlie pain hypersensitivity (Neugebauer and Li, 2003) (**Figure 9**). For example, induction of arthritis has been shown to result in increased responsiveness of CeA neurons to nociceptive afferent input, reduction of response threshold, and receptive field enlargement (Neugebauer and Li, 2003) (**Figure 9**). This arthritis-induced amygdala sensitization is dependent on the activation of mGluR1, both NMDA and non-NMDA ionotropic glutamate receptors, and the CGRP1 receptor (Li and Neugebauer, 2004a, 2004b; Han et al., 2005b).

Sensitization of amygdala neurons is preserved in slices obtained from arthritic animals (**Figure 9**). This has allowed for further examination of the mechanisms of amygdala sensitization at a cellular level. Whole-cell voltage-clamp recordings of CeA neurons from brain slices revealed enhanced synaptic transmission and increased excitability in CeA neurons after the induction of arthritis, visceral pain, or neuropathic pain (Neugebauer et al., 2003; Han et al., 2004, 2005b; Ikeda et al., 2007). Interestingly, in the neuropathic pain model, the degree of amygdala potentiation positively correlates with the degree of behavioral hypersensitivity (Ikeda et al., 2007). Consistent with the *in vivo* recording, the changes in synaptic transmission in slices from arthritic and visceral pain animals are dependent on the activation of mGluR1, NMDA receptors, and the CGRP1 receptor. Surprisingly, amygdala potentiation after visceral pain is not dependent on NMDA receptor activation, suggesting that different types of pain activate different molecular pathways in the amygdala. Persistent pain-induced amygdala sensitization correlates with upregulation of mGluR1 protein expression levels and with increased phosphorylation of the NR1 subunit of the NMDA receptor in the amygdala (Neugebauer et al., 2003; Bird et al., 2005). Finally, enhancement of group III mGluR-mediated inhibition of CeA synaptic transmission (Han et al., 2004) and increases in PKA-mediated NMDA receptor function (Bird et al., 2005) have also been observed after the induction of arthritis.

Despite all the progress made in characterizing the responses of amygdala neurons to noxious stimuli under conditions of persistent pain, very little is known about the contribution of the amygdala to the behavioral expression of injury-induced persistent hypersensitivity. Numerous studies have repeatedly demonstrated that lesions or chemical inactivation of the amygdala do not affect baseline nociception. Surprisingly, at present, the effect of lesions or chemical inactivation of the amygdala on injury-induced persistent hypersensitivity has not been evaluated. However, ERK activation is observed in noxious-responsive amygdala neurons during inflammation, and pharmacological blockade of ERK activation in the amygdala reduces inflammation-induced hypersensitivity (Carrasquillo and Gereau, 2007) (**Figures 8 and 9**). In addition, blockade of mGluR1 or the CGRP1 receptor in the amygdala has been shown to reduce arthritis-induced hypersensitivity, demonstrating that neuroplastic changes in the amygdala indeed contribute to behavioral hypersensitivity (Han et al., 2005b; Han and Neugebauer, 2005). Moreover, pharmacological activation of ERK in the amygdala has been shown to induce behavioral hypersensitivity that mimics inflammation-induced hypersensitivity but occurs in the absence of peripheral tissue injury, suggesting that ERK activation in the amygdala is sufficient to induce pain hypersensitivity (Carrasquillo and Gereau, 2007).

Similar to the ACC, the amygdala has also been proposed to mediate an emotional component of pain. Consistent with this, lesions of the amygdala significantly reduce conditioned place avoidance induced by paw inflammation, electric foot shock, or visceral pain in rats (Tanimoto et al., 2003; Gao et al., 2004). In addition, blockade of mGluR1, mGluR5, or the CGRP1 receptor in the amygdala decreases vocalization after noxious stimulation of an arthritic knee, a behavioral response that has been proposed to represent an affective component of pain (Han et al., 2005a, 2005b; Han and Neugebauer, 2005).

4.05.5 Cognitive Component of Pain

Many psychobehavioral studies have demonstrated that pain-related neural activity, and concurrently,

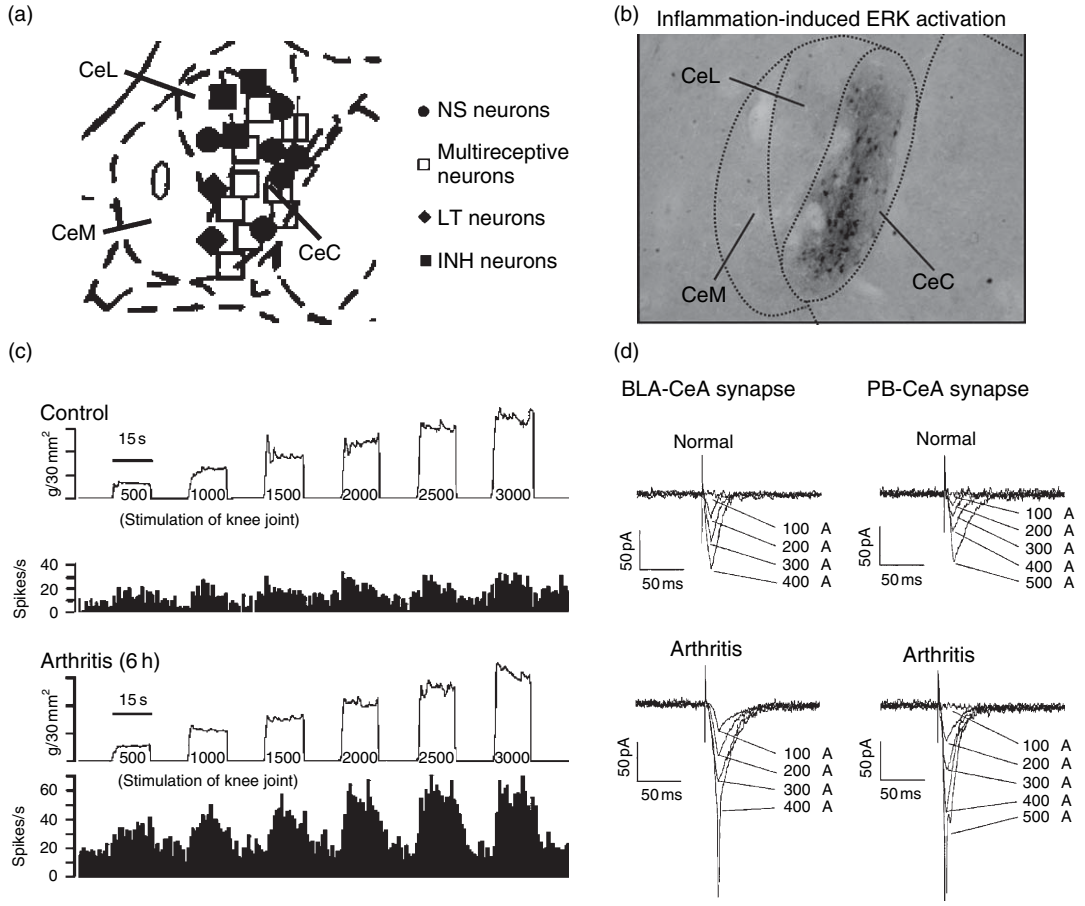

Figure 9 Neuroplastic changes in the amygdala occur after tissue injury. (a, b) Diagrams depicting the subdivisions of the central nucleus of the amygdala (CeA) in a rodent coronal brain section. CeM, medial subdivision; CeL, lateral subdivision; CeC, lateral capsular subdivision. (a) Amygdala neurons with knee-joint input are localized to the lateral capsular subdivision of the CeA. NS, nociceptive specific; LT, low threshold; INH, inhibited. (b) Immunohistochemistry for phospho-ERK in the amygdala after formalin-induced inflammation of one hindpaw. Inflammation-induced ERK activation is localized to the lateral capsular subdivision of the CeA. (c) Responses of amygdala neurons to deep tissue stimulation increase after the induction of arthritis. Representative single-unit recordings in the amygdala in response to graded stimulation of the knee joint in control animals and after the induction of arthritis. Arthritic animals show increased background activity and deep tissue stimulation-evoked responses in the amygdala when compared to control animals. (d) Synaptic transmission in the amygdala is enhanced after the induction of arthritis. Lower thresholds for evoked EPSCs and orthodromic spike generation were observed in slices from arthritic animals after stimulation of either the basolateral amygdala-central amygdala (BLA-CeA) or the parabrachial area-central amygdala (PB-CeA) when compared to slices from control animals. Adapted from (a) Neugebauer V and Li W (2002) Processing of nociceptive mechanical and thermal information in central amygdala neurons with knee-joint input. *J. Neurophysiol.* 87: 103–112; (b) Carrasquillo Y and Gereau RW IV (2007) Activation of the extracellular signal-regulated kinase in the amygdala modulates pain perception. *J. Neurosci.* 27: 1543–1551; (c) Neugebauer V and Li W (2003) Differential sensitization of amygdala neurons to afferent inputs in a model of arthritic pain. *J. Neurophysiol.* 89: 716–727; and (d) Neugebauer V, Li W, Bird GC, Bhave G, and Gereau RW IV (2003) Synaptic plasticity in the amygdala in a model of arthritic pain: Differential roles of metabotropic glutamate receptors 1 and 5. *J. Neurosci.* 23: 52–63.

the sensation of pain, can be strongly modulated by emotions and cognitive awareness (Turk, 2003; Lewandowski, 2004). For many years, anecdotal evidence has supported the idea that attention and distraction can influence pain perception. Distraction has thus been commonly used by parents and pediatricians to perform procedures that produce minor discomfort and pain in children such as injections, cleaning of wounds, and tooth extraction. Scientific studies in both humans and nonhuman primates also support the hypothesis that attention and distraction influence pain perception (Villemure

and Bushnell, 2002). These studies show that increased attention to a painful stimulus increases both pain intensity ratings and neuronal activity in certain brain regions such as the ACC, thalamus, and the prefrontal cortex and that, conversely, distraction or diverted attention from the pain stimulus decreases pain intensity ratings, reported unpleasantness of pain, and neuronal activity (Villemure and Bushnell, 2002). Although much progress has been made in elucidating the neural mechanisms of modulation of pain perception by attention and distraction, the results of these studies are hard to interpret because of the difficulty in controlling and measuring the degree of attention between subjects and because other factors such as vigilance, mood, and anxiety can also contribute to the reported pain and the unpleasantness ratings.

Anticipation or expectation can also strongly influence the perception of pain (Bushnell et al., 2004; Vase et al., 2004). This works in both directions; thus, anticipation or expectation of a painful stimulus increases the intensity of perceived pain, and expectation of pain relief decreases the intensity of perceived pain. The latter is classically exemplified by the phenomenon of placebo analgesia. Placebo analgesia is accompanied by decreases in neuronal activity of pain-related brain regions such as the ACC, insular cortex, and thalamus (Vase et al., 2004). Conversely, anticipation and expectation of a painful stimulus activates brain regions associated with pain processing such as the ACC, prefrontal cortex, insular cortex, and PAG (Bushnell et al., 2004). Interestingly, ACC activity in response to painful stimulation is very similar to the activation induced by anticipation of a painful stimulus even when the anticipation is not followed by painful stimulation. These results suggest that cognitive processes such as expectation can strongly influence the brain's responses to certain stimuli and ultimately affect the perception of pain. The power of cognitive awareness in pain perception was very well exemplified in a recent study by deCharms and colleagues at Stanford University, which showed that both healthy volunteers and chronic pain patients can learn to control their pain-induced neural activity in the ACC by using various cognitive strategy guidelines and real-time neuroimaging feedback (deCharms et al., 2005). This study specifically showed that modulation of ACC activity is accompanied by an associated change in reported pain perception.

4.05.5.1 Implications for Pain Management

An interesting yet counterintuitive fact is that injury is neither necessary nor sufficient to induce pain (Fields, 2000). In many instances, pain is not necessarily the manifestation of an injury but rather the manifestation of pathophysiological neural changes in the pain neuraxis. In support of this hypothesis, studies in both animals and humans have shown that electrical stimulation of certain brain regions can elicit pain in the absence of injury (Fields, 2000). Furthermore, as mentioned in previous sections of this chapter, pharmacological manipulations in the amygdala or the ACC can mimic inflammation-induced pain hypersensitivity in the absence of tissue injury or can result in avoidance learning in the absence of peripheral noxious stimulation, respectively (Johansen and Fields, 2004; Carrasquillo and Gereau, 2007) (**Figure 8**). A classic clinical example of pain without injury is seen in the phantom limb syndrome, when patients with amputated limbs report feelings of pain in the missing limb.

The limbically augmented pain syndrome (LAPS) theory could offer an explanation for situations in which pain is not accompanied by any obvious injury. The LAPS theory states that stress and exposure to emotionally traumatic events lead to a sensitized corticolimbic state that is analogous to central sensitization in the spinal cord and brainstem, but occurs in supraspinal structures that subserve both nociceptive processing and affective regulation (Rome and Rome, 2000). This sensitized corticolimbic state can in turn increase the perception of pain.

The scientific evidence demonstrating that emotions and cognitive factors strongly influence pain perception and the data suggesting that neuronal modifications in different regions of the pain neuraxis could explain these psychological modulations changed the clinical view of pain and consequently the approaches that are typically used for pain management. In addition to the more traditional pharmacological, physical, and surgical treatments for chronic pain, now a cognitive-behavioral approach is also commonly included in standard pain management practices. Cognitive-behavioral therapy (CBT) is designed to offer patients strategies to cope with their pain by identifying beliefs and fears that interfere with their functioning and well-being (Osborne et al., 2006). CBT has been shown to improve not only the reported pain intensity but also other non-pain-related variables such as mood, depression, pain interference, disability, return to work, and health care utilization (Kerns et al., 2006).

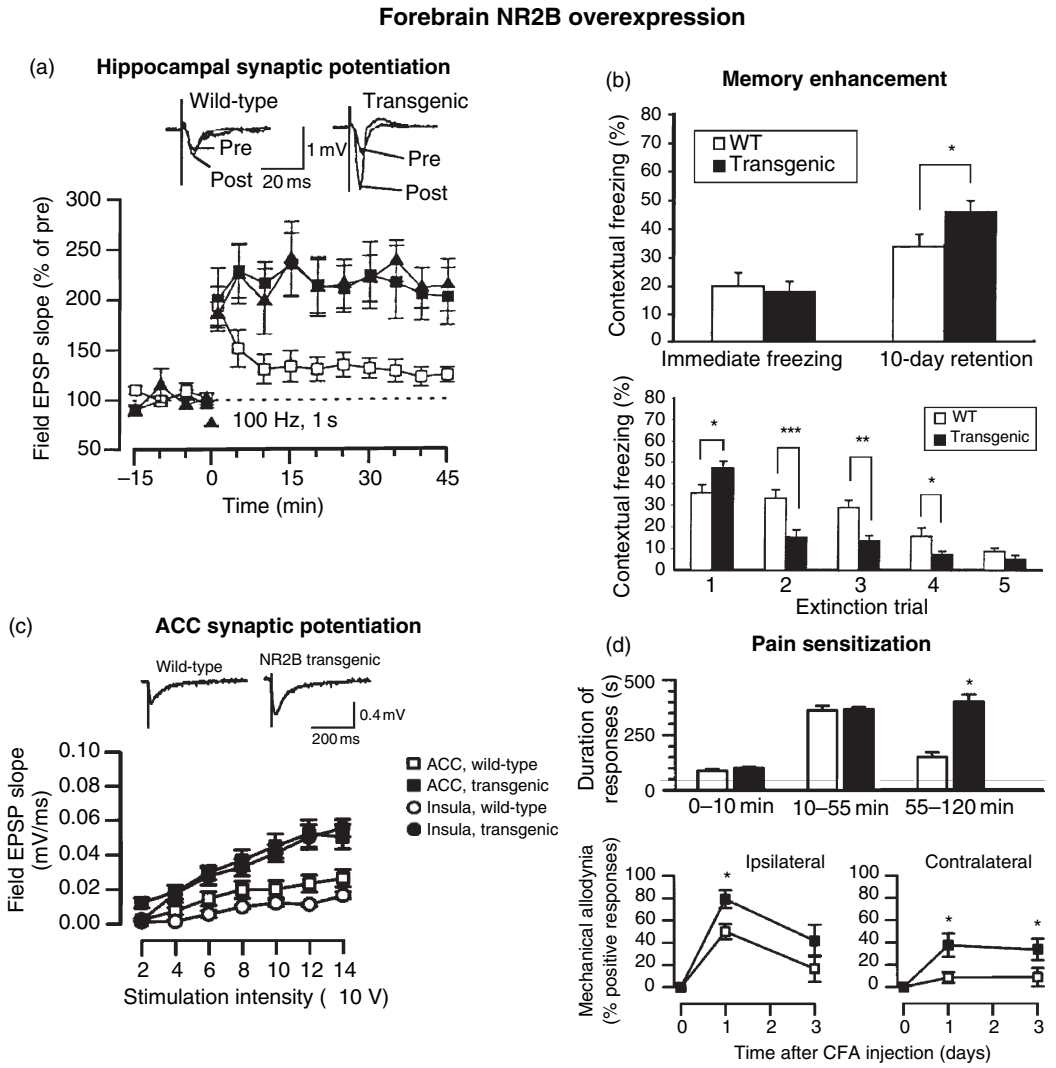

Figure 10 Overexpression of *N*-methyl-D-aspartate-type glutamate receptor subunit (NR2B) in the forebrain facilitates synaptic potentiation in the hippocampus and the ACC and enhances learning and memory and pain hypersensitivity in mice. (a) Synaptic potentiation in the hippocampus of NR2B-overexpressing mice. Time course of evoked excitatory postsynaptic potentials (EPSCs) in slices from wild-type (WT) and transgenic animals. Tg-1, filled squares; Tg-2, filled triangles; WT, open squares. Tetanic stimulation-evoked EPSPs are potentiated in NR2B overexpressing mice when compared to WT. Inset: Representative evoked EPSP before (pre-) and after (post-) tetanic stimulation in WT (left) and transgenic (right) slices. (b) Enhancement of contextual fear memory (top panel) and faster fear extinction (bottom panel) in NR2B-overexpressing mice. Top panel: Animals received a single conditioned stimulus/unconditioned stimulus (CS/US) pairing training. Retention test was performed 10 days after training. Percentage of freezing rate was increased in NR2B-overexpressing mice when compared to WT. Bottom panel: Animals received a single CS/US pairing training and were then subjected to five extinction trials. Percentage of freezing decreased faster in NR2B-overexpressing mice than in WT mice. (c) NR2B overexpression enhances NMDA receptor-mediated synaptic responses in the ACC. The slope of the field EPSP in response to graded stimulation intensities is higher in slices from NR2B-overexpressing mice than in slices from WT animals. Inset: Representative field EPSPs recorded from ACC slices of WT and NR2B-overexpressing animals. (d) Behavioral responses to intraplantar injection of formalin (top panel) or complete Freund's adjuvant (CFA) (bottom panel) are increased in NR2B-overexpressing mice. Top panel: Total time that WT (□) and NR2B-overexpressing (■) mice spent engaging nociceptive behavior in each phase of the formalin test. NR2B-overexpressing mice spent more time engaging in nociceptive behavior in the third phase of the formalin test when compared to WT mice. Bottom panel: The percentage of positive responses to mechanical stimulation was measured before (time 0) and 1 and 3 days after intraplantar injection of CFA. Increased percentage of responses after CFA was observed in NR2B-overexpressing mice (■) when compared to wild-type mice (□). Adapted from (a, b) Tang YP, Shimizu E, Dube GR, et al. 4.05.6 Learning and Memory Versus Chronic Pain

As we have discussed in this chapter, neural changes occur at different sites in the pain neuraxis in response to injury. This plasticity is thought to underlie the development and maintenance of chronic pain. Similar changes in excitability and synaptic strength occur in the hippocampus, cortex, and amygdala and are thought to underlie learning and memory. The similarities in the cellular mechanisms underlying pain and learning and memory are striking; many cellular processes and signaling molecules that are known to be important mediators of pain are also important regulators of learning and memory (Ji et al., 2003). The overlapping function of these cellular processes in pain and learning and memory was evident in genetically modified mice that overexpress NR2B in the forebrain (Tang et al., 1999; Wei et al., 2001) (**Figure 10**). Overexpression of NR2B in the forebrain resulted in facilitation of synaptic potentiation in the hippocampus and in superior performance in learning and memory tasks (Tang et al., 1999). A separate study showed that, unfortunately, these NR2B-overexpressing mice are smarter at the expense of also being more susceptible to pain (Wei et al., 2001). As in the hippocampus, enhanced synaptic responses were also observed in NR2B-overexpressing mice in the ACC and insular cortex, two key structures for pain processing. Accordingly, these mice also exhibited enhanced nociceptive responses after inflammation. The similarities in the neural mechanisms underlying pain and learning and memory have made the development of novel analgesic therapies even more challenging. At the same time, as discussed in the previous section of this chapter, the tight relationship that exists between pain and cognition has led to the development of a cognitive-behavioral approach to managing chronic pain that has been shown to be highly effective in helping patients cope with their pain.

4.06 Molecular Mechanism of Associative Learning in the Bee

U. Müller, Saarland University, Saarbruecken, Germany

4.06.1 Associative Olfactory Learning in Bees

To cope with the highly variable environment, as well as individual and social tasks, honeybees perform a variety of behaviors including orientation, foraging, and social communication. When searching bees discover flowers providing food, they learn to associate the visual and olfactory signals with the reward (nectar and pollen) and quickly optimize their foraging strategy based on nectar flow and sucrose concentration. For optimal learning, stimuli of food sources like odor and color (conditioned stimuli, CS) that predict reward have to be perceived before the bees actually experience the sucrose reward (unconditioned stimuli, US) (reviewed in Menzel and Müller, 1996). This associative learning under natural conditions reveals many characteristics of associative learning in mammals. Studying the honeybee's learning behavior in the laboratory was a major breakthrough and provided the opportunity to study associative conditioning of the proboscis extension reflex (PER) at the behavioral, the cellular, and the molecular level under controlled conditions (**Figure 1**). The PER that is elicited by an appetitive stimulus (sucrose) is conditioned by pairing an odor stimulus (CS, conditioned stimulus) with a sucrose reward (US, unconditioned stimulus). A single pairing that lasts only a few seconds induces an associative memory that is initially at a high level but decays over the following days (Menzel and Müller, 1996; Menzel, 1999). As in other model systems, repetitions of conditioning trials induce a stable memory (**Figure 2(a)**). In the honeybee, three successive conditioning trials, given within a time window of a few minutes, induce a long-lasting memory that is stable for many days (>7 days) and which shows all properties of a long-term memory (LTM) (Menzel and Müller, 1996). Memories induced by a single or by repeated conditioning trials differ in their sensitivity to amnestic treatments like cooling. While cooling immediately after a single-trial conditioning impairs memory formation, the same treatment after multiple-trial conditioning does not (Menzel et al., 1974; Erber et al., 1980; Müller, 1996). Thus, repetition of conditioning trials accelerates the transfer into amnesia-resistant memory.

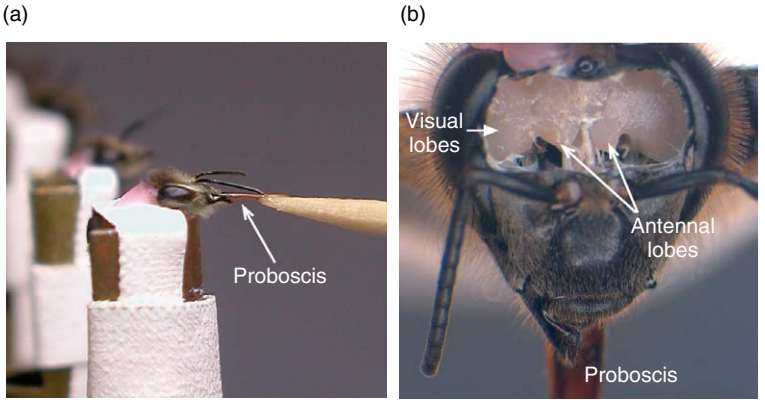

Figure 1 Honeybees fixed in metal tubes for olfactory conditioning of the proboscis extension reflex (PER). (a) Bees mounted in the metal tubes can freely move their proboscis and antennae. Stimulation of the antennae or the proboscis with sucrose solution (toothpick) elicits the PER. (b) Dorsal view of a honeybee head with open head capsule. The direct access to neuronal networks like the antennal lobes allows monitoring of neuronal activity and manipulation of signaling cascades during learning *in vivo*.

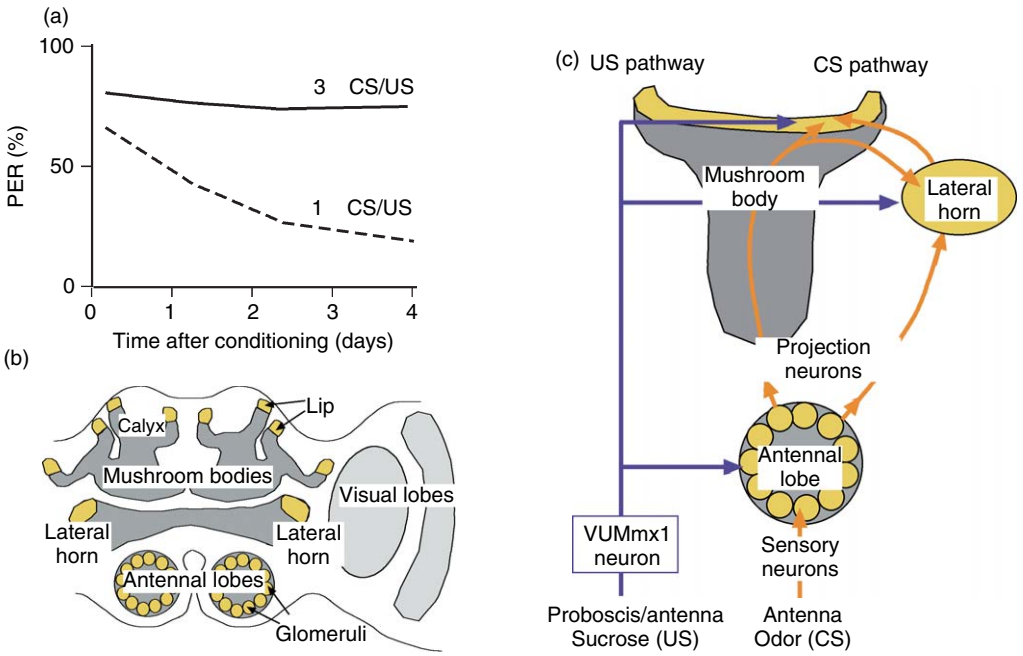

Figure 2 Associative olfactory learning in honeybee and the underlying neuronal circuits. (a) Associative conditioning of the PER consists of the pairing of an odor, the conditioned stimulus (CS), with a following sucrose reward, the unconditioned stimulus (US). A single pairing (1×CS/US) that lasts a few seconds leads to formation of a memory that decays over days. Multiple conditioning trials (3×CS/US with an intertrial interval of 2 min) induce a robust long-term memory that provides the basis for the analysis of the molecular signaling cascades underlying learning and memory formation. (b) The schematic section through the honeybee brain shows the major neuronal circuits implicated in processing olfactory and visual information. While the antennal lobes and the visual lobes are primary sensory centers, the mushroom bodies are sites that process different sensory modalities. The antennal lobes with their glomerular structure, the lip of the mushroom body calyces, and the lateral horn are areas implicated in olfactory information processing. (c) The neuronal circuits that mediate CS and the US information are well characterized in honeybees. CS pathway: the antennal lobes are the primary processing site of odor information and receive their input from sensory neuron in the antenna. CS information leaves the antennal lobes via projection neurons that transmit the information to the calyces of the mushroom bodies and the lateral horn. The antennal lobes, the calyces of the mushroom bodies, and the lateral horn are convergence sites of the CS and the US pathways. These brain areas are innervated by the ventral unpaired median (VUM) mx1 neuron that can substitute the US function in associative learning. The neuronal circuits connecting the output sites of these brain areas to the motor circuitry mediating the PER are unknown.

4.06.2 Neural Circuits Mediating Associative Olfactory Learning

The brain areas and neuronal circuits mediating odor information (CS pathway) and reward information (US pathway) in associative learning in the honeybee have been analyzed using a variety of techniques and approaches. While histological and immunohistological techniques provided the basic information concerning morphological features of the neuronal pathways, studies using electrophysiological and optical recording approaches in intact animals added important functional aspects to our knowledge of the neuronal circuits involved in CS and US processing (**Figures 2(b)** and **2(c)**).

4.06.2.1 CS Pathway

Olfactory information from the chemosensory receptors on the antennae is relayed via the antennal lobes (AL) to the calyces of the mushroom bodies (MB) and the lateral horn (LH) (**Figure (2c)**). In each AL, the 160 glomeruli comprise sites of dense synaptic connections between sensory neurons (≈60 000), local interneurons (4000) and projection neurons (PNs) (≈800) (Galizia and Menzel, 2000). A considerable fraction of the local interneurons connecting the glomeruli within an AL exhibit gamma-aminobutyric acid (GABA) immunoreactivity (Schäfer and Bicker, 1986). This GABAergic network modulates the overall activity in the ALs and, together with a second glomerular-specific inhibitory network, contributes to the sharpening of the odor representation at the level of output neurons that transmit the information to higher-order neuropils (Sachse and Galizia, 2002). Blocking of the inhibitory network in the ALs impairs odor discrimination but not learning (Stopfer et al., 1997).

Different types of PNs transmit odor information from the AL to the lip region of the MB calyces and the LH in the lateral protocerebrum (**Figure 2(c)**). While PNs in the median antennocerebral tract show odor-specific activity profiles for different odors and conduct the information with a delayed code, the PNs in the lateral antennocerebral tract have rather unspecific broadband activity profiles for different odors and transmit the information without delay (Müller et al., 2002). This points to a dual coding of odor information by extracting and transmitting different features in the time domain by different sets of PNs. Immunohistochemical studies demonstrate the presence of acetylcholinesterase and acetylcholine receptors in the PNs and their target area, the lip region of the MB. Thus, the major CS input into the MBs seems to be cholinergic (Kreissl and Bicker, 1989).

The MBs, which consist of densely packed Kenyon cells (KC) are prominent, well-characterized brain structures and play a central role in learning and memory formation in several species (*See* Chapters 1.28, 4.07). The olfactory input by the PNs is confined to the lip region of the calyces. Optical recording techniques demonstrate that odors evoke combinatorial activity patterns in both the glomeruli of the ALs and the lip region of the MBs. While these patterns are prominent at the level of the ALs, odors generate only brief and sparse responses at stimulus onset in the KC of the MBs (Szyszka et al., 2005). The inhibitory recurrent neurons connecting output areas of MBs with input in the lip region of the MBs are probably involved in this process (Ganeshina and Menzel, 2001).

4.06.2.2 US Pathway

Appetitive chemosensory pathways from the antennae and the proboscis project to the suboesophageal ganglion and terminate near motor neurons involved in proboscis extension. Ventral unpaired median (VUM) neurons receive chemosensory input, and the single identified VUMmx1 neuron can substitute for the US function in associative learning, as demonstrated by depolarization of VUMmx1 shortly after a CS presentation (Hammer, 1993). The VUMmx1 innervates the ALs, the MBs, and both LHs and thus converges with brain areas that process odor information (**Figure 2(c)**). Injections of octopamine, the putative transmitter of VUMmx1 (Kreissl et al., 1994), either into the ALs or the MBs substitute for the US function (Hammer and Menzel, 1995, 1998), supporting the role of VUMmx1 in reward processing in these two brain areas. Pairing of CS stimulation with octopamine injection into either the AL or the MB leads to a conditioned response as tested after 20 min, supporting independent contributions of the AL and MB in memory formation. This function in memory formation, however, differs between the AL and the MB, since only CS presentation followed by octopamine injections into the AL leads to a normal detectable acquisition. Such different roles of the ALs and the MBs have initially been proposed by experiments using local cooling of AL and MB as amnestic treatment to interfere with associative learning (Menzel et al., 1974; Erber et al., 1980).

4.06.3 The Molecular Cascades Mediating CS and US Pathways in Olfactory Learning

The robust learning paradigm in combination with the accessibility and the size of the honeybee brain provides the unique opportunity to apply biochemical techniques to monitor *in vivo* induced activities of signaling cascades (Hildebrandt and Müller, 1995a,b). Rapid termination (<0.5 s) of biochemical reactions by liquid nitrogen freezing of the whole animal, followed by freeze-drying, tissue dissection, and optimized biochemical assays, allows the determination of learning-induced activation of signaling cascades in brain areas like the ALs and the MBs at defined times after *in vivo* stimulation.

The search for the signaling cascade contributing to US processing revealed a specific role of the cyclic adenosine monophosphate (cAMP)-dependent protein kinase A (PKA). Stimulation of the antenna with sucrose, the US, induces a fast transient activation of PKA in the ALs (Hildebrandt and Müller, 1995b) that is back to baseline within a few seconds. US-induced PKA activation in the ALs is stimulus specific, since odor stimulation (CS) or mechanical stimulation of the antennae does not affect PKA activity (Hildebrandt and Müller, 1995b). The exclusively US-induced PKA activation in the ALs is sensitive to the monoamine reuptake blocker reserpine and thus depends on the monoamines present in the AL. One of the latter is octopamine, the putative transmitter of the VUMmx1 neuron that densely innervates the ALs. Thus, octopamine is responsible for linking US stimulation to transient PKA activation (Hildebrandt and Müller, 1995a).

The PKA immunostaining is to its largest extent detected in the local interneurons that connect the glomeruli within the AL (Müller, 1997a). This, together with the biochemical measurements and the dense innervation of the ALs by the VUMmx1 neuron, suggests a global modulatory function of US-induced processes mediated via the octopamine–cAMP/PKA cascade in the AL. The observation that silencing expression of the octopamine receptor in the honeybee specifically impairs olfactory learning but not odor discrimination (Farooqui et al., 2003), together with the specific requirement of octopamine in *Drosophila* appetitive, but not aversive, olfactory learning (Schwaerzel et al., 2003), points to a conserved role of octopamine in insect appetitive learning.

In addition to the specific activation of the cAMP/PKA pathway, US stimulation also triggers Ca^{2+}-regulated signaling cascades like the Ca^{2+}-phospholipid-dependent protein kinase C (PKC) in the AL (Grünbaum and Müller, 1998). In contrast to the US-specific activation of the cAMP/PKA pathway, PKC is activated by both US and CS stimulation (Grünbaum and Müller, 1998). Inhibition of the transient CS- or US-induced PKC activation does not affect associative learning, suggesting that PKC-mediated processes may contribute to chemosensory information processing rather than to learning and memory formation.

In addition to the ALs, the VUMmx1 neuron innervates the lip region of the MB calyces that receives olfactory input from the ALs (**Figure 2(c)**). In contrast to the ALs, however, US stimulation does not activate the cAMP/PKA cascade in the MBs *in vivo*. This, together with the observation that octopamine stimulates the cAMP/PKA cascade in cultured KC from the MBs (Müller, 1997a), points to a different coupling of the octopamine receptors in the MBs: most likely, US stimulation activates octopamine receptors that trigger Ca^{2+}-regulated signaling cascades in the MBs (Balfanz et al., 2005). The observed differences in the expression of voltage-sensitive and Ca^{2+}-dependent currents in neurons of the ALs and the MBs (Grunewald, 2003) support the idea that information in olfactory learning is processed differently in ALs and MBs.

4.06.4 Associative Conditioning: Induction of Molecular Processes Underlying Memory Formation

During associative conditioning, parameters of the CS and US stimulus (strength, duration) and the temporal relations between stimuli are deciding factors for the process of memory formation. Depending on these parameters, different molecular processes are triggered during the short training phase, and depending on the triggered molecular processes, distinct forms of memory are developed. At least three memory phases can be identified in the various model systems: a short-term memory (STM) in the range of minutes, a mid-term memory (MTM) in the range of hours, and a stable LTM which lasts for days and weeks. In honeybees, as in many other systems, the LTM can be pharmacologically divided into a translation-dependent early phase (eLTM, 1–2 days)

and a transcription-dependent late phase (lLTM, ≥3 days) (Menzel, 1999; Müller, 2002). The defined period of associative conditioning (seconds to minutes) and the experimental accessibility of the convergence sites of CS and US processing in honeybees provided the ideal situation to determine the learning-induced dynamic activation of molecular signaling cascades and their contribution to formation of distinct memory phases *in vivo*.

4.06.5 Induction of LTM: The Critical Role of the cAMP/PKA Cascade

The requirement of cAMP/PKA-dependent processes in LTM formation and processes of long-lasting neural plasticity is observed in all systems investigated so far and seems to be conserved throughout the animal kingdom (*See* Chapters 4.07, 4.10, 4.21). Blocking of PKA during and immediately after the training phase leads to a selective loss of LTM, while STM and MTM are unaffected (Müller, 2000). Direct measurements show that the temporal dynamics of US-triggered PKA activation in the ALs is modified by the temporal sequence of CS and US stimuli and by the number of successive conditioning trials (**Figure 3**). A single CS/US forward-pairing, which induces a weak olfactory memory, leads to a transient increase in PKA activity that returns to basal levels 60 s after the conditioning trial. Repetition of CS/US forward-pairings (3× CS/US with an intertrial interval of 2 min) that induce LTM prolongs PKA activity in the ALs up to more than 3 min. US stimulation alone, as well as single or repeated US/CS backward-pairings, which do not induce appetitive memory, lead to a significantly shorter but similar pattern of PKA activation. This first *in vivo* evidence for a link between the sequence

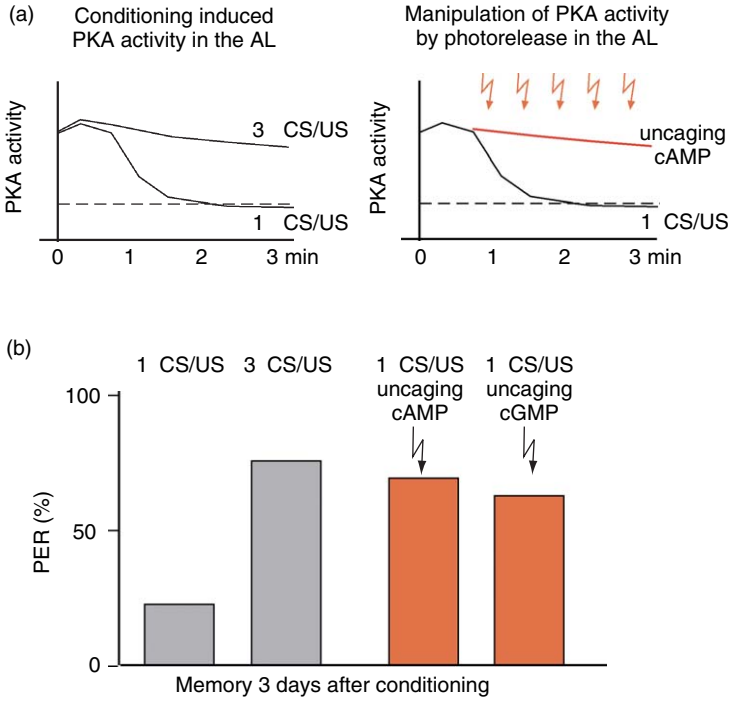

Figure 3 Induction of LTM requires a prolonged PKA activation in the antennal lobes. (a) The activation pattern of PKA in the antennal lobes depends on the sequence and the number of successive conditioning trials. While a single CS/US pairing induces a transient activation of about 1 min, repeated CS/US pairings (2-min intertrial interval) that induce an LTM lead to a prolongation of PKA activity up to more than 3 min. Local uncaging of cAMP in the antennal lobes enables the imitation of the prolonged PKA activation *in vivo,* while the animal receives a single CS/US pairing. (b) Honeybees are trained under conditions allowing access to the brain to photorelease cAMP or cyclic guanosine monophosphate (cGMP) during conditioning. Under these conditions honeybees form an LTM as tested 3 days after 3×CS/US pairings, but not after a single CS/US pairing. A single CS/US pairing together with the imitation of the prolonged PKA activation by uncaging cAMP in the AL induces LTM. Since the prolonged PKA activation is mediated via the nitric oxide/cGMP cascade, single CS/US pairing combined with uncaging of cGMP in the AL also induce LTM.

and number of CS and US stimulation and temporal dynamics of PKA activation in the ALs suggested that prolonged PKA activation in the AL is involved in the formation of associative LTM.

This hypothesis was tested by photolytic release of caged cAMP in the ALs (**Figure 1(b)**) to artificially prolong PKA activation during olfactory conditioning. A single conditioning trial combined with the local replay of the prolonged PKA activation in the ALs *in vivo* is sufficient to induce long-lasting memory (**Figures 3** and **4**). These experiments provided direct functional evidence for a link between conditioning parameters, temporal patterns of PKA activation in the ALs, and formation of LTM in intact animals.

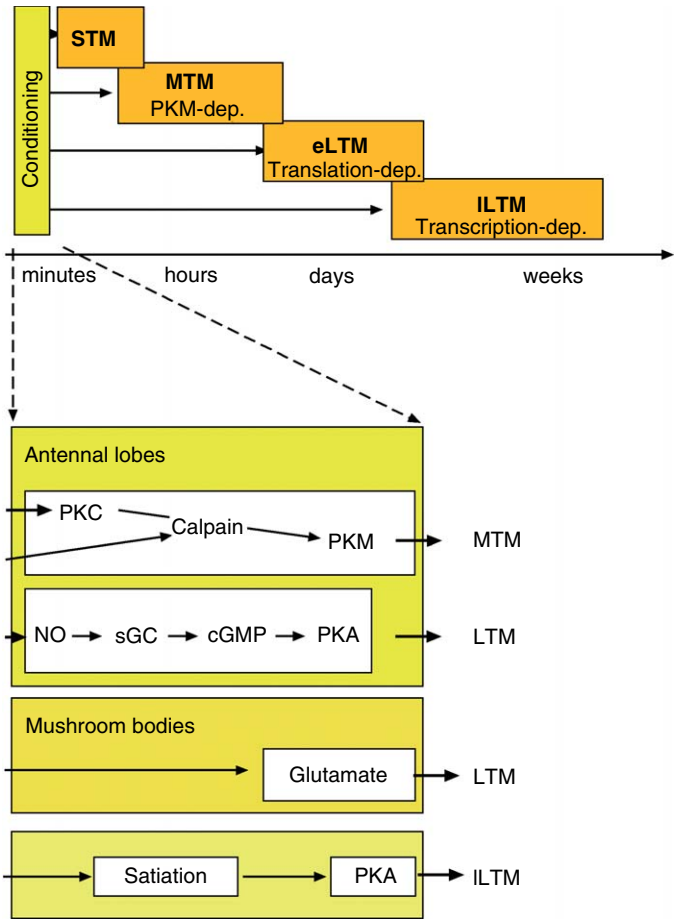

Figure 4 Scheme of the molecular mechanisms underlying the induction and maintenance of different memory phases in honeybees. As in other species, different memory phases are mechanistically distinguishable in the honeybee. While short-term memory (STM) and mid-term memory (MTM) can be formed by existing proteins, long-term memory (LTM) requires protein and RNA synthesis. LTM can be pharmacologically dissected into an early phase (eLTM) that requires protein synthesis and a late phase (lLTM) that, in addition, requires RNA synthesis. STM, MTM, and LTM are induced independently and by parallel processes. Two independent processes involved in maintenance of MTM and induction of LTM are localized in the antennal lobes. MTM requires the formation of a constitutive protein kinase M (PKM) for its maintenance. PKM is formed in the antennal lobes by cleaving protein kinase C (PKC) by the protease calpain. Also located in the antennal lobes is the molecular process underlying the prolonged activation of the protein kinase A (PKA) that is required for LTM induction. This prolonged PKA activation is mediated by activation of the soluble guanylate cyclase (sGC) by nitric oxide (NO) and induces subsequent processes of LTM formation. In addition to the antennal lobes, processes located in the mushroom bodies also contribute to LTM formation. Photolytic release of glutamate in the mushroom bodies immediately after conditioning facilitates LTM formation. The satiation status during conditioning modulates learning and memory formation. The formation of the late LTM can be specifically rescued via a PKA-dependent process, indicating that eLTM and lLTM are induced by two parallel PKA-dependent mechanisms. The molecular targets triggered by these early events in the ALs and the MBs are presently unknown.

However, the molecular processes triggered by the prolonged PKA activation in the ALs that finally lead to LTM are unknown.

Artificial prolongation of PKA activation in the ALs, in conjunction with single-trial conditioning, does not reach the level of conditioned responses that is achieved after multiple-trial conditioning. Thus, it is possible that other molecular processes or neural circuits (e.g., in the MBs) also contribute in parallel to LTM induction.

4.06.6 Induction of LTM: The Nitric Oxide/cGMP System Acts as a Signal Integrator during Associative Conditioning

In the nervous system, nitric oxide (NO) has been implicated in various physiological functions including chemosensory information processing and learning (Müller and Hildebrandt 1995; Müller, 1996, 1997b). Inhibition of NO synthase (NOS) in honeybees that is mainly localized in brain areas like the ALs and the lip of the MB calyces impair both LTM formation (Müller, 1996) and prolonged PKA activation (Müller, 2000). The finding that blocking of the soluble guanylate cyclase, the major target of NO in neuronal tissues, also impairs multiple-trial induced prolonged PKA activation and LTM formation provided first evidence for a crosstalk between cyclic guanosine monophosphate (cGMP) and cAMP signaling in this system. Theoretically, cGMP can interact with the cAMP cascade via cGMP-dependent protein kinase, cGMP-regulated phosphodiesterases, and cyclic nucleotide-gated channels. Although the target of cGMP has not yet been identified *in vivo*, the synergistic activation of honeybee PKA by cAMP and cGMP (Leboulle and Müller, 2004) points to a direct function of cGMP in the prolonged increase in PKA activity in the AL.

This systemic analysis does not allow for localizing the contributing brain areas. Again the uncaging technique served as valuable approach to verify that the prolonged PKA activation in the ALs is mediated via NO and cGMP *in vivo* (**Figures 3** and **4**). As demonstrated with uncaging cAMP, a single conditioning trial followed by photorelease of cGMP leads to formation of a long-lasting memory (**Figure 3**). A single conditioning trial in combination with uncaging NO in the ALs impairs memory formation. Although the reason for this is unknown, photolyzing NO in the ALs may interfere with other functions of NO in signal processing in the ALs. It has been demonstrated that blocking NO in the AL impairs odor discrimination (Hosler et al., 2000). Due to the localization and Ca^{2+}-dependence of NOS, the odor-specific changes in Ca^{2+}-concentrations in subsets of glomeruli during odor processing (Joerges et al., 1997) may induce an odor-specific release of NO required for odor discrimination. The artificial release of NO within the whole ALs would interfere with such a process. Moreover, the NO/cGMP system in the ALs is also implicated in integrative processing of appetitive signals during habituation (Müller and Hildebrandt, 1995). Characterizing the temporal aspects of NO and cGMP function using the uncaging technique *in vivo* revealed clear differences between NO/cGMP function in associative and nonassociative learning. Both the cellular network mediating the NO/cGMP function and the temporal parameters of the stimulus-induced activation of the NO/cGMP system differ between associative learning and habituation (Müller and Hildebrandt, 2002). Irrespective of their differences, however, both NO/cGMP-mediated processes contribute to integrative signal processing during application of stimuli. In case of associative learning, the function of the NO/cGMP system in a very narrow time window during conditioning is critical for induction of LTM and thus for processes that become evident days later (**Figure 4**).

4.06.7 Glutamate-Mediated Signaling Cascades in the Mushroom Bodies Are Involved in Memory Formation

Glutamate is the major excitatory transmitter in the mammalian brain and plays a central role in neuronal plasticity in vertebrates (*See* Chapters 4.16, 4.20). Although the function of glutamate as main transmitter at insect neuromuscular junctions is well studied, the role of glutamate in the insect brain is poorly understood. The existence of glutamate-like immunoreactivity (Bicker et al., 1988), glutamate-induced ion currents (Barbara et al., 2005), glutamate transporters, and glutamate receptors (Kucharski et al., 2000; Funada et al., 2004; Zannat et al., 2006) provides considerable evidence for a potential role of glutamate in the honeybee brain.

Systemic application of drugs affecting reuptake of glutamate before repeated training trials impairs memory tested after 24 h but does not affect acquisition or memory tested at 1 h (Maleszka et al., 2000).

A similar effect is observed by injection of MK-801, a noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonist (Si et al., 2004). Although interpretation of the function of glutamate transmission based on pharmacological studies is difficult, a molecular approach used in *Drosophila* (Xia et al., 2005) supports the idea of an implication of glutamate in insect learning. Stable and transient knockdown of NMDA receptors in the whole *Drosophila* brain disrupts aversive olfactory learning and impairs long-term memory. However, as in the honeybee, the particular brain site at which glutamate influences memory remains unclear. Photolytic uncaging of glutamate in the honeybee brain revealed direct evidence for a defined spatial and temporal contribution of glutamate in LTM formation (Locatelli et al., 2005) and, in addition, overcame problems caused by the insufficient pharmacological characterization of the drugs used on insect glutamate receptors and reuptake systems.

Uncaging glutamate in the MBs immediately after a weak training protocol (single-trial training) improves the formation of a long-lasting memory (2 days) and thus mimics the effect of a strong training protocol (**Figure 4**). The effect of glutamate seems to be confined to a time window after associative training, since release of glutamate immediately before training has no effect. This post-conditioning effect of glutamate release on late memory formation allows two interpretations: Either it mimics a situation that is usually induced by repeated conditioning trials and thus facilitates learning, or post-conditioning release of glutamate directly contributes to early processes of memory formation. The function of glutamate is restricted to the MBs circuitry, since glutamate release in the ALs does not affect processes of learning or memory formation. The demonstrated role of glutamate in memory formation strengthens the notion that glutamatergic neurotransmission is a conserved key element in neural plasticity across species.

4.06.8 Induction and Maintenance of MTM: The Ca^{2+}-Dependent Cleavage of PKC by Calpain

Calcium-mediated signaling cascades play a fundamental role in the regulation of cellular processes. The signaling cascade that involves PKC is implicated in synaptic plasticity in various systems (*See* Chapter 4.22). Initiated by the finding that both US and CS stimulation induce a transient PKC activation in the ALs, the function of the signaling cascade that involves PKC has been analyzed in detail (Grünbaum and Müller, 1998). The temporal dynamics of PKC activation in the ALs are independent of the sequence of CS and US stimulation and of the number of successive conditioning trials. Inhibition experiments reveal evidence that these transient PKC modulations during the conditioning phase do not directly contribute to learning or memory formation. In maintenance of a specific memory phase, however, a function of the signaling cascade involving PKC has been demonstrated.

Repeated conditioning trials that induce LTM lead to an increase in PKC activity in the ALs beginning 1 h after conditioning and lasting up to 3 days (Grünbaum and Müller, 1998). This long-lasting elevation of PKC activity is not induced by a single conditioning trial. Two independent and mechanistically distinct mechanisms contribute to this training-induced increase in PKC activity. In the early phase, ranging from 1 to 16 h, the increased PKC activity can be attributed to a constitutively active PKC, a form of PKC known as PKM. PKM is formed by cleavage of the activated PKC by the Ca^{2+}-dependent protease calpain. Inhibition of calpain activity during conditioning eliminates the early phase of elevated PKC activity from 1–16 h after training. This supports the idea that training activates PKC and calpain. Only activated PKC is susceptible to calpain action resulting in the production of PKM. The inhibition of calpain during conditioning impairs memory in a time window between 1 and 16 h after learning, suggesting that learning-triggered PKM production is required for maintaining the MTM (**Figure 4**). This is supported by the observation that blocking calpain does not affect acquisition, the early memory phase up to 30 min, and memory after 1 day.

The late phase of training-induced elevation of PKC activity observed 1–3 days after learning is eliminated by injection of blockers of protein and RNA synthesis in a narrow time window during and after conditioning. Thus, induction of the two mechanistically different processes expressing the early and late phase of elevated PKC activity occur in parallel during and/or shortly after conditioning. The mechanism underlying the elevated PKC activity in the late phase, as well as its function in memory formation, is unclear. It is probably one of several parallel mechanisms occurring in different neuronal circuits required for the formation of the late phase of long-term memory.

4.06.9 Influence of Satiation Reveals a Parallel Function of the cAMP Cascade in the Process of Memory Formation

In addition to parameters concerning the relation and number of US and CS stimulation during associative learning, factors like stress, satiation, etc., influence learning and memory formation. Although the latter parameters are usually strictly controlled in behavioral experiments, the manipulation of satiation level during associative learning in honeybee uncovered new features of the molecular machinery leading to LTM formation (Friedrich et al., 2004).

As in other paradigms using appetitive associative conditioning, a reliable induction of LTM in the honeybee requires training of hungry animals. Only multiple-trial conditioning of animals starved for about 18 h leads to a robust acquisition and induction of MTM and the two LTM phases, eLTM and lLTM. An additional feeding 4 h before multiple-trial conditioning is sufficient to impair acquisition and all subsequent memory phases. Such an additional feeding also impairs memory induced by a single-trial conditioning. This is of particular importance, since presently only manipulations of satiation during learning or amnestic treatment by cooling immediately after learning have been shown to interfere with memory induced by a single conditioning trial. The restriction of the different satiation levels to the time window of conditioning and the impairment of both LTM phases that require the cAMP/PKA cascade during conditioning (Müller, 2000; Friedrich et al., 2004) pointed to a contribution of the cAMP/PKA cascade in satiation-dependent impairment of memory formation. Determination of the basal PKA levels in honeybee brains at different satiation levels revealed a characteristic difference: hungry bees starved for 18 h show higher basal PKA activity in the brain than bees fed 4 h before. Elevating the low basal PKA activity levels in animals fed 4 h before conditioning specifically rescues the transcription-dependent lLTM (**Figure 4**). This is remarkable, since acquisition, MTM, and eLTM are still impaired. Since in all model systems, both eLTM and lLTM require PKA for their induction, the findings in honeybees support the existence of two parallel cAMP/PKA pathways implicated in LTM formation: one triggers molecular cascades leading to translation-dependent eLTM, and the other is involved in triggering cascades required for transcription-dependent lLTM. The specific rescue of lLTM by elevating basal PKA activity in fed animals suggests that other molecular pathways involved in learning and memory formation also contribute to the network of molecular interactions between satiation and learning processes.

4.06.10 Summary

The accessibility of the honeybee brain provides the basis for the analysis of learning-induced changes of signaling cascades in defined brain areas. The conditioning-induced transient activation of different signaling cascades occurs in a narrow time window of a few minutes during and after conditioning and is highly dependent on the training parameters, which are critical for induction of distinct memories. The temporal action of signaling cascades can be imitated by local uncaging of substances activating these cascades. Thus, combination of behavioral and biochemical techniques reveals important insights into the organization of the molecular network underlying memory formation *in vivo*.

The temporal analysis of the conditioning-induced activation of PKA, which plays a conserved role in LTM formation in all model systems, demonstrated a critical function for a prolonged PKA activation in the ALs in LTM formation. This prolonged PKA activation is mediated by the NO/cGMP system and is necessary to induce molecular processes underlying eLTM and lLTM. An independent, PKA-mediated process specifically implicated in lLTM formation could be identified by altering the bee's satiation level during conditioning. The network of molecular processes implicated in LTM formation also includes processes localized in the MBs. Here, signaling cascades activated by the neurotransmitter glutamate are involved in processes that facilitate LTM formation, an observation that supports the idea that the function of glutamate in synaptic plasticity is conserved. The molecular processes involved in induction and maintenance of MTM are independent of those underlying induction of LTM. In the ALs, conditioning triggers the cleavage of PKC by calpain that results in production of PKM. The autonomously active PKM is specifically required to maintain MTM in the range of a few hours.

Taken together, the temporal and spatial analysis of signaling cascades triggered by associative learning in honeybees reveals a parallel organization of the molecular network contributing to memory formation. Such a parallel-organized network is perfect for the fine-tuning of the multiphasic process of memory formation by training parameters and other factors influencing learning like satiation, stress, and circadian rhythm.

4.07 Molecular and System Analysis of Olfactory Memory in *Drosophila*

G. Isabel and T. Preat, ESPCI-CNRS, Paris, France

4.07.1 Introduction: Three Types of Olfactory Memories and a Memory Center

Drosophila melanogaster has been used as a model system in investigating many cellular and developmental processes. The *Drosophila* central nervous system is composed of neurons and glia that operate on the same fundamental principles as their mammalian counterparts. Even though the *Drosophila* brain has only 100 000 cells (Ito et al., 2003), it produces complex behaviors and sustains various forms of learning and memory, which are highly amenable to analysis by current genetic methods. Moreover, *Drosophila* studies make it possible to investigate different concepts of memory that may eventually be generalized to other species, because roughly 50% of human genes have a *Drosophila* ortholog (Rubin et al., 2000).

4.07.1.1 Olfactory Aversive Conditioning

We will focus on the most commonly used paradigm to assess *Drosophila* memory, olfactory aversive conditioning (*See* also Chapter 1.28). This paradigm was instrumental in the discovery of most learning and memory mutants, and still contributes to our increasing comprehension of molecular and cellular processes that underlie associative memory. Importantly, the characterization of specific anatomical and memory mutants has allowed us to partially decipher the dynamics of memory phases in this system.

The principle, originally developed by Quinn et al. (1974) and improved by Tully and Quinn (1985), is as follows: for training, a single associative-learning trial consisting of an odor (the conditioned stimulus, CS^+) is accompanied by electric shocks (the unconditioned stimulus, US); and after a short rest period, a second odor (the conditioned stimulus, CS^-) is presented in

absence of shock. To test memory, flies are placed in an apparatus where they can choose between two compartments that are presented simultaneously: one containing the CS^+ odor, the other one the odor CS^-. After 2 min of test, flies from each compartment are isolated and counted to calculate a memory performance index (PI) that typically ranges from 0 (no memory) to 1 (perfect score). This protocol generates immediate memory scores of around 0.85, indicating that the majority of flies are able to learn and remember. To increase the efficiency of this process, our laboratory has developed an automated conditioning setup that allows parallel training of six groups of flies by means of a barrel (for schematic representation, see Pascual and Preat, 2001).

If flies are submitted to one training cycle (i.e., odor 1 paired with electric shock reinforcement for 1 min, hereafter called the short protocol), 1-day memory retention is weak. Multiple massed repetitions (hereafter called the massed protocol) of this single cycle generate memory that can be measured for a few days. Multiple spaced repetitions with a rest period of 15 min between each cycle (hereafter called the long protocol) generate a stabilized memory, called long-term memory (LTM), which can be measured for 1 week (Tully et al., 1994).

In addition to these quantitative variations, an important question is whether the different protocols induce distinct types of memory. Several general treatments have been used to disrupt specific memory components in wild-type flies. After the short protocol, 3-h memory retention is disrupted by submitting the flies to a cold shock immediately after training, but becomes progressively more resistant when this treatment is administrated at later times (Quinn and Dudai, 1976; Tully et al., 1994). This observation characterizes two memory phases, one anesthesia-sensitive memory (ASM, or labile memory) and one anesthesia-resistant memory (ARM, or consolidated memory). ASM and ARM are also generated after the massed protocol. Flies fed with an inhibitor of protein synthesis, cycloheximide, show a disrupted LTM but normal ARM (Tully et al., 1994) and ASM (Dudai, 1977), suggesting that unlike ARM and ASM, LTM depends on *de novo* protein synthesis (cf **Table 1**). These results suggest that flies can form three different types of olfactory memory, and the search for mutants that affect these phases differently is a major goal of *Drosophila* memory research.

4.07.1.2 The Mushroom Bodies Are the Center of Olfactory Memory

Olfactory receptor neurons, located in the antennae and maxillary palps, project their axons into the antennal lobes (ALs). From the ALs, projection neurons convey the olfactory information via the antennoglomerular tract in part to mushroom bodies (MBs) (**Figure 1**), a pair of prominent and characteristically shaped neural centers. In the 1970s and 1980s, the function of the MBs was assessed in different insect species with classical interventionism approaches, cooling or ablation (Menzel et al., 1974; Erber et al., 1980). In the cockroach, MBs are a specialized neuropile involved in processing and storing multimodal sensory information (Li and Strausfeld, 1997). Over the years, MBs have been implicated in olfactory learning and memory (Davis, 2005), and in a variety of complex functions including courtship learning (Mehren et al., 2004), context generalization in visual learning (Liu et al., 1998), walking activity (Martin et al., 1998), and sleep (Joiner et al., 2006; Pitman

Table 1 Synopsis of different memory phases, the protocols that generate them, and their properties

	Anesthesia-sensitive memory	*Anesthesia-resistant memory*		*Long-term memory*
Duration	Short-lasting memories: Short-term memory (STM) lasting a few minutes and middle-term memory (MTM) lasting a few hours	Semi-stabilized memory lasting a few days		Stabilized memory lasting more than 1 week
Protocol	All protocols	Short protocol	Massed protocol	Long protocol
Anesthesia treatment	Sensitive	Resistant	Resistant ?	Resistant ?
Protein-dependent synthesis	No	No		Yes

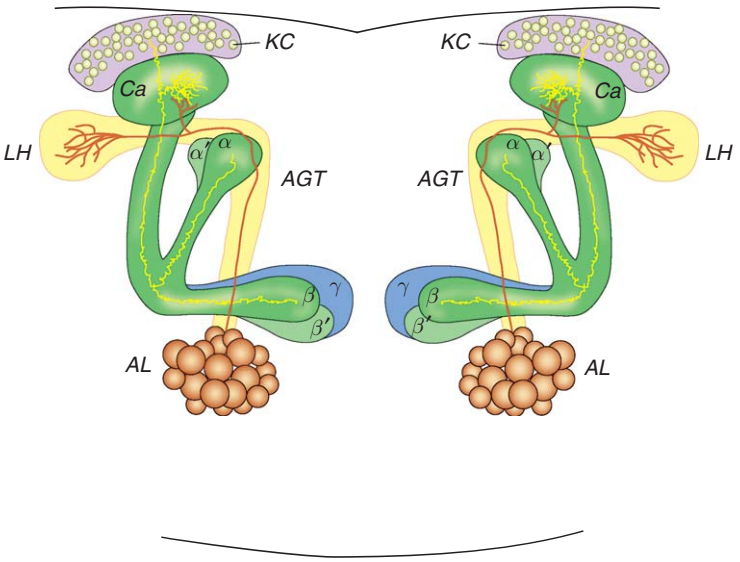

Figure 1 *Drosophila* olfactory system. Olfactory sensory neurons project to the antennal lobes (AL). From there, projection neurons project through the antennoglomerular tract (AGT) and connect mushroom body (MB) dendrites localized in the calyx (Ca), as well as the lateral horn (LH). Each MB is composed of about 2500 neurons, the Kenyon cells (KC). Three types of KC project in five lobes: α/β, α'/β', and γ.

et al., 2006). In *Drosophila*, MBs are composed of three main classes of neurons whose axons divide to form two vertical lobes (α and α') and three median ones (β, β', and γ) (Crittenden et al., 1998) (**Figure 1**).

Brain mutants with MB structural defects were first isolated in the 1980s. Unlimited numbers of animals with the same anatomical defect could be assessed using mutants, without interventionism. This helped to highlight the role of MBs in olfactory learning and memory (Heisenberg et al., 1985). However, one caveat of this approach is that the anatomical defects are generally not specific to the MBs (de Belle and Heisenberg, 1994). An alternative approach was used to generate flies without MBs (de Belle and Heisenberg, 1994). Hydroxyurea, an anti-mitotic agent, was fed to newly hatched wild-type larvae. At this early developmental stage, only five neuroblasts – the neurons' precursor cells – are mitotically active within each brain hemisphere: the four that generate the MBs, and one in the antennal lobe. Thus, hydroxyurea treatment leads to viable adults flies with almost no MBs. These flies turned out to show no olfactory memory (de Belle and Heisenberg, 1994), although abilities to mediate olfactory memory (shock reactivity, olfaction, and locomotor behavior) were intact. Together, these data strongly implicate the MBs in associative olfactory memory.

The essential role of MBs in olfactory memory is further outlined by the high expression in the MBs of many proteins involved in learning and memory, as will be seen.

4.07.2 Short-Lasting Memories

4.07.2.1 The cAMP Pathway Plays a Key Role in Associative Memory

We do not intend to review here in detail all *Drosophila* learning and memory genes, or the various conditioning protocols (for review see Waddell and Quinn, 2001; Dubnau et al., 2003b; Heisenberg, 2003; Davis, 2005; McGuire et al., 2005; Skoulakis and Grammenoudi, 2006). Rather, we will describe the different approaches that have allowed the analysis of *Drosophila* associative memory at the molecular, cellular, network, and systemic levels.

The strength of *Drosophila* molecular genetic tools underlies the discovery and the dissection of new molecular pathways involved in memory. The use of mutants, and in particular the recently designed conditional mutants, is a powerful means to link the molecular, cellular, network, and system levels. The global experimental plan is to generate random single-gene mutations and to select mutants that show a specific learning or memory defect. In the second

step, the aim is to identify the mutated gene and to understand its function in memory (Benzer, 1973). The first screens for *Drosophila* learning and memory mutants were produced by Seymour Benzer and colleagues more than 30 years ago. Four thousand fly stocks carrying ethyl methane sulfonate-induced mutations were tested for their ability to learn in an olfactory conditioning assay (Quinn et al., 1974; Dudai et al., 1976; Quinn et al., 1979). The first *Drosophila* learning and/or memory mutants characterized were *dunce* (*dnc*) and *rutabaga* (*rut*). Biochemical approaches showed that *dnc* flies were deficient in one form of cyclic adenosine monophosphate (cAMP) phosphodiesterase activity (Byers et al., 1981; Davis and Kiger, 1981), and that *rut* flies were deficient in the activity of a Ca^{2+}/calmodulin-sensitive adenylyl cyclase (Livingstone et al., 1984). The current view is that Rut adenylyl cyclase could act during learning as a coincidence detector for the US and CS, because of the ability of adenylyl cyclase to respond to two different types of signals, namely extracellular monoamines and intracellular calcium levels (Livingstone et al., 1984; McGuire et al., 2003).

However, EMS-induced mutations are often difficult to localize in genome, and therefore the main problem with these first learning and/or memory mutants was to identify the mutated gene. The first step consists of genetically mapping the mutation by complementation tests, using *Drosophila*'s deletion collection. This, however, only defines a broad area covering many other genes (Dudai et al., 1976; Livingstone et al., 1984). Thus, the cloning of the responsible gene took years and was facilitated by the use of new mutant alleles induced by the insertion of a transposable P-element. Description of P-element insertions within 200 nucleotides of the *rut* transcription start site identified *rut* as the gene for the Ca^{2+}/calmodulin-responsive adenylyl cyclase (Han et al., 1992; Levin et al., 1992). On the other hand, new EMS-induced *dnc* mutants came from a screen for female sterility mutants (Mohler, 1977). The *dnc* gene was identified by recombinational mapping of *dnc* mutations with restriction site polymorphisms as genetic markers (Davis and Davidson, 1984) and by identification of homologous cDNA clones to known phosphodiesterases (Chen et al., 1986). *dnc* encodes a cAMP-specific-phosphodiesterase II. Another mutant, *amnesiac* (*amn*) mutant, was identified in a screen for flies with affected memory (Quinn et al., 1979). The *amn* gene was later identified thanks to a P-element-induced allele, which acts as a second site suppressor of the *dnc* female sterility phenotype, and has been repeatedly isolated since (Feany and Quinn, 1995; Moore et al., 1998; Toba et al., 1999). The Amn peptide shows some similarity to a putative adenylyl cyclase activating peptide (PACAP). The biochemical activity of Amn is unknown, but both the genetic and molecular evidence suggests that Amn acts through adenylyl cyclase to increase the concentration of cAMP (Feany and Quinn, 1995).

Discoveries of these proteins displaying major roles in memory processes suggested important roles for intracellular cAMP and cell signaling cascade in olfactory learning. Protein kinase A (PKA) being a major effector for cAMP, Drain et al. tested the hypothesis that PKA is involved in memory processes (Drain et al., 1991). PKA is a tetramer composed of two catalytic (C) and two regulatory (R) subunits. In the absence of cAMP, regulatory subunits bind to the catalytic subunits and inhibit their activity, and conversely, at elevated levels, cAMP binds to the regulatory subunits, which then release the catalytic subunits to phosphorylate target proteins. Protein kinase inhibitor (PKI) is a PKA inhibitory peptide that binds the PKA catalytic subunit and prevents its release in response to cAMP. Ubiquitous PKI overexpression disrupts olfactory memory (Drain et al., 1991).

Another approach identified a new mutant of the catalytic subunit gene (DCO) of PKA. Enhancer detection screening is a combination of histological screening and P-element mutagenesis. The modified P-element carries a reporter gene and is randomly inserted in genome by classical techniques of mutagenesis. Screening is based upon the fact that expression of the reporter gene mimics the expression of the endogenous gene where this reporter gene was inserted (**Figure 2**). The aim is to first find by histology lines whose reporter expression pattern includes the MBs. The integrated P-element may disrupt expression of the MB-expressed gene; therefore testing memory performance of the mutant lines identifies new proteins involved in this process. Mutants in the catalytic subunit gene of PKA were isolated by this approach (Skoulakis et al., 1993). Reduction of 80% PKA activity in heteroallelic mutants of DCO generated a memory disruption. The R-type I subunit of PKA is also crucial for associative learning (Goodwin et al., 1997).

An additional study outlining the important role of cAMP signaling in learning and memory came from a study of mutations in neurofibromatosis type 1 (*Nf1*) *Drosophila* homolog. Mutations in the human *NF1* gene cause benign and malignant tumors of the nervous system and generate learning deficits in humans (Ferner et al., 1996; North et al., 1997; Gutmann, 1999). Mice heterozygous for *Nf1*

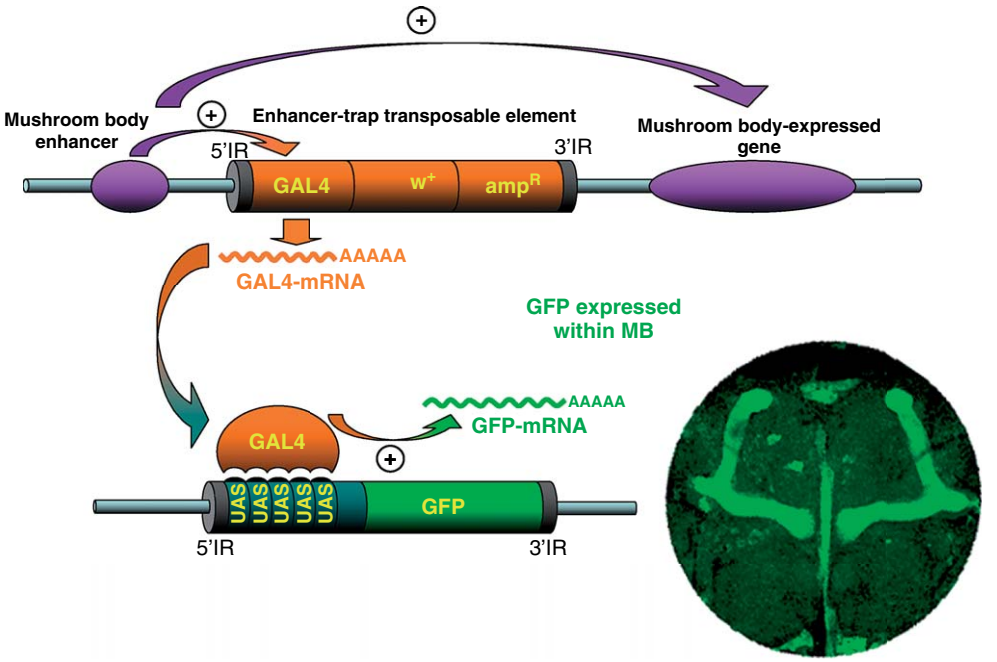

Figure 2 The GAL4/upstream activating sequence (UAS) system. When an enhancer-trap transposable element is inserted near transcription enhancers that control expression in a given structure, the GAL4 gene that is contained in the P-element is expressed in the same structure. If this fly also contains a reporter gene downstream of the UAS sequences, GAL4 will drive transcription of the reporter. GFP, green fluorescent protein; MB, mushroom body.

mutations have an increased predisposition to learning impairment (Silva et al., 1997). The *Drosophila* NF1 protein shows a high degree of conservation with the human protein (60%). Flies lacking NF1 at the adult stage show an olfactory memory defect, suggesting that the human homolog is involved in learning and memory, and memory impairment is not due to developmental defect (Guo et al., 2000). Genetic and biochemical analysis have revealed that NF1 inhibits Ras activity (Cichowski and Jacks, 2001; Zhu and Parada, 2002). Interestingly, NF1 also participates in the activation of adenylyl cyclase, increasing cAMP levels via at least two distinct pathways: by an NF1/Ras-dependent mechanism stimulated by growth factors and by an NF1/Gαs-dependent pathway, acting through Rut (Hannan et al., 2006). By overexpressing a constitutively active PKA catalytic subunit in an *NF1* mutant background, Guo et al. rescued the NF1 memory defect, suggesting the biochemical deficiency in the *NF1* mutants must reside upstream of PKA induction in the cAMP pathway (Guo et al., 2000).

In conclusion, the cAMP is particularly important to support olfactory associative memory. Both a lack (in *rut, DCO, amn, NF1*) or an excess (in *dunce*) of cAMP pathway activity can cause memory impairment, and the learning score of double mutant *dnc*, *rut* is reduced when compared with either single mutants (Tully and Quinn, 1985), which suggests that cAMP levels have to be finely regulated during memory formation to control behavioral plasticity. Alternatively, Dnc and Rut may act in different subsets of neurons.

4.07.2.2 Mushroom Bodies and the cAMP Pathway

Drosophila MBs are required for olfactory learning and memory, and insights from mutants have indicated that the cAMP pathway plays a key role in memory establishment. Nevertheless, until recently it remained to be proved that cAMP metabolism is strictly required in the MBs for learning and memory. A powerful tool for spatial control of gene expression is the GAL4/UAS enhancer-trap technique (Bellen et al., 1989; Wilson et al., 1989; Brand and Perrimon, 1993) (**Figure 2**), which enables selective activation of any cloned gene in a wide variety of tissues and cells. With this system (Brand and Perrimon, 1993), Connolly and colleagues (1996) ectopically stimulated MB cAMP signaling by expressing a constitutively activated Gα_s-protein (Gα_s^*). Permanent adenylyl cyclase activation

specifically in the MBs leads to an impaired associative memory.

That memory is impaired after ablation or functional disruption of a brain structure does not necessarily imply that the memory trace itself is localized within this structure. To localize short-term memory (STM), it was necessary to rescue the memory abilities of a mutant by expressing the corresponding protein in a specific brain structure. As seen earlier (**Figure 1**), MBs are composed of three main classes of neurons. One class of neurons bifurcates to generate one vertical branch in the α lobe and one horizontal branch in the β lobe; another generates one branch in another vertical lobe, the α' lobe, and one in the horizontal β' lobe; and a third class of neurons generates a single projection into the horizontal γ lobe (Crittenden et al., 1998). Zars and colleagues showed that expression of Rut Ca^{2+}/calmodulin adenylyl cyclase (Rut-AC) in γ lobes of MBs, but not in α/β lobes, partially restores a normal learning capacity in *rut* flies (Zars et al., 2000), whereas McGuire et al. reported that Rut-AC has to be expressed simultaneously in γ and α/β lobes to rescue the memory defect due to *rut*. A new recent study indicates that marginal *rut* rescue is observed when cyclase is expressed only in some α/β neurons (depending on the odor pair used for conditioning), an intermediate rescue is observed with γ expression, while a full rescue is obtained with α/β and γ expression (Akalal et al., 2006).

However, in these experiments, Rut was expressed not only in the MBs at the adult stage, but also during development. Thus, the behavioral rescue might have been due to the correction of an MB developmental defect, an indirect cause of the learning defect. To circumvent this hypothesis, techniques have been developed to control spatial and temporal expression of a protein. Using the TARGET and SWITCH methods (**Figure 3**), Ron Davis and his team showed that the presence of Rut in adult $\alpha/\beta/\gamma$ lobes of MBs alone was sufficient to rescue *rut* memory defect (McGuire et al., 2003; Mao et al., 2004).

These discoveries raise a new set of questions. For example, at which step of information processing are the MBs involved: acquisition, consolidation, or retrieval? Do the MBs carry a memory trace or are they a relay? These challenging problems are being solved with new genetic and imaging techniques.

4.07.2.3 Mushroom Bodies Anatomic-Functional Maps

A sophisticated approach to disturb neuronal circuits, based on a rapid and reversible blockage of synaptic

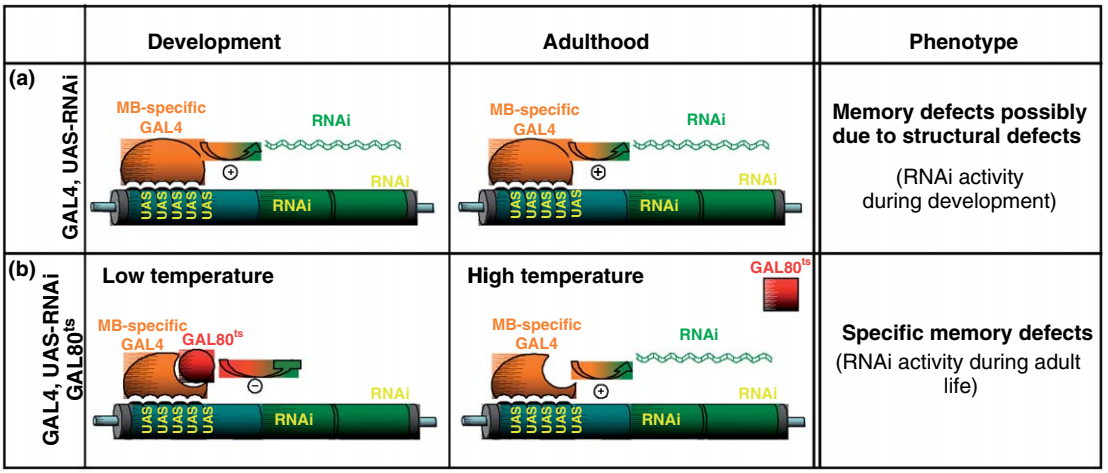

Figure 3 The TARGET technique helps us to discriminate between developmental and adult physiological effects. A sequence encoding an inverted repeat RNA (RNAi) is placed under UAS control. (a) GAL4 activates RNAi expression during development and adulthood. A memory defect could be caused indirectly by structural defects during development. (b) The TARGET system solves this problem. Flies are maintained at low temperature during their developmental stages. At this temperature, $GAL80^{ts}$ inhibits the transcription activity of GAL4, so that no RNAi is expressed. When adults emerge, they are transferred at permissive temperature (30 °C); the $GAL80^{ts}$ protein becomes ineffective and GAL4 activates the transcription of the RNAi in adult MBs. The putative memory defects are due to the decreased concentration of the mRNA targeted by the RNAi. In another use of the TARGET system, Rut expression in adult *rut* mutant background was sufficient to rescue *rut* memory defect (McGuire et al., 2003).

transmission, was developed by Kitamoto (2001). The *shibire* (*shi*) gene encodes a microtubule-associated guanosine triphosphatase (GTPase), dynamin, which is involved in endocytosis and is essential for synaptic vesicle recycling and maintenance of the readily releasable pool of synaptic vesicles. The temperature-sensitive allele, shi^{ts1}, is defective in vesicle recycling at the restrictive temperature (>29 °C), resulting in a rapid blockade of synaptic transmission. The shi^{ts1} mutation has a dominant effect, blocking chemical synapses even in the presence of a normal shi^{+} allele. Expression of the shi^{ts1} tool can therefore be used within the GAL4/UAS system. The GAL4/UAS-shi^{ts1} approach is very powerful, as it allows us to inhibit particular brain circuits at precise times. To determine whether the MBs are required during the acquisition, consolidation or retrieval phases, the temperature-sensitive Shi^{ts1} protein was specifically expressed in MB neurons in order to transiently disrupt synaptic neurotransmission (Dubnau et al., 2001; McGuire et al., 2001; Schwaerzel et al., 2002). It was shown that the synaptic outputs of MB neurons are required during retrieval of the STM but not during acquisition or consolidation. Which of the MB lobe outputs are required for STM retrieval? Two groups implicated mainly α/β and γ neurons (Dubnau et al., 2001; Schwaerzel et al., 2003), while another study suggested that only the α/β neurons were required (McGuire et al., 2001). Using a γ-specific Gal4 driver, we showed that γ neuron output is indeed required for STM and middle-term memory (MTM) retrieval (Isabel et al., 2004). All together, these initial studies indicate that a STM/MTM trace is localized at α/β and γ output synapses or upstream of these synapses. Interestingly, it was shown recently that α'/β' lobes are involved in acquisition and consolidation but not in memory retrieval (Krashes et al., 2007), showing that the MB lobes play very distinct roles.

Taken together, these experiments suggest that associative memory requires the sequential involvement of different subsets of MB neurons: α'/β' lobes for acquisition and consolidation, and $\alpha/\beta/\gamma$ for memory retrieval. However, as seen above, Rut-AC is thought to act as the major temporal integrator of associative learning (Livingstone et al., 1984), and the learning defect of *rut* flies can be totally rescued by expression of Rut-AC only in the $\alpha/\beta/\gamma$ lobes (McGuire et al., 2003; Akalal et al., 2006). This observation is paradoxical with the shi^{ts1}approach, which shows that α'/β' lobes (Krashes et al., 2007), but not $\alpha/\beta/\gamma$ lobes, are required for acquisition. It is possible that α'/β' neurons stimulate α/β or γ neurons. Perhaps the coincidence detection model is too simple, and further studies will be necessary to elucidate this discrepancy.

4.07.2.4 Imaging Mushroom Bodies and Antennal Lobes

One major caveat of *Drosophila* central brain studies is that direct electrophysiological analysis is scarce (Wilson et al., 2004), due to the small size of neuron cell bodies (less than 5 μm in diameter). To circumvent this difficulty, two partially alternative approaches have been followed: analysis of learning and memory mutants at the neuromuscular junction (Zhong and Wu, 1991; Renger et al., 2000), which avoids the complexity of brain physiology, as well as the analysis of isolated MB neurons in culture (Wright and Zhong, 1995). These experimental systems can provide interesting molecular and cellular information, but they are inadequate for assessing neuronal function at the level necessary for a global understanding of memory systems.

Odor processing occurs in a complex tissue environment, and the identification of the repertoire of brain cell assemblies involved in olfactory memory requires visualization of their network activity at high spatial and temporal resolution, in relatively intact preparations. Optical neural activity recordings allow the study of brain activity with micrometer spatial resolution, and activity-sensitive fluorescent probes have been recently used in *Drosophila*. Those sensors are proteins, and their expression can therefore be restricted to specific subsets of neurons with the GAL4/UAS system. Several sensors have been successfully brought to *Drosophila*, including those that monitor the local change of pH that accompanies neurotransmitter release (Yu et al., 2004) or changes in the intracellular calcium concentration that provide a valuable indicator of electrical activity (Aequorin (Rosay et al., 2001); Cameleon (Fiala et al., 2002); Camgaroo (Yu et al., 2003); and G-CaMP (Wang et al., 2003, 2004b)). Using the G-CaMP reporter and two-photon microscopy, stereotyped odor-evoked patterns have been observed in the antennal lobe glomeruli (Wang et al., 2003) and in the MBs (Wang et al., 2004b).

The ultimate goal of future imaging studies is to build a functional map of cell assemblies encoding memory in different regions of *Drosophila* brain, by comparing the activity of trained and naive animals, in normal flies or memory mutants. A first step, achieved as a transient change in the spatial code, was

observed in the antennal lobe of wild-type flies 3 min after olfactory associative conditioning (Yu et al., 2004). What happens to MB calcium concentrations during memory processes? The G-CaMP reporter was driven in α/β lobes to assess whether these lobes, which are functionally active during memory retrieval (McGuire et al., 2001; Isabel et al., 2004; Akalal et al., 2006), present an odor-evoked calcium signal dependent on associative short-lasting memory (Yu et al., 2006). Surprisingly, although calcium responses to odor and electric shock can readily be detected in the α/β neurons, one pairing of odor and electric shock did not alter odor-evoked calcium concentration in these neurons. Yu et al. suggest two alternative explanations. Firstly, short-lasting memory traces are not formed in α/β neurons but in other types of MB neurons such as α'/β' lobes, a hypothesis which fits with *shi*^{ts1}experiments driven in α'/β' neurons (Krashes et al., 2007), and/or γ lobes (Yu et al., 2006). Secondly, short-lasting memory traces might be produced by calcium-independent cellular mechanisms (Yu et al., 2006).

4.07.2.5 Around the Mushroom Bodies

MBs are innervated by two groups of well-characterized amnesiac and dopaminergic neurons that are involved in olfactory associative memory: dopaminergic neurons (DNs) and the dorsal paired median (DPM) neurons that express the Amn peptide.

4.07.2.5.1 Dopaminergic neurons are required for aversive conditioning

Dopamine (DA) is a neuromodulator that is involved in appetitive reinforcement in mammals (Mirenowicz and Schultz, 1996) and in *Aplysia* (Brembs et al., 2002). It has been known for a while that *Drosophila* synthesizes DA (Hirsh and Davidson, 1981; Livingstone and Tempel, 1983; Wright, 1987; Neckameyer and Quinn, 1989). The recent genetic and imaging tools developed in *Drosophila* allow us to assess the roles of DA in learning and memory. Based on the fact that tyrosine-hydroxylase (TH) is the rate-limiting step in DA biosynthesis, a Gal4-driver whose expression mimics that of TH was tested (Friggi-Grelin et al., 2003). This tool has allowed the identification of six neuronal dopaminergic clusters that project in particular to MBs and to the central complex (Friggi-Grelin et al., 2003), confirming earlier TH and DA immunolabeling studies (Nassel and Elekes, 1992). By combining the TH-GAL4 driver and UAS-Shi^{ts1}, Schwaerzel et al. showed that blocking DNs only during acquisition disrupts STM (Schwaerzel et al., 2003). Thus DNs are required for aversive conditioning, and could convey US (in this case, electric shock) information (Schwaerzel et al., 2003). Another study has shown that in naive flies, electric shock generates a strong activity in the DNs, whereas the odor generates a weak signal. However, after several pairings between the odor and the shock, odor-evoked activity is significantly prolonged. In agreement with the behavioral approach (Schwaerzel et al., 2003), *in vivo* imaging therefore suggests that DNs play a role in aversive conditioning in *Drosophila* (Riemensperger et al., 2005). To study if the activation of DNs is sufficient to mediate the aversive cue, Schroll et al. have developed a technique to remotely stimulate DNs. By expressing a light-activated cation channel (channelrhodopsin-2), in larvae, DNs can be stimulated specifically by illuminating the larvae with blue light. The authors used a discriminatory learning paradigm: one odor (CS^+) is associated with a reinforcing salt stimulus as the aversive US, while another odor (CS^-) is presented without salt (Gerber and Hendel, 2006). Interestingly, the reinforcing salt stimulus could be replaced functionally by DN activation with blue light. DNs are therefore sufficient to convey the US for aversive conditioning (Schroll et al., 2006).

4.07.2.5.2 Dorsal paired median neurons are required for consolidation

Although *amn* is an MTM mutant (Quinn et al., 1979) putatively involved in cAMP metabolism (Feany and Quinn, 1995), Amn is not expressed in the MB but in the DPM neurons which project onto all the MB lobes (Waddell et al., 2000). In the *amn* mutant, expression of wild-type Amn in the DPM neurons re-establishes normal MTM (Waddell et al., 2000). Conversely, when Shi^{ts1} is expressed at restrictive temperature into DPM, MTM is affected (Waddell et al., 2000). Blocking the DPM during the consolidation phase only (Keene et al., 2004), and more precisely, 30 min after conditioning (Keene et al., 2006), phenocopies the *amn* mutant memory defect (Waddell et al., 2000). Scott Waddell's group has used an elegant approach to determine the site of action of DPM neurons projecting onto the MBs. By driving Dscam expression, a protein involved in axonal guidance (Wang et al., 2002), in the DPM neurons during development, DPM innervation of the $\alpha/\beta/\gamma$ lobes is disrupted. However, those flies show normal memory, indicating that MTM is stabilized in α'/β' lobes in response to DPM. Co-expression of Dscam

and Shi^{ts1} abolishes memory (Keene et al., 2006) and confirms the role of the α'/β' lobes during memory consolidation. Also, as mentioned above, Amn might activate an adenylyl cyclase. Thus, Amn could activate Rut via a G-protein-coupled receptor, in order to extend MTM. However, *rut* MTM is rescued when Rut is specifically expressed in the $\alpha/\beta/\gamma$ lobes of the MBs, even though Amn stimulates the α'/β' lobes. It is therefore difficult to imagine that Amn is directly involved in Rut activation, unless Amn diffuses into the $\alpha/\beta/\gamma$ lobes. Since it is likely that DPM neurons also synthesize acetylcholine (Keene et al., 2004), it is possible that this transmitter is directly involved in the stimulating MBs.

Yu et al. took an imaging approach to study the function of the Amn-expressing DPM neurons in memory. DPM neurons respond to both the shock (the US) and to the odor (the CS), and pairing the CS and the US increases odor-evoked calcium signals in the same time window during which DPM neuron synaptic transmission is required for normal memory (Yu et al., 2005). Interestingly, the delayed olfactory memory trace of DPM neuron processes that innervate the vertical lobes is branch-specific (Yu et al., 2005). Conclusions from the behavioral experiments using Shi^{ts1} (Waddell et al., 2000; Keene et al., 2004, 2006) are therefore strengthened by imaging. One hypothesis is that the α'/β' neurons and the DPM neurons form a mutually reinforcing loop that is necessary for this consolidation (Krashes et al., 2007).

4.07.3 Anatomical, Molecular, and Systemic Analysis of Consolidated Memories: Anesthesia-Resistant Memory and Long-Term Memory

4.07.3.1 Anesthesia-Resistant Memory

As described earlier, ARM is a semi-stabilized memory that can be generated either by a single training cycle or massed training (ARM is a subset of total memory, whose proportion increases with time after training, conversely to ASM).

4.07.3.1.1 Anesthesia-resistant memory is localized in mushroom bodies

MBs are involved in acquisition, consolidation, and retrieval of short-lasting memory, but does ARM depend on MBs? To assess the anatomical location of ARM, flies whose different MB neurons were blocked by Shi^{ts} were trained for one cycle, submitted 1 h afterward to a cold shock to disrupt ASM, and tested 1 h after that to measure ARM. When α/β neurons are blocked, ARM is almost totally abolished, whereas γ neuron blockade does not disrupt ARM. Thus we showed that ARM generated after one training cycle relies mainly on α/β neurons MBs (Isabel et al., 2004).

4.07.3.1.2 Molecular pathways

4.07.3.1.2.(i) Radish *Radish* (*rsh*) is a mutant whose residual memory is erased by cold-shock anesthesia (Folkers et al., 1993). Thus *rsh* is specifically deficient in ARM, and it is the only currently known mutant that presents this characteristic. The *rsh* gene was localized within a 180-kb interval in the 11D-E region of the X chromosome, and several candidate genes were identified (Folkers et al., 1993). Recently, Josh Dubnau's group reported that the gene responsible for the *rsh* phenotype was a phospholipase A2 (PLA2), whose expression could rescue the mutant defect (Chiang et al., 2004). However, this rescue experiment could not be reproduced, and it turned out that PLA2 maps 95 kb outside the behaviorally determined deletion interval (Folkers et al., 2006). Instead a second team has reported that *rsh* encodes a novel protein, corresponding to the predicted gene CG15720, and containing possible nuclear localization motifs and 23 predicted PKA and 14 predicted PKC phosphorylation sequences (Folkers et al., 2006). Expression of this gene under the control of an inducible heat-shock promotor in a *rsh* background restores normal ARM (Folkers et al., 2006). The Rsh protein is highly expressed in the MBs (Folkers et al., 2006), which corroborates the behavioral localization of ARM (Isabel et al., 2004).

4.07.3.1.2.(ii) Atypical protein kinase M The atypical protein kinase M (aPKM) is a persistently active truncated isoform of atypical protein kinase C (aPKC). Overexpression of either a mouse or *Drosophila* aPKM transgene enhances memory after massed conditioning, but not after spaced training (Drier et al., 2002). It is therefore conceivable that aPKC is a molecular component of ARM. Because this effect is not blocked in a *rsh* background, the authors proposed that PKM acts downstream of *rsh*. In support of this, inhibition of aPKM disrupts consolidated memory after massed conditioning (Drier et al., 2002).

4.07.3.2 Long-Term Memory

4.07.3.2.1 Long-term memory is localized in vertical lobes of mushroom bodies

MB lobes are known to be required to form short-lasting memory: α'/β' lobes for acquisition and consolidation and $\alpha/\beta/\gamma$ for retrieval. Are MBs involved in LTM? We have identified in our lab the *alpha-lobes absent* (*ala*) mutant, which shows abnormal MB anatomy (Boquet et al., 2000). This mutant shows a particularly unusual MB phenotype: 10% of *ala* individuals possess all five MB lobes, 36% lack the horizontal β and β' lobes, and 4.5% lack vertical α and α' lobes (the remaining subpopulations present different MB phenotypes in the left and the right hemispheres) (Pascual and Preat, 2001). The *ala* mutant flies were trained according to the three following procedures: the short protocol, massed protocol, and long protocol. We analyzed separately the brains of flies that had made the correct and the wrong choice during the memory test, to calculate the memory score of each class of *ala* mutants. The *ala* flies lacking α/α' lobes display a normal STM and ARM, but no LTM at 24 h (Pascual and Preat, 2001) or 5 h (Isabel et al., 2004) after spaced conditioning. Thus, MBs, and more precisely, the α/α' vertical lobes, are necessary to form LTM (Pascual and Preat, 2001). By expressing Shi^{ts1} in α/β lobes, it was further shown that α lobe outputs are required during LTM retrieval (Isabel et al., 2004). Is there an LTM trace in the α vertical lobes?

The G-CaMP reporter was driven in α/β neurons to analyze whether these lobes present an odor-evoked calcium level dependent on associative long-lasting memory (Yu et al., 2006). Whereas α/β neurons presented no increase in calcium during STM, α branches, but not β branches (which belong to the same group of neurons), present an increase in response to conditioned odor after spaced conditioning. This result corroborates the behavioral data (Pascual and Preat, 2001; Isabel et al., 2004). Moreover, Ron Davis's group has shown that this increased calcium signal is blocked after inhibition of protein synthesis, and also by the expression of the inhibitory form of the transcription factor Creb (see next section for details), which blocks LTM (Yu et al., 2006). The authors confirmed that *amn* is required to form LTM, as the mutant fails to increase calcium activity after LTM conditioning (Yu et al., 2006). The hypothesis that DPM neurons participate in LTM consolidation is supported by the observation of a delayed memory trace in the DPM neurons that innervate vertical lobes (Yu et al., 2005, 2006).

4.07.3.2.2 Molecular pathways

4.07.3.2.2.(i) Transcriptional regulation

4.07.3.2.2.(i).a Creb

PKA, in response to increased cAMP, is believed to activate a subset of Creb family proteins in the nucleus (Bacskai et al., 1993) that could in turn activate gene expression required for LTM. The *Drosophila* Creb family gene produces seven alternatively spliced isoforms, among which is a PKA-responsive transcriptional factor (dCreb-a) and another that is an antagonist of the PKA-responsive transcription (dCreb2-b) (Yin et al., 1995). LTM is disrupted by dCreb2-b repressor overexpression (Yin et al., 1994; Perazzona et al., 2004), likely due to inhibition of the gene expression required to establish LTM. Yin and colleagues reported that flies overexpressing the dCreb2-a activator generated LTM after a single training cycle (Yin et al., 1995). However, this result could not be replicated, and it was shown that the original dCreb2-a transgenic flies carried an accidental mutation that produced a truncated protein with no DNA binding domain (Perazzona et al., 2004). Moreover, ubiquitous adult induction of the correct Creb2-a isoform led to lethality (Perazzona et al., 2004), likely because of ectopic expression of downstream proteins. The exact role of Creb in LTM formation therefore remains to be elucidated.

4.07.3.2.2.(i).b Notch

Notch is a signaling receptor controlling cell fate determination and pattern formation in development (Artavanis-Tsakonas et al., 1999). This transmembrane protein is cleaved in response to ligands such as Delta. Its cytoplasmic part can enter the nucleus to promote regulation of gene expression (Kidd et al., 1998; Schroeter et al., 1998; Struhl and Adachi, 1998). Besides its involvement in development, Notch is required for the regulation of neurite outgrowth in the adult mammalian brain (Sestan et al., 1999). Because of this role in neural ultrastructure regulation, and thus potentially in neuronal plasticity (Wang et al., 2004a) and memory (Costa et al., 2003) in mammals (for review, see Costa et al., 2005), its role in associative memory in *Drosophila* was assessed independently by two teams (Ge et al., 2004; Presente et al., 2004). To circumvent developmental roles of Notch, inducible Notch

manipulations were performed at the adult stage. A temperature-sensitive Notch mutant allele and a dominant-negative Notch mutant displayed intact STM and ARM and impaired LTM when adult flies were submitted to the nonpermissive temperature for 2 days (Ge et al., 2004; Presente et al., 2004). Because these experiments do not demonstrate where Notch is required in the brain, the authors used RNAi-mediated Notch repression, restricted to the MBs by means of an MB-specific driver. MB Notch impairment led to an LTM defect (Presente et al., 2004). Finally, overexpression of a wild-type copy of Notch generates a protein synthesis-dependent memory resembling LTM after only one or two spaced training cycles, a protocol that normally induces only short-lasting memories (Ge et al., 2004). The identity of the Notch ligand(s), and the downstream gene(s) regulated by Notch signaling during LTM, remain to be discovered.

4.07.3.2.2.(ii) Translational regulation

4.07.3.2.2.(ii).a Staufen/pumilio pathways

Dubnau and colleagues (Dubnau et al., 2003a) tested a behavioral screen for LTM mutants, parallel to microarray experiments aimed to select genes with altered expression after LTM training. This work led to the identification of several proteins involved in mRNA processing as well as in translation (Dubnau et al., 2003a): (1) Pumilio is a protein known to act as a transcript-specific translational repressor, regulating localized mRNA translation in oocytes; (2) Staufen and Oskar mediate the translocation of several proteins to posterior poles of oocytes; and (3) eIF-5C is a translation initiation factor. In the adult brain, these genes are preferentially expressed in the MB. Disruption of either of these four genes impairs LTM. Thus LTM requires local mRNA translation regulation, possibly postsynaptically in the MB calyces or presynaptically in the vertical lobes.

4.07.3.2.2.(ii).b RNA-induced silencing complex

In an elegant study, Ashraf et al. (2006) showed that protein synthesis at the synapse is required for LTM, and that LTM formation depends on calcium/calmodulin-dependent kinase II (CaMKII) signaling, a pathway also implicated in synaptic plasticity in mammals (Kelleher et al., 2004). By driving the expression of a tagged CaMKII in projection neurons that link olfactory sensory neurons to MBs, they showed that the recruitment of CaMKII to postsynaptic sites in the antennal lobe glomeruli is required to induce LTM (Ashraf et al., 2006). By performing this expression in different mutant backgrounds, they further showed that synaptic protein synthesis is regulated by the RNA interference silencing complex (RISC).

4.07.3.2.2.(iii) Posttranslational regulation of long-term memory formation

4.07.3.2.2.(iii).a Crammer

We have described *crammer* (*cer*), a gene involved specifically in the formation of LTM (Comas et al., 2004). The *cer* mutant has reduced LTM but normal STM, MTM, and ARM. Interestingly, in the wild-type strain, *cer* expression is transiently reduced 3 hours after LTM training. As the Cer peptide is an inhibitor of cysteine proteinases, the decrease in its expression shortly after intensive training must lead to a transient activation of its cysteine proteinase(s) target(s) (Comas et al., 2004). The overexpression of *cer* in glial cells but not in MB neurons induces an LTM decrease, indicating that glial cells expressing *cer* might be involved in LTM formation. However, in this experiment Cer is overexpressed during development, and further experiments should be carried out to disrupt or overexpress Cer specifically during the adult stage in glia cells. Whether Cer is secreted to act on MB neurons or whether Cer is involved only within glial cells also remains to be resolved. In conclusion, this work suggests that regulation of cysteine proteases is required to perform LTM, possibly in glia cells surrounding the MBs (Comas et al., 2004).

4.07.3.2.2.(iii).b Tequila

Mutations in the human neurotrypsin gene are associated with nonsyndromic mental retardation (MR) (Molinari et al., 2002). An important question is whether the MR generated by this mutation is a consequence of a brain development defect and/or a consequence of a physiological plasticity defect. To address this question, we took advantage of the high degree of homology between the human and the fly genomes, and the genetic tools offered by the fly model. Tequila (teq), a serine protease, is the *Drosophila* ortholog of the human neurotrypsin. First, we showed that a constitutive *teq* mutant has normal STM and ARM, but presents an LTM defect. To study whether Teq regulation for LTM processing is required in the MBs, RNAi-mediated Teq inhibition was induced in these structures. LTM in these flies was specifically impaired. To further study

whether Teq is required only in the adult stage or during development, the inducible Gene-Switch system was used to disrupt Teq specifically in adult stage. LTM was disrupted, but not STM or ARM, which conclusively demonstrates that Teq is required for the plasticity process and not for development. Is Teq transcription finely regulated during LTM formation? Levels of Teq mRNA in adult heads were measured at different times after spaced conditioning and showed an approximately 30-fold increase 4 h after training. This increase took place in MBs, especially in the MB peduncle (a dense structure where axons project before giving rise to lobes), as shown by immunostaining 5 h after training. Interestingly, transient Teq silencing in the adult stage, before but not during training, had no impact on LTM, showing that LTM impairment is reversible if Teq is naturally expressed *de novo* after artificial disruption. We conclude that this serine protease is required for information processing and functional plasticity in *Drosophila* and could have a preponderant role in postnatal cognition processes in children (Didelot et al., 2006).

4.07.3.3 Dynamics of Memory Phases

The short protocol induces two labile phases: STM, which is disrupted in mutants affected for cAMP metabolism and lasts about 30 min, and MTM, which is disrupted in *amn* flies and lasts for a few hours. STM and MTM are both anesthesia-sensitive, as they are erased if flies are cooled down to 4 °C after conditioning. This property suggests that STM and MTM are sustained by brain electrical activity.

LTM is induced by the long protocol and can be measured for at least 1 week. What are the dynamics of memory phase interaction in *Drosophila*? In a previous model, information acquired during learning is processed into consolidated memories (ARM and LTM) by passing sequentially through two earlier memory phases (STM and MTM) (Tully et al., 1994). In contrast, we recently proposed a model that involves two parallel memory pathways, one with cAMP-dependent STM/MTM, and the other with ARM (**Figure 4**). Indeed, *dnc* and *rut* retain a significant level of early memory (Tully and Quinn, 1985), suggesting that an adenyl cyclase-Rut-independent learning might exist. Moreover, ARM levels in *rut*, *amn* are close to normal (Folkers et al., 1993; Tamura et al., 2003; Isabel et al., 2004), while their labile memories are strongly affected. Thus ARM does not seem to depend on STM/MTM as

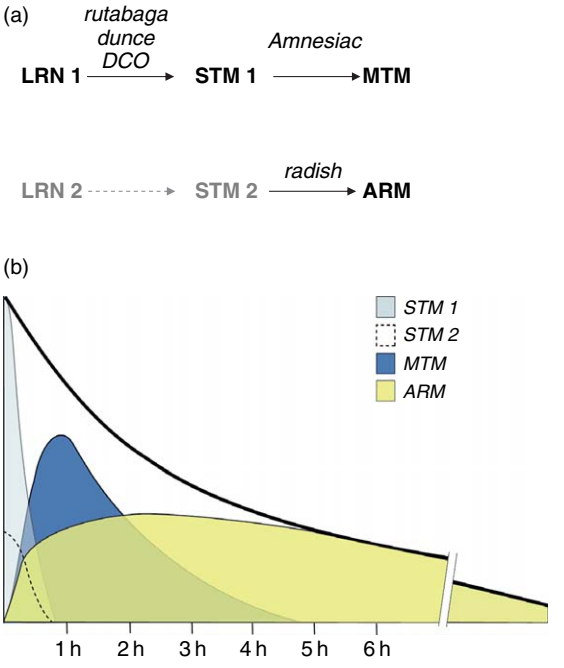

Figure 4 Model of associative memory phases (a) and temporal dynamics of memory phases (b) generated by a single cycle of conditioning (short protocol). LRN, learning; STM, short-term memory; MTM, middle-term memory; ARM, anesthesia-resistant memory; DCO, catalytic subunit gene.

previously suggested (Tully et al., 1994). Instead a second learning process could give rise to an STM 2 phase and later to ARM (**Figure 4**).

What are the relationships between ARM and LTM? To answer this question, the *ala* mutant was trained with the long protocol, and the memory of flies lacking vertical α/α' lobes was measured at 30 min and 5 h after the training. The 30-min memory was normal, but, surprisingly, the 5-h memory was close to zero. Memory performance was normal at 5 h when flies without vertical lobes were trained with the short protocol (Isabel et al., 2004) (**Figure 5**). Why does a longer training cycle give rise to weaker memory? The *ala* flies display no LTM because they lack the vertical lobes, the center for LTM. These flies show a normal ARM 5 h after the short protocol, but no ARM after the long protocol. This result suggests that ARM is erased after LTM conditioning. Thus the consolidated memory phases generated by olfactory conditioning are exclusive (**Figure 6**) (Isabel et al., 2004). Why is ARM erased after LTM conditioning? We propose that ARM could act as a gating mechanism for LTM formation, avoiding a heavy cascade of gene expression in absence of intensive spaced conditioning.

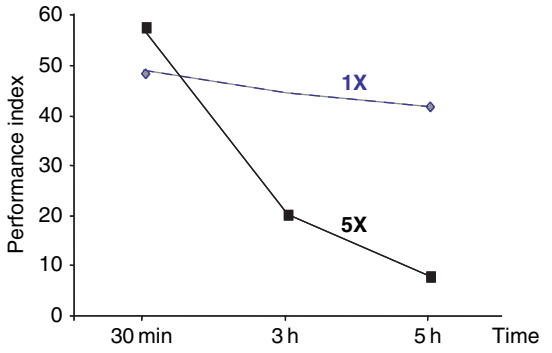

Figure 5 In flies without MB alpha lobes, which normally sustain long-term memory, the long protocol decreases memory performance at 5 h in comparison with the short protocol. Grey line, short protocol; black line, long protocol.

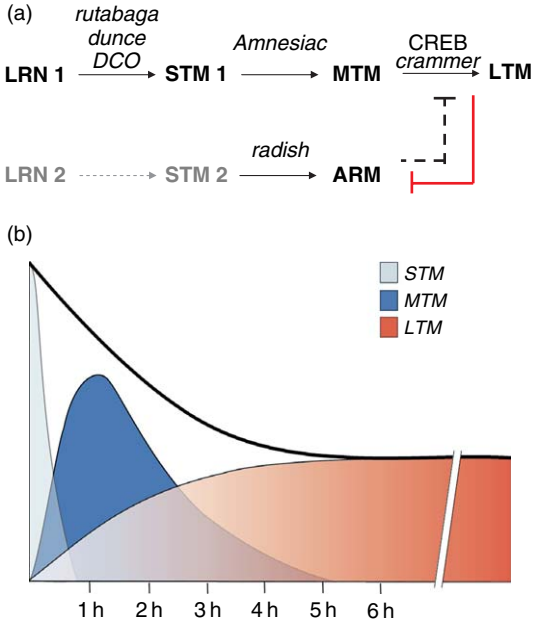

Figure 6 Model of associative memory phases (a) and temporal dynamics of memory phases (b) generated by five cycles of conditioning (long protocol). LRN, learning; STM, short-term memory; MTM, middle-term memory; ARM, anesthesia-resistant memory; LTM, long-term memory.

Despite the relative simplicity of the *Drosophila* brain, this model suggests a cognitive complexity more frequently associated with mammalian models. It supports the idea that *Drosophila* is a valid model to study some of the molecular and cellular mechanisms involved in normal or pathological human memory (Shulman et al., 2003).

4.08 Molecular Mechanisms of Associative Learning in *Hermissenda*

T. Crow, L.-M. Tian, and J.-J. Xue-Bian, University of Texas Medical School, Houston, TX, USA

4.08.1 Introduction

A central focus in the history of studies of mentation is on how basic associations are formed and retained in memory. This characteristic of memory has been addressed from a descriptive perspective by the laws of association: similarity, contrast, and contiguity proposed by Aristotle, and further expanded by the philosophical school of British Associationism led by Locke, Berkeley, and Hartley (Watson, 1968). These early formulations led to a further elaboration of the role of contiguity in memory to include both simultaneous and successive associations. Within this historical context it is not surprising that the law of association by contiguity became the mainstay of several theories of learning proposed by behaviorists (Hilgard and Bower, 1966). Associations formed by contiguity are an essential feature of Pavlovian conditioning. Within the Pavlovian tradition, the response to the conditioned stimulus (CS) was conditional upon its pairing with the unconditioned stimulus (US), and the transfer of the response-evoking properties of the US to the CS as a result of pairing (contiguity) provided the critical evidence in support of the formation of an association in memory. In part, due to the detailed knowledge of the anatomy of sensory systems and the experimental control over the timing of stimulation of specific sensory pathways, Pavlovian conditioning paradigms have provided the opportunity to study the mechanisms underlying the formation of basic associations in memory at a cellular, synaptic, and molecular level. There is now a rich data base on Pavlovian conditioning generated from diverse species that represents sufficient complexity characteristic of different forms of memory.

The primary focus of cellular and molecular studies of Pavlovian conditioning has been on nondeclarative or procedural memory that is expressed by performance not dependent upon conscious recall. Recent studies of eyeblink conditioning employing trace procedures have explored the role of Pavlovian conditioning in declarative or conscious memory systems (Clark et al., 2002). The analysis of Pavlovian conditioning in the less complex nervous systems of higher invertebrates has been useful in elucidating the sites of memory storage, leading to an analysis of mechanisms of memory that underlie well-documented examples of associative learning.

The nudibranch mollusk *Hermissenda crassicornis* is one preparation that has contributed to an understanding of Pavlovian conditioning at the cellular, molecular, and systems levels. Pavlovian conditioning

in *Hermissenda* involves changes in intrinsic excitability and synaptic efficacy at multiple sites within the neural circuit supporting the generation of the conditioned response (CR). The modifications produced by Pavlovian conditioning involve the engagement of multiple cellular mechanisms within identified sensory neurons (photoreceptors) and interneurons that are expressed by alterations in the properties of channels in excitable membranes. Initial acquisition and long-term retention involve both presynaptic and postsynaptic mechanisms. The actions of several second messenger systems contribute to both acquisition and retention of associative memory. Short-term memory involves posttranslational modifications of proteins by several signaling pathways and is expressed by changes in both synaptic connections and intrinsic excitability. Intermediate-term memory requires translation and posttranslational modifications, but not transcription. Long-term memory requires posttranslational modifications, new mRNA and protein synthesis, and structural modifications and is expressed by long-term changes in intrinsic cellular excitability and synaptic efficacy.

4.08.2 Pavlovian Conditioning

Classical conditioning of *Hermissenda* follows the Pavlovian tradition where the CS and US elicit different responses prior to training. Stimulation of the CS and US pathways conveys different sensory information to the central nervous system. Before conditioning, light, the CS, does not elicit either of the unconditioned responses (UCRs) that have been studied in *Hermissenda:* foot-shortening and inhibition of forward ciliary locomotion. Stimulation of statocyst hair cells of the graviceptive system using rotation or orbital shaking, the US, elicits foot-shortening and a reduced rate of forward ciliary locomotion (Alkon, 1974; Crow and Alkon, 1978; Farley and Alkon, 1982; Lederhendler et al., 1986; Matzel et al., 1990b). Pavlovian conditioning produces both light-elicited inhibition of ciliary locomotion, which results in a suppression of *Hermissenda's* normal positive phototaxis (Crow and Alkon, 1978, 1980; Crow and Offenbach, 1983; Crow, 1985a), and CS-elicited foot-shortening (Lederhendler et al., 1986) (see **Figure 1**).

Both conditioned foot contraction and inhibition of ciliary locomotion involve the development or emergence of a new response to the CS, not the potentiation, through US presentations, of an already existing response to the CS referred to as alpha conditioning or reflex potentiation (e.g., Schreurs, 1989; Sahley and Crow, 1998). In both of the CRs there is a transfer of functional aspects of the response-evoking properties of the US to the CS (Crow and Alkon, 1978; Lederhendler et al., 1986;

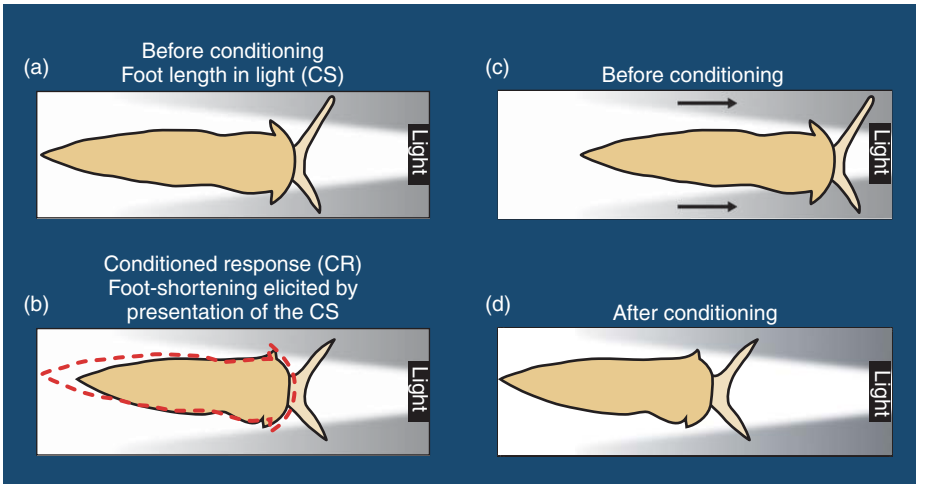

Figure 1 Pavlovian conditioning of foot-shortening and phototaxic inhibition in *Hermissenda.* (a) Foot length in light (CS) before conditioning. (b) CR foot-shortening elicited by the CS. Red outline indicates foot length in light before conditioning. (c) Light-elicited ciliary locomotion toward a light source (phototaxis) assessed before conditioning. (d) Inhibition of light-elicited ciliary locomotion detected after Pavlovian conditioning. Random or pseudorandom presentations of the CS and US do not produce either inhibition of ciliary locomotion or CS-elicited foot-shortening. Figure adapted from Crow T (2004) Pavlovian conditioning of *Hermissenda*: Current cellular, molecular, and circuit perspectives. *Learn. Mem.* 11: 229–238; used with permission from Cold Spring Harbor Laboratory Press.

Matzel et al., 1990b). The two CRs are proposed to develop independently (Matzel et al., 1990b), which is consistent with results showing that the neural circuitry supporting foot contraction and ciliary locomotion consists of different neuronal components (Crow and Tian, 2003a,b) (see the section titled 'Neural circuitry'). Retention of conditioned behavior persists for several days to weeks, depending upon the number of conditioning trials presented in initial acquisition (Crow and Alkon, 1978; Alkon, 1983; Harrigan and Alkon, 1985).

Pavlovian conditioning in *Hermissenda* has been shown to express many of the characteristics of Pavlovian conditioning in vertebrates, such as extinction (Richards et al., 1984), CS specificity (Crow and Offenbach, 1983), and conditioned inhibition (Britton and Farley, 1999). Conditioning is dependent upon the temporal association of the CS and US, involving both contiguity (Crow and Alkon, 1978) and contingency (Farley, 1987a,b). Extra CS and US presentations inserted into a sequence of CS-US pairings attenuate conditioning (Farley, 1987a). Conditioning in the two different behavioral response systems supporting the two CRs is sensitive to both CS-US contiguity and forward inter-stimulus-interval manipulations (Matzel et al., 1990c).

4.08.3 Neural Circuitry

The anatomy and synaptic organization of the two sensory structures (visual and graviceptive) mediating the CS and US have been described in detail (Alkon and Fuortes, 1972; Alkon, 1973a,b; Alkon and Bak, 1973; Detwiler and Alkon, 1973). In addition, many of the sites of convergence providing for synaptic interactions between the CS and US pathways have been identified (Alkon, 1973a,b; Alkon et al., 1978; Akaike and Alkon, 1980; Crow and Tian, 2000, 2002a,b, 2003a, 2004, 2006). Light produces a depolarizing generator potential and an increase in spike activity in the five photoreceptors in each eye (Dennis, 1967; Alkon and Fuortes, 1972). The primary sensory neurons of the pathway mediating the US consist of the 13 hair cells in each gravity-detecting statocyst. Rotation or gravity produces a depolarizing generator potential and an increase in the spike frequency of the stimulated hair cells (Alkon, 1975). There are multiple sites of convergence between the CS and US pathways.

1. The first site is between the primary sensory neurons, photoreceptors, and hair cells. Statocyst hair cells project monosynaptically to photoreceptors and receive monosynaptic input from photoreceptors (**Figure 2**). Stimulation of statocyst hair cells elicits a monosynaptic GABAergic (GABA: gamma-aminobutyric acid) inhibitory postsynaptic potential (IPSP) in type B photoreceptors (Alkon et al., 1993; Sakakibara et al., 1993; Blackwell, 2002a).

2. It has been proposed that hair cells also project polysynaptically to photoreceptors through a serotonergic modulatory pathway based upon behavioral, physiological, and immunohistochemical studies (Crow and Bridge, 1985; Land and Crow, 1985; Auerbach et al., 1989; Farley and Wu, 1989; Grover et al., 1989;

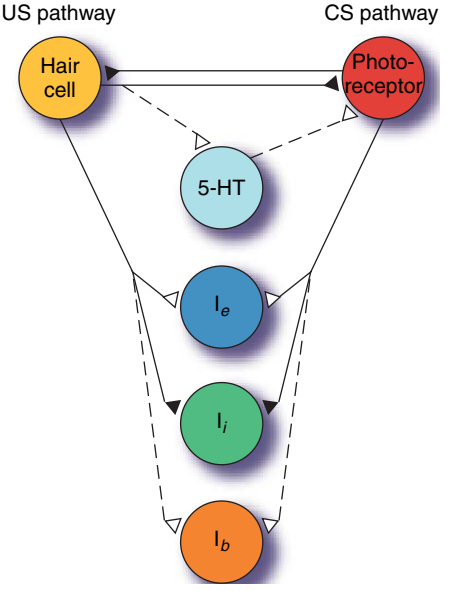

Figure 2 Sites of convergence between identified components of the CS and US pathways that result in intrinsic cellular plasticity in photoreceptors and type I_e interneurons, and proposed plasticity in type I_b interneurons. Statocyst hair cells project directly (monosynaptic) and indirectly (polysynaptically) through proposed serotonergic interneurons (5-HT) to identified photoreceptors. Caudal hair cells inhibit photoreceptors, and cephalic hair cells are inhibited by type B photoreceptors. Hair cells and photoreceptors form monosynaptic connections with type I_e and type I_i interneurons and form polysynaptic connections with type I_b interneurons. (▲) Inhibitory synaptic connections; (Δ) excitatory synaptic connections. Solid lines represent established monosynaptic connections, and dashed lines polysynaptic connections, with potential interneurons not yet identified. Figure adapted from Crow T (2004) Pavlovian conditioning of *Hermissenda*: Current cellular, molecular, and circuit perspectives. *Learn. Mem.* 11: 229–238; used with permission from Cold Spring Harbor Laboratory Press.

Crow and Forrester, 1991; Acosta-Urquidi and Crow, 1993; Rogers and Matzel, 1995; Yamoah and Crow, 1995, 1996; Tian et al., 2006). Serotonergic-immunoreactive varicosities encircle the optic nerve before entry into the cerebropleural ganglion (Land and Crow, 1985). However, the source of the serotonergic input to the photoreceptors has not yet been identified.

3. Statocyst hair cells and photoreceptors also form monosynaptic connections with type I_e and I_i interneurons (Akaike and Alkon, 1980; Crow and Tian, 2000, 2002a) and polysynaptic connections with type I_b interneurons (Crow and Tian, 2003a, 2004) (**Figure 2**).

The CS modulates ciliary locomotion through monosynaptic connections between photoreceptors and type I_e and I_i interneurons and polysynaptic connections between photoreceptors and type III_i inhibitory interneurons (see **Figure 3**). Type III_i inhibitory interneurons form monosynaptic connections with identified ciliary motor neurons located in the pedal ganglia. Activation of ciliary motor neurons is produced by a light-dependent reduction in the spike activity of type III_i inhibitory interneurons. Ciliary locomotion is reduced or inhibited by the US due to hair cell excitation of type I_e interneurons that in turn excite type III_i inhibitory interneurons, resulting in inhibition of ciliary motor neurons. An additional pathway that may modulate ciliary locomotion is the monosynaptic excitatory projections from type I_b interneurons to ciliary motor neurons (Crow and Tian, 2004). Interneurons projecting to motor neurons that innervate the foot have also been identified and have provided for the analysis of reflex movements of the foot modified by Pavlovian conditioning (Goh and Alkon, 1984, Goh et al., 1985; Crow and Tian, 2004).

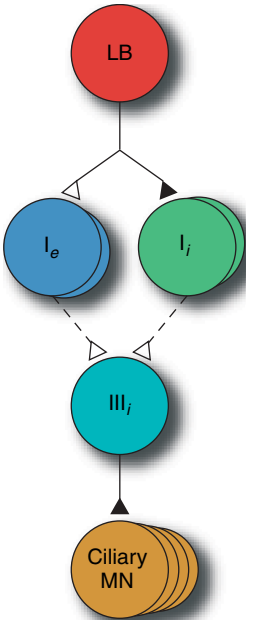

Figure 3 Components of the circuit involved in visually mediated ciliary locomotion in *Hermissenda.* Only synaptic connections with a single type B photoreceptor (LB) are shown. Monosynaptic connections are depicted by solid lines, and polysynaptic connections with dashed lines. Filled triangles denote inhibitory synapses, open triangles excitatory. As shown in the circuit diagram, identified photoreceptors project directly to aggregates of 'on' and 'off' neurons: type I_e and I_i interneurons. MN, motor neuron.

4.08.4 Cellular and Molecular Mechanisms Underlying Short-, Intermediate-, and Long-Term Memory Formation

Contemporary views of memory and its formation over time indicate that both declarative and nondeclarative forms of memory involve multiple stages with different underlying mechanistic requirements. A number of *in vivo* and *in vitro* procedures involving one or several training trials have been employed in Pavlovian conditioning studies of *Hermissenda* to examine the early events supporting the formation of short-, intermediate-, and long-term memory. The different protocols involving one or several conditioning trials produce behavioral changes and physiological modifications that can be detected within minutes following training (Crow, 1983; Farley and Alkon, 1987; Matzel et al., 1990a,b; Matzel and Rogers, 1993; Crow et al., 1998; Ramirez et al., 1998; Epstein et al., 2003; Kuzirian et al., 2006). Since the two sensory pathways mediating the CS and US are totally intact in the isolated nervous system, *in vitro* Pavlovian conditioning procedures can be applied to the isolated circumesophageal nervous system. Pairing the CS (light) with mechanical perturbations of the statocyst produced by piezoelectric stimulation (US) sufficient to depolarize hair cells, or rotation of the isolated nervous system (US), produces electrophysiological correlates in type B photoreceptors that are similar to correlates produced by multi-trial *in vivo* procedures (Matzel et al., 1990a; Matzel and Rogers, 1993; Gandhi and Matzel, 2000). A multi-trial *in vitro* procedure involving pairing the CS with extrinsic

current depolarization of identified statocyst hair cells (nominal US) also produces conditioning correlates in type B photoreceptors (Farley and Alkon, 1987). The results of these investigations depend upon the various conditioning protocols, the efficacy of the US, and the duration of CS-US stimulation.

4.08.4.1 One-Trial Conditioning

To more precisely control when the initial learning occurs and to not confound time after conditioning, when memory is tested, with varying numbers of conditioning trials, a one-trial *in vivo* conditioning procedure was developed that produces a pairing-specific long-term inhibition of normal light-elicited ciliary locomotion (Crow and Forrester, 1986). Pairing the CS (light) with the direct application of 5-hydroxytryptamine (5-HT, nominal US), one of the proposed transmitters of the US pathway to the exposed nervous system of otherwise intact *Hermissenda* produces inhibition of light-elicited ciliary locomotion when the animals are tested 24 h following the conditioning trial. An *in vitro* analog of the one-trial procedure involving pairing the CS with 5-HT application has been used with the isolated circumesophageal nervous system to examine mechanisms underlying the development of short-, intermediate-, and long-term memory. A one-trial *in vitro* procedure consisting of pairing the CS with mechanical perturbation of the statocyst produces a significant Ca^{2+}-dependent increase in input resistance of type B photoreceptors (a correlate of enhanced excitability) that is detected within minutes postconditioning (Matzel and Rogers, 1993). In addition, a one-trial *in vitro* procedure involving GABA application to the region of the photoreceptor terminal branches (nominal US) paired with a 10-s depolarization of the type B photoreceptors (nominal CS) produces an increase in the input resistance of the B photoreceptors that persists for at least 10 min (Matzel and Alkon, 1991). These studies indicate that the application of a neurotransmitter, when paired with depolarization resulting in a brief period of Ca^{2+} elevation, is sufficient to produce enhanced excitability, and the procedures may engage the essential components for the formation of associations underlying conditioning.

4.08.4.2 Long-Term Memory Following Multi-Trial Conditioning

The analysis of electrophysiological and biophysical modifications detected following multi-trial Pavlovian conditioning has focused upon two sites of convergence between the CS and US pathways. The first site is in the primary sensory neurons (photoreceptors) of the pathway mediating the CS (Crow and Alkon, 1980). Neural modifications in the primary sensory neurons of conditioned animals involve both enhanced excitability that is intrinsic to identified type A and type B photoreceptors (Crow and Alkon, 1980; Alkon et al., 1982, 1985; Farley and Alkon, 1982; West et al., 1982; Crow, 1985b; Frysztak and Crow, 1993, 1997) and facilitation of synaptic connections between identified photoreceptors (Frysztak and Crow, 1994, 1997; Gandhi and Matzel, 2000), and photoreceptors and interneurons (Crow and Tian, 2002b, 2003b). The intrinsic modifications in type B photoreceptors are expressed by enhancement of the amplitude of CS-elicited generator potentials and a concomitant increase in spike frequency, increased excitability to extrinsic current, decreased spike frequency accommodation, and a reduction in the peak amplitude of voltage-dependent (I_A, I_{Ca}) and Ca^{2+}-dependent ($I_{K(Ca)}$) currents (Crow and Alkon, 1980; Alkon et al., 1982, 1985, 1992, 1993; Farley and Alkon, 1982; Alkon, 1984; Crow, 1985b; Goh et al., 1985; Collin et al., 1988; Farley et al., 1990; Matzel et al., 1990a; Frysztak and Crow, 1993, 1994, 1997; Blackwell, 2000; 2002a,b; Muzzio et al., 2001).

The increase in the amplitude of CS-elicited generator potentials is in part the result of a reduction in I_A and $I_{K(Ca)}$. In type B photoreceptors of conditioned animals, the peak amplitude of I_A is significantly reduced and exhibits more rapid inactivation as compared to controls (Alkon et al., 1985). However, both the delayed rectifier (I_K) and inward rectifier (I_h) may play a role in conditioning-dependent enhanced excitability. The application of 5-HT to the isolated nervous system enhances the peak amplitude of I_h and decreases the peak amplitude of I_K and I_A in type B photoreceptors (Acosta-Urquidi and Crow, 1993). In addition, 5-HT reduces the amplitude of $I_{K(Ca)}$ and decreases I_{Ca} in type B photoreceptors (Yamoah and Crow, 1995). The reduction in $I_{K(Ca)}$ produced by 5-HT is a consequence of the decrease in I_{Ca} by 5-HT rather than a direct effect of 5-HT on $I_{K(Ca)}$. In conditioned animals, type A photoreceptors exhibit a decrease in the amplitude of light-elicited generator potentials, enhanced excitability to extrinsic current, increases in CS-elicited spike activity, and a significant increase in the magnitude of I_K (Farley et al., 1990; Frysztak and Crow, 1993, 1997; Farley and Han, 1997). Multi-trial conditioning does not result

in changes in either I_A or $I_{K(Ca)}$ in type A photoreceptors, in contrast to the modifications in type B photoreceptors (Farley and Han, 1997).

In addition to intrinsic enhanced excitability in sensory neurons produced by multi-trial conditioning, changes in synaptic strength between identified sensory neurons and interneurons occur following conditioning. The amplitude of the monosynaptic IPSP between the medial type B photoreceptor and medial type A photoreceptor is significantly enhanced in conditioned animals (Frysztak and Crow, 1994; Gandhi and Matzel, 2000). The second convergence site between the CS and US pathways is the monosynaptic connection between type B photoreceptors and type I interneurons. Multi-trial conditioning produces facilitation of monosynaptic and complex PSPs in identified type I_e and I_i interneurons (Crow and Tian, 2002b). In addition to conditioning-dependent synaptic facilitation, type I interneurons also express intrinsic enhanced excitability with conditioning. Extrinsic current pulses elicit significantly more spikes in type I_e interneurons of conditioned animals as compared to pseudorandom controls.

Therefore multi-trial conditioning in *Hermissenda* results in both presynaptic and postsynaptic modifications. The enhanced excitability of type B photoreceptors, expressed by an increase in both the amplitude of CS-elicited generator potentials and the number of action potentials elicited by the CS, may be a major contributor to changes in the duration and amplitude of CS-elicited complex PSPs and increased CS-elicited spike activity in type I interneurons of conditioned animals (Crow and Tian, 2002b). However, facilitation of the amplitude of the monosynaptic IPSP between type B photoreceptors and type I_i interneurons and the monosynaptic excitatory postsynaptic potential (EPSP) between type B photoreceptors and type I_e interneurons of conditioned animals may involve both pre- and postsynaptic mechanisms.

4.08.5 Second Messenger Systems

4.08.5.1 Protein Kinase C

Protein kinase C (PKC) activation contributes to enhanced excitability and synaptic facilitation underlying the formation of short- and long-term memory in *Hermissenda* (Farley and Auerbach, 1986; Neary et al., 1986; Matzel et al., 1990a; Crow et al., 1991; Farley and Schuman, 1991). PKC is translocated from the cytosol to membrane in the nervous system of *Hermissenda* by treatment with a phorbol ester (12-O-tetradecanoylphorbol-13-acetate (TPA)). The bath application of a phorbol ester (phorbol 12,13-dibutyrate (PDB)) and injection of PKC into type B photoreceptors results in a reduction in the peak amplitude of two K^+ currents, I_A and $I_{K,(Ca)}$, that resemble changes in conductances detected following multi-trial Pavlovian conditioning (Farley and Auerbach, 1986).

Nine conditioning trials produce a foot-shortening CR elicited by the CS that is detected within minutes after the last conditioning trial (Matzel et al., 1990a). An *in vitro* conditioning procedure consisting of nine training trials of the CS paired with rotation of the isolated circumesophageal nervous system (US) enhances type B photoreceptor excitability and increases the amplitude of the plateau phase of the CS-elicited generator potential. The conditioning-dependent change in excitability of type B photoreceptors is blocked by the broad-spectrum kinase inhibitor 1-(5-isoquinolinesulfonyl)-2-methylpiperizine (H-7) applied in artificial seawater during *in vitro* conditioning. A second *in vitro* procedure involving pairing the CS with extrinsic current depolarization of the B photoreceptors (nominal US) produced enhanced excitability of the B photoreceptors which is also blocked by preconditioning application of H-7 or sphingosine (Matzel et al., 1990a).

One-trial *in vivo* conditioning consisting of pairing the CS with the application of 5-HT to the exposed but otherwise intact circumesophageal nervous system produces short-term enhanced excitability, intermediate-term enhanced excitability, and long-term enhanced excitability of type B photoreceptors (Crow and Forrester, 1991, 1993a; Crow et al., 1991). The induction of short-term enhanced excitability following one-trial conditioning is blocked by the protein kinase inhibitors H-7 and sphingosine and by downregulation of PKC produced by pretreatment with TPA (Crow et al., 1991; Crow and Forrester, 1993b). However, while H-7, sphingosine, or downregulation of PKC by TPA blocks short-term enhanced excitability, the same treatments do not block long-term enhanced excitability produced by one-trial conditioning (Crow and Forrester, 1993b). Therefore short- and long-term enhanced excitability produced by one-trial *in vivo* conditioning involve independent or parallel processes and differential contributions of second messengers. *Thus, the expression of long-term memory produced by one-trial conditioning does not depend upon the induction of short-term memory.*

Consistent with previous studies, the induction of enhanced excitability in type B photoreceptors produced by five *in vitro* conditioning trials involving the CS paired with depolarizing current stimulation of an identified statocyst hair cell is blocked by pretreatment with PKC inhibitors (Farley and Schuman, 1991). However, the contribution of PKC to the expression of long-term enhanced excitability depends upon the conditioning protocol and the number of conditioning trials. Previously established long-term enhancement produced by one-trial *in vivo* conditioning is not reversed by the broad-spectrum kinase inhibitor H-7 or the PKC inhibitors sphingosine or staurosporine (Crow and Forrester, 1993a). In contrast, long-term enhanced excitability in type B photoreceptors produced by multi-trial Pavlovian conditioning is attenuated by H-7 or sphingosine, suggesting that long-term enhanced excitability is dependent upon persistent kinase activity (Farley and Schuman, 1991).

Lateral type A photoreceptors exhibit an increase in the number of spikes elicited by the CS and extrinsic current following multi-trial Pavlovian conditioning (enhanced excitability) (Frysztak and Crow, 1993). Injection of the PKC inhibitor peptide PKC(19-36) into lateral type A photoreceptors 24–48 h following multi-trial conditioning reverses enhanced excitability within 16 min postinjection, suggesting that either a long-lived activator or a constitutively active kinase contributes to the expression of enhanced excitability in lateral A photoreceptors (Frysztak and Crow, 1997). Injection of the control noninhibitory peptide [glu^{27}] PKC(19-36) does not reverse enhanced excitability in lateral A photoreceptors of conditioned animals. PKC activation also contributes to the induction of 5-HT-dependent synaptic facilitation, but persistent PKC activity is not required for long-term synaptic facilitation. Short-term synaptic facilitation of the connection between type B and type A photoreceptors is produced by bath application of 5-HT (Schuman and Clark, 1994; Frysztak and Crow, 1997). Injection of the PKC inhibitor peptide PKC(19-36) into medial type B photoreceptors blocks 5-HT-induced synaptic facilitation of the IPSP recorded in the medial type A photoreceptor (Frysztak and Crow, 1997). However, injection of PKC(19-36) into medial type B photoreceptors following multi-trial Pavlovian conditioning does not reduce or reverse established synaptic facilitation of the IPSP recorded in medial type A photoreceptors. Thus PKC contributes to the induction of short-term synaptic facilitation of the monosynaptic connection between types B and A photoreceptors, but not to the expression of long-term synaptic facilitation of the same monosynaptic connection between type B and A photoreceptors.

4.08.5.2 Extracellular Signal-Regulated Protein Kinase

One-trial *in vitro* conditioning of the isolated nervous system involving the CS paired with 5-HT results in the increased $^{32}PO_4$ labeling of a protein with an apparent molecular weight consistent with extracellular signal-related kinase (ERK). The increased phosphorylation of the protein following one-trial conditioning is blocked by pretreatment with the MEK1 (MAPK/ERK kinase) inhibitor PD098059 (Crow et al., 1998). Assays of ERK activity with brain myelin basic protein as a substrate shows greater ERK activity for nervous systems from one-trial *in vitro* conditioned animals as compared to controls that received the CS and 5-HT unpaired. In addition, Western blot analysis of phosphorylated ERK with a phospho ERK antibody shows a significant increase in ERK phosphorylation after one-trial conditioning as compared with unpaired controls. The increased phosphorylation is blocked by pretreatment with a MEK1 inhibitor (PD098059). Following a multi-trial conditioning procedure consisting of 10–15 trials, circumesophageal nervous systems from conditioned animals exhibit significantly greater ERK phosphorylation as compared with pseudorandom controls (Crow et al., 1998).

PKC contributes to the 5-HT-dependent activation of the ERK pathway. The phorbol ester TPA increases ERK phosphorylation that is blocked by pretreatment with PKC inhibitors. TPA-dependent ERK phosphorylation is also blocked by the MEK1 inhibitors PD0988059 or U0126. The increased phosphorylation of ERK by 5-HT is attenuated, but not blocked, by pretreatment with the Ca^{2+} chelator BAPTA-AM or pretreatment with PKC inhibitors Gö6976 or GF109203X (Crow et al., 2001). This suggests that Ca^{2+}-dependent PKC activation contributes to ERK phosphorylation, although a PKC-independent pathway also contributes to 5-HT-dependent ERK phosphorylation and activation.

4.08.5.3 Memory Formation Is Ca^{2+}-Dependent

The photoreceptors in the eyes of *Hermissenda* exhibit a spatial segregation of function. Phototransduction takes place in the apical region where the rhabdomere

abuts the lens, and spike generation occurs near the distal end of the axon close to the location of synapses on the terminal processes. Therefore light and rotation have spatially separated physiological consequences in type B photoreceptors. Both light and depolarization increase cytosolic Ca^{2+} levels in photoreceptors (Connor and Alkon, 1989; Sakakibara et al., 1993; Blackwell, 2000, 2002a,b; Muzzio et al., 2001). Light activates phospholipase C (PLC) to produce an increase in inositol trisphosphate (IP_3) and diacylglycerol (DAG) (Sakakibara et al., 1986, 1994). IP_3 opens rhabdomeric Na^+ and Ca^{2+} channels, which result in a depolarizing generator potential and Ca^{2+} influx (Blackwell, 2000). IP_3 also binds to its receptor (IP_3R), which triggers Ca^{2+} release from the endoplasmic reticulum (Blackwell and Alkon, 1999). The Ca^{2+} influx from the rhabdomere and the IP_3R-gated storage compartment can cause Ca^{2+} release from the ryanodine receptor-gated (RyR) compartment (Blackwell and Alkon, 1999).

Rotation (US) produces a depolarizing generator potential in identified statocyst hair cells and elicits a monosynaptic GABAergic IPSP in the photoreceptors (Alkon et al., 1993; Sakakibara et al., 1993; Rogers et al., 1994; Blackwell, 2002a). The US is also proposed to activate a polysynaptic serotonergic pathway that projects to type B photoreceptors (Land and Crow, 1985; Crow and Forrester, 1986, 1991). Both 5-HT (Rogers and Matzel, 1995; Yamoah and Crow, 1996) and GABA (Yamoah and Crow, 1996) are linked to a pertussis toxin–sensitive G-protein. These proteins can activate multiple second messenger systems (see **Figure 4**), several of which have been implicated in one-trial and multi-trial classical conditioning. The primary focus of 5-HT effects has been on the modulation of membrane conductances in type B photoreceptors (e.g., Farley and Wu, 1989; Acosta-Urquidi and Crow, 1993; Yamoah and Crow, 1996). In addition, the induction of 5-HT-dependent enhanced excitability in type B photoreceptors is Ca^{2+} dependent, since BAPTA loading of photoreceptors before 5-HT application blocks the induction of enhanced excitability (Falk-Vairant and Crow, 1992). However, the precise role of 5-HT in the induction and expression of long-term intrinsic enhanced excitability and synaptic facilitation is poorly understood. In contrast, it is proposed that GABA binding to G-protein-coupled receptors on photoreceptors activates phospholipase A_2 (PLA_2) to liberate arachidonic acid (AA) that interacts with Ca^{2+} to synergistically stimulate PKC (Muzzio et al., 2001) and create a back-propagating wave of Ca^{2+}

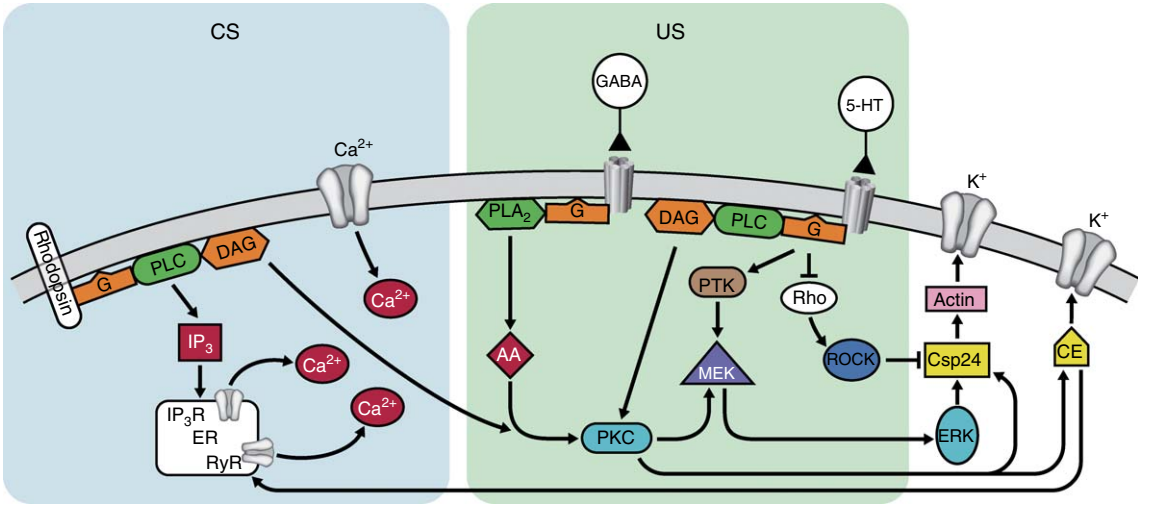

Figure 4 Mechanisms of memory formation produced by Pavlovian conditioning in *Hermissenda.* Acquisition involves the interaction of Ca^{2+} with the second messenger pathways regulated by neurotransmitter release in the unconditioned stimulus (US) pathway. Light (CS) activates phospholipase C (PLC) to produce an increase in inositol trisphosphate (IP_3) and diacylglycerol (DAG). The depolarizing generator potential and IP_3 effects on endoplasmic reticulum (ER) result in an increase in intracellular Ca^{2+}. Transmitters in the US pathway bind to G-protein-coupled receptors (G) to activate phospholipase A_2 (PLA_2), increase arachidonic acid (AA), and activate protein kinase C (PKC), nonreceptor protein tyrosine kinase (PTK), extracellular signal-regulated kinase (ERK), and the Rho GTPase/Rho-associated protein kinase (Rho/ROCK) pathway. Enhanced excitability is a consequence of short-term and long-term modification of K^+ channels by calexcitin (CE) and conditioned stimulus pathway protein 24 (Csp24). MEK, MAPK/ERK kinase; 5-HT, serotonin; GABA, gamma-aminobutyric acid.

released from intracellular stores (Ito et al., 1994; Blackwell, 2002a). When the CS and US are repeatedly paired, the Ca^{2+} influx due to light, IP_3R stores, RyR stores, and voltage-gated Ca^{2+} channels sums together (Blackwell and Alkon, 1999). The large increase in cytosolic Ca^{2+} combined with DAG and AA acts to synergistically activate PKC by translocation of PKC to the membrane (Lester et al., 1991). Each pairing of the CS and US has been proposed to incrementally increase the proportion of PKC translocated to the membrane that would contribute to the phosphorylation of K^+ channels (Muzzio et al., 1997, 2001; Alkon et al., 1998).

4.08.5.4 Long-Term Memory Depends Upon Translation and Transcription

The existence of mechanistic differences between short- and long-term enhanced excitability are illustrated by studies showing that inhibition of protein synthesis during one-trial *in vivo* conditioning blocks long-term enhanced excitability without affecting the induction or expression of short-term enhanced excitability (Crow and Forrester, 1990). Moreover, long-term enhanced excitability produced by one-trial conditioning is blocked by inhibition of mRNA synthesis, which does not affect the induction of short-term enhanced excitability (Crow et al., 1997). This result indicates that long-term memory following one-trial *in vivo* conditioning is dependent upon both translation and transcription.

The time-dependent development of enhanced excitability following one-trial *in vivo* conditioning is biphasic; enhancement reaches a peak at 3 h, decreases toward baseline control levels at 5–6 h, and increases to a plateau at 16 to 24 h postconditioning (Crow and Siddiqi, 1997). Enhanced excitability following one-trial conditioning involves an intermediate phase of memory consolidation that requires protein synthesis but not mRNA synthesis (Crow et al., 1999). The phosphorylation of a cytoskeletal-related protein, Csp24 (see the section titled 'Proteins regulated by Pavlovian conditioning') is associated with the intermediate phase, but not the short-term phase. Reducing the concentrations of 5-HT used in one-trial conditioning produces a short-term (< 1 h) associative enhancement of excitability that does not involve the posttranslational modification of Csp24 (Crow and Xue-Bian, 2000).

The conditioned foot contraction CR is expressed at a retention interval of 5 min following two or nine conditioning trials (Ramirez et al., 1998). However, nine conditioning trials are required for 90-min retention. *In vivo* incubation of animals with the protein synthesis inhibitor anisomycin during conditioning does not affect the expression of the CR at the 5-min retention interval, but attenuates conditioning at the 90-min interval for the group that received nine conditioning trials. A protocol involving *in vitro* conditioning of the isolated nervous system produces similar results to the effects of anisomycin on conditioned behavior. Two conditioning trials produce a short-term protein synthesis–independent increase in excitability that decreases within 45 min, and nine conditioning trials produce a persistent protein synthesis–dependent increase in type B photoreceptor excitability detected at 90 min (Ramirez et al., 1998). Applying anisomycin 5 min after the ninth conditioning trial does not affect the retention of enhanced excitability.

However, a recent study has challenged the view that protein synthesis occurring after the learning event is necessary and sufficient for the formation of long-term memory. PKC activation produced by bryostatin application on days before conditioning leads to the expression of proteins that can support long-term memory produced by later Pavlovian conditioning. Two conditioning trials typically result in a short-term (~7 min) foot-shortening CR. A 4-h exposure to bryostatin on two days preceding conditioning results in a long-term (>1 week) CR produced by two conditioning trials that is not blocked by anisomycin (Alkon et al., 2005).

4.08.6 Morphological Modifications in the Sensory Neurons of Conditioned Stimulus Pathway

Ultrastructural and electrophysiological analyses indicate that synaptic interactions between photoreceptors, other sensory neurons, and interneurons is in the neuropil of the cerebropleural ganglion (Crow et al., 1979). Changes in the morphology of secondary and terminal photoreceptor processes within the neuropil are produced by conditioning. Structural changes characterized by a contraction or reduction of dendritic boundary volumes enclosing labeled medial-type-B photoreceptor arborizations occur in conditioned animals as compared to unpaired controls (Alkon et al., 1990). This suggests that selective synaptic pruning may be a correlate of Pavlovian conditioning. Three-dimensional reconstructions of the volume of the terminal arborizations at the

synaptic connections between all pairs of identified photoreceptors double-labeled with different fluorescent dyes revealed that most project to the intermediate and lateral segments in the ventral region of the lateral B photoreceptor, a region of the lateral type B photoreceptor that is not contracted by conditioning (Kawai and Crow, 2004). The structural changes in type B photoreceptor dendritic volume observed with multi-trial conditioning have also been observed following an *in vitro* conditioning procedure. As compared to unpaired controls, five *in vitro* conditioning trials produce a contraction of the terminal branches along a central lateral axis of fluorescently labeled type B photoreceptors imaged with confocal microscopy (Kawai et al., 2002). The change in terminal branch morphology occurs within an hour after *in vitro* conditioning and is not observed at the synaptic connections between hair cells and photoreceptors (Kawai et al., 2002). The structural remodeling of the type B photoreceptor terminal branches following *in vitro* conditioning is blocked with anisomycin pretreatment (Kawai et al., 2003). In addition to changes in dendritic volume, changes in the volume of photoreceptor somas occur following activation of PKC with a phorbol ester (Lederhendler et al., 1990). Phorbol-induced changes involve outgrowths from the cell surface, similar to blebs, that alter the soma volume.

4.08.7 Proteins Regulated by Pavlovian Conditioning

Different *in vivo* and *in vitro* conditioning protocols have been used to study proteins regulated by conditioning. Multi-trial conditioning produces posttranslational modifications in a number of proteins; however, only a few of the full-length cDNAs have been cloned and the phosphoproteins fully characterized. Calexcitin (CE) is a guanosine triphosphate (GTP) and Ca^{2+}-binding protein found in *Hermissenda* photoreceptors (Neary et al., 1981; Alkon et al., 1998; Kuzirian et al., 2001). CE is activated by elevated Ca^{2+} and binds to the RyR to increase cytosolic Ca^{2+} concentrations (Ascoli et al., 1997; Nelson et al., 1996, 1999). CE is phosphorylated by PKC, which results in translocation of CE to membrane compartments where it decreases K^+ currents. Phosphorylation of CE also results in binding to the Ca^{2+}-ATPase transporter to increase the rate of Ca^{2+} removal from the cytosol (Alkon et al., 1998). Multi-trial conditioning increases the phosphorylation of CE (Neary et al., 1981) and increases CE in B photoreceptors, specifically in Ca^{2+} sequestering organelles such as endoplasmic reticulum (ER) and within mitochondria and photopigments (Kuzirian et al., 2001). The increased CE levels in B photoreceptors of conditioned animals results in increased excitability via K^+-channel inactivation and internal Ca^{2+} release from ER due to increased CE binding to ryanodine receptors.

In addition to CE, one-trial and multi-trial conditioning regulates other proteins found in the CS pathway and circumesophageal nervous system (Crow et al., 1996, 1997, 1999; Crow and Siddiqi, 1997; Crow, 2004). The phosphorylation of conditioned stimulus pathway protein 24 (Csp24) is regulated by Pavlovian conditioning and is involved in both intermediate-term and long-term memory. Csp24 is a cytoskeleton-related protein that is homologous to members of the family of multi-domain β-thymosin repeat proteins (Crow and Xue-Bian, 2000, 2002; Crow et al., 2003). Actin co-precipitates with Csp24 and is colocalized with Csp24 in the cytosol of B photoreceptor cell bodies (Crow and Xue-Bian, 2002). In addition, recombinant Csp24 binds to and sequesters G-actin *in vitro,* and phosphorylation of Csp24 by one-trial *in vitro* conditioning increases the co-precipitation of actin with anti-Csp24 (Redell et al., 2007).

Csp24 is phosphorylated by procedures that produce intermediate-term and long-term enhanced excitability, but not after *in vitro* procedures that result in only short-term enhanced excitability of photoreceptors (Crow and Xue-Bian, 2000). Several signaling pathways regulate Csp24 phosphorylation; thus it can integrate a number of signals that result in cytoskeletal remodeling. Inhibitors of PKC and MEK1 reduce Csp24 phosphorylation produced by *in vitro* conditioning. In addition to PKC and ERK regulation of Csp24, Rho GTPase activity and its downstream target Rho-associated protein kinase (ROCK) contribute to the posttranslational regulation of Csp24 through an inhibitory pathway (Crow et al., 2004). The ROCK inhibitor Y-27632 significantly increases Csp24 phosphorylation, and the Rho activator lysophosphatidic acid decreases Csp24 phosphorylation (Crow et al., 2004). In addition, the application of 5-HT to the isolated nervous system decreases Rho activity and increases the phosphorylation of Csp24. Inhibition of cyclin-dependent kinase 5 by butyrolactone also reduces Csp24 phosphorylation. Incubation of isolated *Hermissenda* nervous systems with *Csp* antisense oligonucleotides decreases Csp24 expression, and treatment with antisense oligonucleotides before

one-trial *in vitro* conditioning blocks intermediate-term enhanced excitability without affecting the induction of short-term immediate enhanced excitability (Crow et al., 2003).

Since Csp24 is associated with the actin cytoskeleton, its regulation by conditioning may influence K^+ channel activity by the spatial and temporal control of actin dynamics. One-trial *in vitro* conditioning of isolated type B photoreceptors produces a significant reduction in the amplitude of I_A and a depolarized shift in the steady-state activation curve of I_A without altering the inactivation curve (Yamoah et al., 2005). The conditioning-dependent changes in I_A are blocked by incubation of the isolated photoreceptors with *Csp* antisense oligonucleotide. Therefore Csp24 contributes to the regulation of voltage-gated channels associated with intrinsic enhanced excitability underlying Pavlovian conditioning.

Interestingly, the distribution of Csp24-like immunoreactivity in lateral type B photoreceptors is changed by one-trial *in vitro* conditioning. Conditioning results in a significant decrease in immunoreactivity in the soma and a significant increase in immunoreactivity in the terminal arborizations of identified lateral type B photoreceptors (Kawai and Crow, 2005).

4.08.8 Overview

Pavlovian conditioning in *Hermissenda* results in both intrinsic enhanced cellular excitability and modifications in synaptic efficacy at multiple loci within the neural circuit responsible for the generation of the CR. The first site of storage for the memory of the associated experience is in the primary sensory neurons of the CS pathway. The modifications in the sensory neurons are spatially segregated. There are alterations in the properties of K^+ channels in the soma that result in an enhancement of the amplitude of the CS-elicited generator potential and a concomitant change in channels in the spike-generating zone that results in a decrease in spike frequency accommodation. In addition, changes in synaptic efficacy result in facilitation of the monosynaptic connections between identified type B and type A photoreceptors and between identified photoreceptors and interneurons. Since the second site of memory storage is in the type I interneurons, the memory for Pavlovian conditioning involves both presynaptic and postsynaptic mechanisms.

Acquisition of short-term, intermediate-term, and long-term memory for Pavlovian conditioning involves the activation of several second messenger cascades, posttranslational modification of proteins, and the synthesis of mRNA and proteins. Acquisition engages the interaction of elevated intracellular Ca^{2+} and arachidonic acid to activate PKC and ERK that is dependent upon CS-US pairings. The mechanism for intrinsic enhanced excitability is different from the mechanisms supporting modifications in synaptic efficacy since long-term synaptic facilitation detected following multi-trial conditioning is not PKC-dependent.

Two proteins that have been fully characterized and are regulated by Pavlovian conditioning are CE and Csp24. The binding of CE to the plasma membrane decreases K^+ conductances and releases Ca^{2+} from internal stores. Csp24 phosphorylation is regulated by one-trial and multi-trial conditioning, is associated with actin, and contributes to long-term intrinsic enhanced excitability produced by the depolarized shift in the steady-state activation of I_A and the concomitant reduction in peak I_A. Therefore, the expression of Csp24 is important in both intermediate-term and long-term memory involving intrinsic enhanced excitability.

The analysis of mechanisms of memory in *Hermissenda* raises a number of questions that are important to an understanding of memory produced by Pavlovian conditioning. How are posttranslational modifications in proteins supporting short-term memory transformed into long-term memory involving both intrinsic enhanced excitability and changes in synaptic efficacy? What are the contributions of presynaptic and postsynaptic modifications to short-term, intermediate-term, and long-term memory? How does the regulation of CE and Csp24 by conditioning result in an alteration in the properties of K^+ channels in excitable membranes? Finally, how are modifications in intrinsic excitability and synaptic strength at several loci integrated within a neural circuit to reconfigure the circuit to support the generation of the conditioned response?

4.09 Molecular Mechanism of Associative Learning in *Lymnaea*

G. Kemenes, University of Sussex, Falmer, Brighton, East Sussex, UK

4.09.1 Introduction

4.09.1.1 Reductionist and Top-Down Approaches to Studying Molecular Mechanisms of Learning and Memory in Mollusks

Historically, there have been two different approaches to the analysis of the molecular mechanisms of learning and memory (*See* Chapters 4.06, 4.07, 4.08, 4.10, 4.38). One, often referred to as a reductionist or simple systems approach, is based on the investigation of molecular pathways involved in long-term neuronal plasticity (heterosynaptic faciliation, long-term potentiation, long-term depression) in neuronal cell cultures, invertebrate ganglia, or mammalian brain slices (Kandel, 2001). This approach rests on the assumption that these forms of synaptic plasticity underlie some forms of learning, such as sensitization or classical conditioning. The other type of approach, commonly known as a top-down approach, starts from the investigation of behavioral aspects of learning and memory and aims to establish causal links between learning-induced molecular changes and the learned behavior itself (Benjamin et al., 2000; Sadile, 1993; McGuire et al., 2005).

Gastropod mollusks (slugs and snails), such as *Aplysia californica, Hermissenda crassicornis, Helix pomatia, Lymnaea stagnalis, Pleurobranchaea californica,* and *Tritonia diomedia,* have been providing extremely useful experimental models for both types of approach since the 1970s (early reviews: Abraham et al., 1972; Willows, 1973; Kandel, 1979; Kandel and Schwartz, 1982; Carew and Sahley, 1986; Byrne, 1987). The main reason for the continuing success of gastropod preparations in learning and memory research is that snails and slugs have easily accessible central nervous systems with unusually large (up to 500 μm) neurons and a variety of well-defined reflex behaviors that can undergo plastic changes during both nonassociative (habituation, sensitization) and associative learning (classical and operant conditioning). These are known as implicit or nondeclarative forms of learning (Milner et al., 1998), during which the memory trace is formed and stored in the same network of neurons, making cellular-level analyses of both memory acquisition and storage feasible in the same system. There is

also an increasing amount of genomic and proteomic information available on mollusks, which has facilitated more in-depth molecular analyses of learning and memory in molluscan models, including the pond snail *Lymnaea stagnalis*.

4.09.1.2 The Roots of Top-Down Analyses of Associative Memory in *Lymnaea*

The predominantly top-down approach to investigations into the cellular and molecular mechanisms of associative learning in *Lymnaea* is rooted in two seemingly disparate fields of research, one almost exclusively physiological, the other purely behavioral (**Figure 1**). In the 1970s *Lymnaea* became a major experimental model system used for the analysis of the organization of central pattern generator (CPG) networks underlying the generation of rhythmic behaviors, such as feeding and respiration (**Figure 2**). Pioneering work in laboratories at Sussex University, Leeds University, and the University of Calgary led to a detailed understanding of how the feeding and respiratory CPGs worked in *Lymnaea* (Benjamin and Rose, 1979; Rose and Benjamin, 1979; McCrohan and Benjamin, 1980a,b; Elliott and Benjamin, 1985a,b; Kyriakides and McCrohan, 1989; Syed et al., 1990, 1992; Syed and Winlow, 1991; Elliott, 1992; Elliott and Kemenes, 1992; Elliott et al., 1992; Kemenes and Elliott, 1994). These studies, together with later work identifying serotonergic (mediated by the transmitter serotonin) and nitrergic (mediated by the gaseous transmitter nitric oxide, NO) modulatory mechanisms in the feeding system (Yeoman et al., 1994a,b, 1996; Elphick et al., 1995; Park et al., 1998; Kobayashi, 2000; Straub and Benjamin, 2001; Korneev et al., 2002), provided a firm physiological foundation for subsequent work aimed at understanding how learning can affect these CPG-driven behaviors (**Figure 1**).

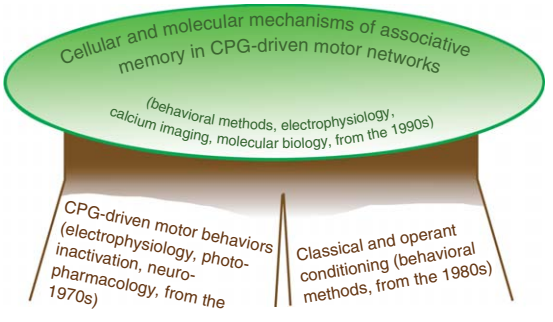

Figure 1 The two roots of current cellular and molecular studies of associative memory in *Lymnaea*.

Shortly after the publication of the first papers describing CPG interneurons, motor neurons, and modulatory neurons of the feeding network (Benjamin and Rose, 1979; Rose and Benjamin, 1979; McCrohan and Benjamin, 1980a,b), seminal behavioral work established the ability of *Lymnaea* to form long-term associative memory after a few pairings or even just a single pairing of a nonfood chemical stimulus and a food stimulus (Alexander et al., 1982, 1984; Audesirk et al., 1982). It was subsequently shown that *Lymnaea* is also capable of forming a positive association between tactile stimuli and food, but only after multiple trials (Kemenes and Benjamin, 1989a). Both the chemical and tactile conditioning paradigms revealed a number of characteristics of associative learning in *Lymnaea* that were shared by learning in vertebrates, such as dependence on age and motivational states, stimulus generalization, discriminative learning, and classical-operant interactions (Audesirk et al., 1982; Kemenes and Benjamin, 1989a,b, 1994). Later on it was also demonstrated that *Lymnaea* can form negative associations between a food conditioned stimulus (CS) and an aversive chemical unconditioned stimulus (US) (classical conditioning) (Kojima et al., 1996) or between a behavior and an aversive tactile stimulus (operant conditioning) (Lukowiak et al., 1996). The wealth of knowledge about the behavioral features of both operant and classical, aversive and reward conditioning, together with a detailed understanding of the neuronal networks underlying the unconditioned behaviors used in these paradigms (feeding and respiration, **Figure 2**), has made *Lymnaea* a very attractive experimental model for top-down analyses of learning and memory.

The two fields of research, physiological analysis of CPGs and behavioral analysis of associative conditioning, started to converge in the mid- to late 1990s when neuronal correlates of both classical and operant conditioning were first described (Whelan and McCrohan, 1996; Kemenes et al., 1997; Kojima et al., 1997; Staras et al., 1998, 1999; Spencer et al., 1999). The most important neuronal aspects of associative learning in *Lymnaea* are discussed in another chapter (*See* Chapter 1.30) as well as several review articles (Kemenes, 1999; Lukowiak and Syed, 1999; Benjamin et al., 2000; Lukowiak et al., 2003b). Detailed analyses of molecular mechanisms of associative memory started in the late 1990s after sufficient information had been obtained on both the behavioral and neuronal aspects of associative learning (**Figures 1** and **2**).

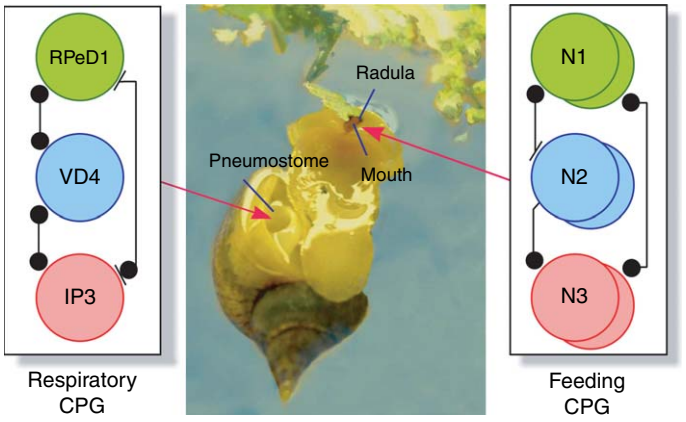

Figure 2 The respiratory and feeding behavior and the underlying CPG networks in *Lymnaea.* The photograph (courtesy of Dr. I. Kemenes) shows a snail hanging upside down on the water surface in an aquarium, simultaneously performing aerial respiration through the open pneumostome and feeding on a piece of lettuce. The cartoon to the left of the photograph shows the three-neuron respiratory CPG responsible for movements of the pneumostome. The cartoon on the right shows the feeding CPG responsible for the synchronized rhythmic movements of the snail's mouth parts, including the radula, which performs rasping movements during feeding. The feeding CPG consists of three main types of CPG neurons, each type having two different subtypes. The respiratory CPG produces a two-phase motor pattern (closure and opening of the pneumostome), whereas the feeding CPG produces a three-phase pattern (radula protraction, rasping, and swallowing). The arrows pointing from the CPG diagrams to the pneumostome and mouth parts, respectively, indicate causal relationships between CPG activity and motor functions performed by these organs. For more details on the two *Lymnaea* CPG networks see the references quoted in the text. 4.09.2 Molecular Analyses of Associative Memory in *Lymnaea*

4.09.2.1 Reward Classical Conditioning of Feeding

Classical (or Pavlovian) reward conditioning in *Lymnaea* is based on forming an association between a nonfood tactile or chemical CS and an unconditioned food stimulus. Associations are formed in the feeding network and lead to a learned change in the behavior, with trained animals producing stronger feeding responses to the CS compared to control animals. **Figure 2** shows a *Lymnaea* feeding on a piece of lettuce (an unconditioned food stimulus) and the CPG network underlying the generation of the three-phase rhythmic snail feeding behavior called rasping. A more detailed description of the *Lymnaea* feeding behavior and underlying neuronal circuitry is presented in another chapter (*See* Chapter 1.30) and previous review articles (Benjamin and Elliott, 1989; Elliott and Susswein, 2002; Benjamin et al., 2005).

4.09.2.1.1 Single-trial reward conditioning

To date, the most detailed information on the molecular mechanisms of associative long-term memory (LTM) in *Lymnaea* has been gained from experiments using single-trial food-reward (also known as appetitive) classical conditioning. In this paradigm, snails are subjected to a conditioning protocol using a single pairing of amyl acetate (pear drops) as a neutral CS with sucrose as a rewarding or appetitive US. In subsequent memory tests with the CS alone, the explicitly paired (CS/US) experimental group shows significantly greater feeding responses to amyl acetate over their own naive responses and all the standard control groups (random, explicitly unpaired, CS alone, US alone) (Alexander et al., 1984; Kemenes et al., 2002; also see **Figure 4**).

The most important finding from the original behavioral studies was that a single pairing of the amyl acetate CS and sucrose US resulted in LTM, which lasted for several weeks (Alexander et al., 1984). This is a remarkable example of robust single-trial learning, which is now very effectively used for analyses of the time course of the molecular mechanisms underlying memory processes. The use of this single-trial paradigm for the analysis of the molecular mechanisms of memory consolidation and reconsolidation has two main advantages. First, after single-trial conditioning, translation- and transcription-dependent memory emerges in a matter of hours (Fulton et al., 2005), allowing this type of memory to be studied on a timescale of a few hours to several weeks. This early emergence of LTM was utilized in recent *in vitro* conditioning experiments investigating the cellular and molecular mechanisms of memory formation in semi-intact preparations, which are only viable for up to 6 h (Ireland, 2006). Second, unlike multi-trial paradigms, single-trial conditioning allows the analyses of the amnestic effects of sharply timed manipulations of key molecular pathways during both memory consolidation (Kemenes et al., 2002; Fulton et al., 2005; Ribeiro et al., 2005) and reconsolidation after the retrieval of memory (Kemenes G et al., 2006).

In semi-intact preparations made from conditioned animals, electrophysiological correlates of the rhythmic conditioned feeding response to amyl acetate were recorded in nerves, motor neurons, and command-like neurons of the feeding system (Kemenes et al., 2002; Straub et al., 2004, 2006; Kemenes I et al., 2006). Moreover, in attempts to localize sites of plasticity, electrical changes, such as maintained depolarization of the modulatory neuron type cerebral giant cells (CGCs) after conditioning, have also been recorded (Kemenes I et al., 2006).

At the molecular level, the most important question to be addressed was whether or not LTM formation after single-trial conditioning (similar to 'flash-bulb' memory known in other systems, including humans, cf. Carew, 1996) is based on the same conserved pathways that were originally described using multi-trial paradigms in other systems. An important clue to suggest that this might be the case is that the broad-spectrum protein synthesis inhibitor anisomycin (ANI), injected in an early time window (10 min to 1 h) after conditioning, blocks the 24-h memory trace (conventionally regarded as LTM) (Fulton et al., 2005). An earlier (5 h) memory trace is blocked by both ANI and actinomycin-D (Act-D), an RNA synthesis blocker, confirming that LTM, defined as memory dependent on early post-training translation and transcription, is present as early as 5 h after single-trial conditioning (Fulton et al., 2005). This observation indicates that single-trial reward conditioning triggers molecular cascades that are involved in the rapid consolidation of long-lasting memory traces. Interestingly, there is only a single early time window of sensitivity to transcription and translation blockers (Fulton et al., 2005) (**Figure 3**), unlike in a number of other studies, which described a temporally distinct second window of protein synthesis-dependent LTM in both vertebrates and invertebrates (Grecksch and Matthies, 1980; Freeman et al., 1995;

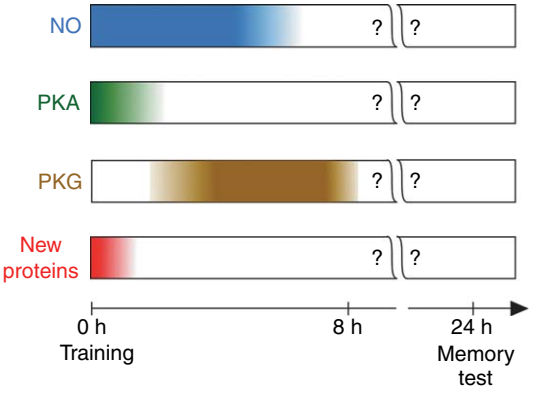

Figure 3 Time windows of requirement for NO, protein kinase A (PKA), protein kinase G (PKG), and new proteins for the consolidation of LTM after single-trial reward classical conditioning. Time windows were only investigated for up to 8 h post-training, so at present it cannot be ruled out (question marks) that there are further time windows between 8 h and 24 h. Data sources: Kemenes I, Kemenes G, Andrew RJ, Benjamin PR, and O'Shea M (2002) Critical time-window for NO-cGMP-dependent long-term memory formation after one-trial appetitive conditioning. *J. (2005) Timed and targeted differential regulation of nitric oxide synthase (NOS) and anti-NOS genes by reward conditioning leading to long-term memory formation. *J. Neurosci.* 25: 1188–1192; Ribeiro MJ, Schofield MG, Kemenes I, O'Shea M, Kemenes G, and Benjamin PR (2005) Activation of MAPK is necessary for long-term memory consolidation following food-reward conditioning. *Learn. Mem.* 12: 538–545.

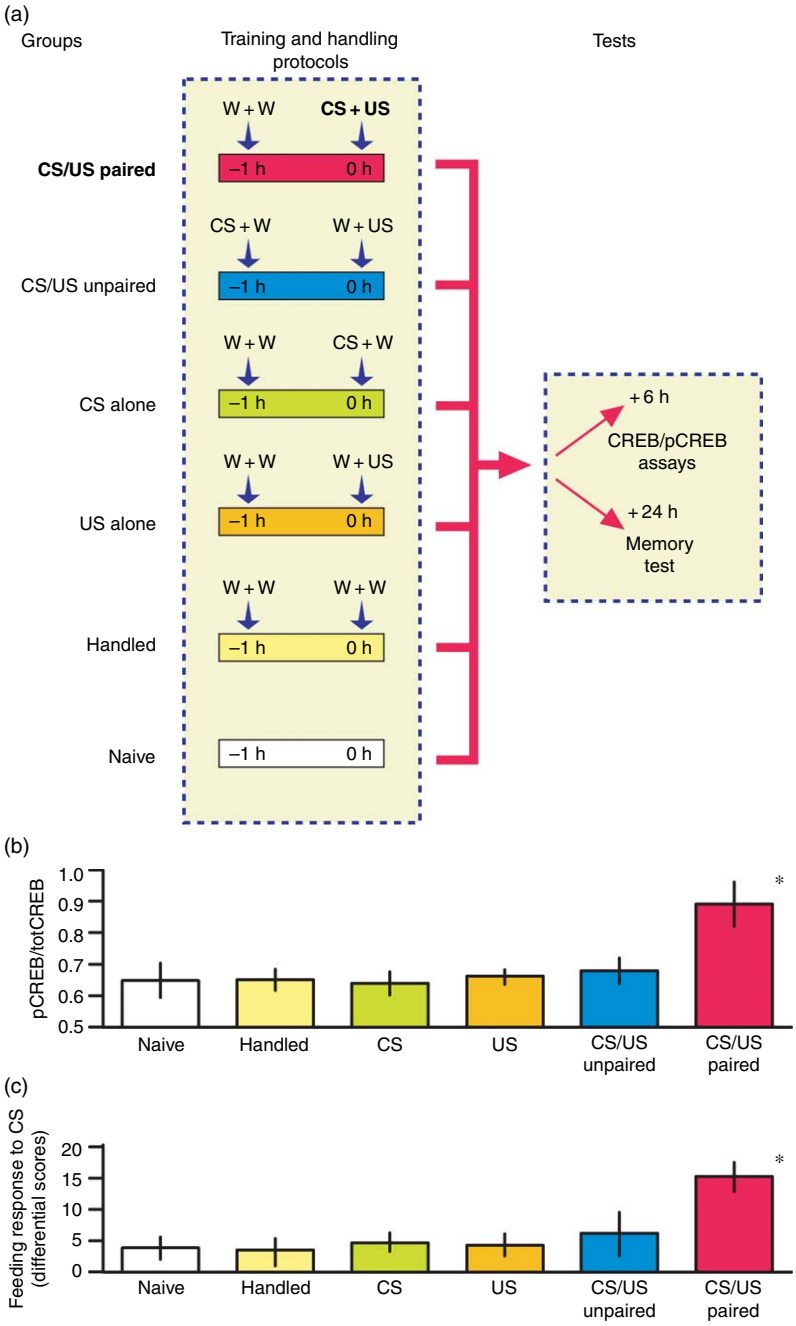

Figure 4 CREB is only phosphorylated after single-trial conditioning with contingent CS (amyl acetate) and US (sucrose) application. (a) The experimental design. An experimental (CS/US paired) and five different control groups were used in the same experiment. Water (W) stimuli were given to balance for disturbance in the experimental dish caused by applications of the CS and/or US solutions. After training or control treatment, each group was randomly divided into two subgroups. One of these groups was dissected for CREB/pCREB assays at 6 h posttraining; the other group was tested with the CS at 24 h posttraining to confirm that LTM had formed. (b) Significant (*, at least $p < .05$, analysis of variance (ANOVA) and post hoc tests) upregulation of pCREB levels in the experimental vs. all the control groups, indicating CS/US pairing-specific activation of CREB. (c) Significant (*, at least $p < .05$, ANOVA and post hoc tests) increase in the feeding response to the CS in the experimental vs. the control groups, indicating associative memory. The feeding response is shown as a difference score obtained by subtracting background feeding responses to water from the CS-induced feeding responses, both measured in 2-min observation periods. Data source: Michel M, Daniels M, Mueller U, Kemenes G (2007) Involvement of PKA and CREB in single-trial reward learning in *Lymnaea*. *Br. Neurosci. Assoc. Abstr.* 19: 57.

Bourtchouladze et al., 1998; Epstein et al., 2003). It has been suggested that 'strong' (i.e., effective) training protocols lead to rapid memory consolidation involving only a single wave of protein synthesis-dependent events, whereas 'weak' (i.e., less effective) training protocols are followed by a more prolonged consolidation phase, containing two or more windows of requirement for new protein synthesis (Bourtchouladze et al., 1998). According to this categorization, single-trial reward conditioning in *Lymnaea* certainly qualifies as a 'strong' training protocol, explaining both the rapid emergence and persistence of the associative memory trace, characteristic of 'flash-bulb' memory.

4.09.2.1.1.(i) CREB and LTM after single-trial reward conditioning Detailed molecular analyses identified highly conserved cyclic adenosine monophosphate (cAMP)-responsive element binding protein (CREB) genes (*Lym-CREB1* and *Lym-CREB2*) and CREB-like proteins in *Lymnaea* (Ribeiro et al., 2003; Sadamoto et al., 2004). A highly conserved CREB-binding protein (CBP) gene (*Lym-CBP*) also has been cloned in *Lymnaea* (Hatakeyama and Kemenes, 2005), further indicating the existence of functional CREB-dependent transcriptional mechanisms. These were important findings because regulation of gene expression during memory consolidation is known to involve a variety of transcription factors, with CREB playing a particularly important role in the switch between short-term and long-term memory storage in a variety of different species and paradigms (Frank and Greenberg, 1994; Stevens, 1994; Goda, 1995; Carew, 1996; Yin and Tully, 1996; Fletcher, 1997; Pittenger and Kandel, 1998; Silva et al., 1998; Alberini, 1999; Lamprecht, 1999; Scott et al., 2002; Tully et al., 2003; Josselyn and Nguyen, 2005). Consistent with a role for CREB in *Lymnaea* LTM is the observation that levels of phosphorylated CREB1 are increased in neurons of the feeding network following reward conditioning (Ribeiro et al., 2003). More recent experiments (Michel et al., 2007) showed that pCREB1 levels only increased in the CS/US paired group, and they remained unaffected in all the standard control groups (**Figure 4**).

4.09.2.1.1.(ii) NO and LTM after single-trial reward conditioning Historically, the first important discovery of the detailed molecular studies of learning and memory in *Lymnaea* was that consolidation of LTM after single-trial reward conditioning is dependent on the NO-cyclic guanosine monophosphate signaling pathway. There is a critical period of sensitivity up to 5 h after conditioning (**Figure 3**) when blocking this pathway by drug injection prevents LTM formation, which was established at both the level of whole animals and the neuronal network responsible for generating the feeding behavior (Kemenes et al., 2002).

Further evidence for a role of NO in LTM came from experiments on single isolated CGCs (Korneev et al., 2005). These giant modulatory neurons express mRNA transcripts from two related nNO synthase (nNOS) genes (*Lym-nNOS1* and *Lym-nNOS2*). Six hours after single-trial conditioning, *Lym-nNOS1* is upregulated compared with controls. This upregulation of the NOS-encoding transcript may be due to an earlier downregulation of the *Lymnaea anti-nNOS* transcript at 4 h that is known to be inhibitory on NOS transcript production. This is a rare example of analysis where the role of a specific signaling molecule in memory formation could be traced from the behavioral to the network and single neuronal level.

4.09.2.1.1.(iii) PKA, MAPK, and LTM after single-trial reward conditioning Other highly conserved molecular pathways that have been implicated in LTM after single-trial reward conditioning in *Lymnaea* are the protein kinase A (PKA) and mitogen-activated protein kinase (MAPK)-dependent signaling cascades. Inhibition of PKA catalytic subunit activity or MAPK phosphorylation blocked 24-h LTM without blocking sensory or motor pathways (Kemenes et al., 2005; Ribeiro et al., 2005). When measured 30 min after conditioning, increased levels of both PKA activity and MAPK phosphorylation were found (Ribeiro et al., 2005), with increased PKA activation also detected when measured in an earlier (5 min) and a later (1 h) time window (Kemenes et al., 2005), indicating a more prolonged dependence of LTM on PKA compared to protein synthesis (**Figure 3**).

A summary of the observations concerning the role of PKA, MAPK, CREB, and NOS/NO in 24-h LTM forming after reward conditioning is presented in **Table 1**. This direct comparison shows an important difference between MAPK and the other signaling molecules investigated in reward conditioning. Unlike the other factors, MAPK is activated not only in response to contingent CS/US application, but also when the CS or US were applied alone or in an unpaired manner (Ribeiro et al., 2005). This observation, together with the fact that preventing MAPK phosphorylation after training blocks LTM, shows that MAPK is necessary but definitely not sufficient for the consolidation of associative LTM

Table 1 A summary of the role of various molecular pathways in the consolidation of associative memory after single-trial reward classical conditioning in *Lymnaea*[a]

Molecule/pathway	*CS alone*	*US alone*	*CS/US unpaired*	*CS/US paired*	*Inhibition blocks associative LTM*
PKA	–	–	–	↑	Yes
MAPK	↑	↑	↑	↑	Yes
CREB	–	–	–	↑	?
NOS/NO	–	–	–	↑	Yes

after single-trial reward conditioning. PKA, CREB, and NOS/NO are selectively activated/upregulated by the associative training protocol, so potentially each of these factors could be sufficient for memory consolidation. However, it is more likely to be the case that these and other signaling molecules make a synergistic contribution to the memory consolidation process, with each molecule and pathway playing an important role in LTM but none of them alone being sufficient for its consolidation.

Interestingly, unlike early inhibition of protein synthesis, inhibition of PKA catalytic subunit activity did not block the expression of memory at 6 h post-training (Kemenes et al., 2005), indicating the involvement of a different signaling molecule (possibly Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII), Wan et al., 2007) in the protein synthesis-dependent consolidation of this earlier memory trace (**Figure 5** and **Table 2**).

Treatment of isolated cerebral ganglia with the adenylate cyclase activator forskolin resulted in massively increased CREB phosphorylation in neuronal nuclei (Ribeiro et al., 2003), indicating a potential link between training-induced PKA activation in the cerebral ganglia (Kemenes et al., 2005) and CREB phosphorylation in conditioned animals. Whether there is any linkage between the NO, PKA, and MAPK signaling pathways has yet to be determined.

4.09.2.1.1.(iv) Time windows of sensitivity of LTM to amnestic treatments after single-trial reward conditioning A summary of the known time windows of sensitivity of the 24-h LTM to inhibition of NO, PKA, protein kinase G (PKG), and protein synthesis is shown in **Figure 3**. Time windows of sensitivity were only investigated in the first 8 h after training, so we cannot rule out that there are also later time windows when these molecular processes are required for the consolidation of the 24-h memory trace. The observation that *Lym-nNOS1* mRNA levels increase at 6 h posttraining (Korneev et al., 2005) strongly suggests an additional later role for NO, perhaps in memory maintenance. The level of phosphorylated CREB1 was also found to be high at 6 h posttraining (Ribeiro et al., 2003), indicating that new transcription and translation still take place after this period. The time windows of requirement for NO and PKA are both wider (Kemenes et al., 2002, 2005) than the time window for requirement for early protein synthesis (Fulton et al., 2005), indicating that the functions of NO and PKA go beyond being upstream components of molecular pathways leading to new protein synthesis shortly after training.

Recently, we have found that, unlike PKA, NO, and new proteins, PKG is not involved in the early processes of memory consolidation (**Figure 3**). This kinase enzyme is, however, required for later memory consolidation processes (between 2 and 8 h posttraining), hardly overlapping with the temporal requirement for PKA (up to 2 h posttraining, Kemenes et al., 2005) but linked to the requirement for NO/soluble guanylyl cyclase (10 min to 6 h posttraining (Kemenes et al., 2002) in a delayed manner.

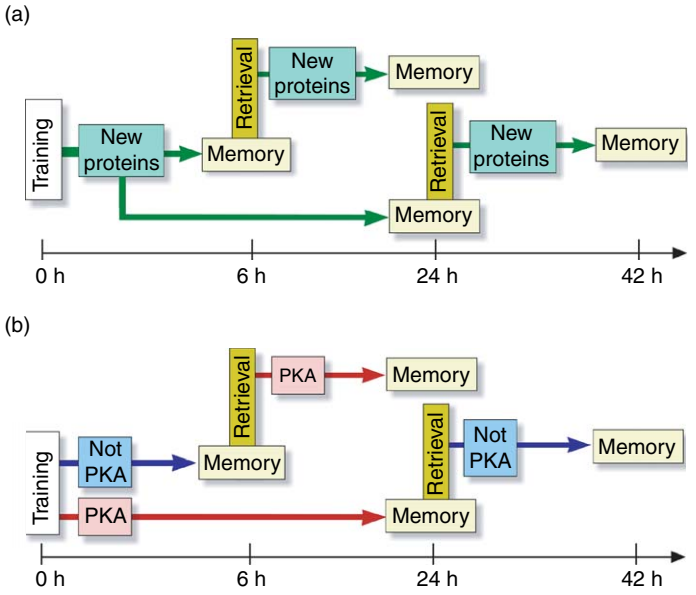

Figure 5 Time-dependent differential requirements for protein synthesis and PKA after training and memory retrieval. (a) New proteins are required for both 6-h and 24-h memory as well as memory reconsolidation after memory retrieval at both time points. (b) By contrast, PKA is only required for 24-h but not 6-h memory, whereas reconsolidation of the retrieved memory is PKA-dependent at 6 h but not at 24 h posttraining. These observations indicate that not PKA, but other signaling molecules are important for memory consolidation at 6 h and for memory reconsolidation at 24 h posttraining. Data sources: Kemenes G, Kemenes I, Michel M, Papp A, and Müller U (2005) Early memory retrieval interferes with late memory expression in a PKA-dependent manner. 4.09.2.1.1.(v) cAMP-dependent molecular cascades and neuronal plasticity contributing to LTM after single-trial reward conditioning

An important link between cAMP-dependent molecular cascades and neuronal plasticity contributing to LTM was found in voltage-clamp experiments, which demonstrated a long-lasting cAMP-induced increase in a low-threshold tetrodotoxin-resistant persistent sodium current of the CGCs (Nikitin et al., 2006). This current makes an important contribution to the CGC somal membrane potential (Staras et al., 2002; Nikitin et al., 2006), which in turn becomes

persistently depolarized after single-trial reward conditioning (Kemenes I et al., 2006). The CGC's synaptic output also became similarly enhanced by somal injection of cAMP (Nikitin et al., 2006) and artificial depolarization of the soma membrane (Kemenes I et al., 2006), lending further support to the notion that cAMP-dependent cascades might support long-lasting plastic changes in ion channel number and/or function, contributing to learning-induced maintained depolarization. The mechanism by which persistent somal depolarization affects synaptic output is likely to be based on a maintained increase in background calcium levels in axon terminals of the CGCs presynaptic to their target neurons (Kemenes I et al., 2006), similar to what was demonstrated previously in mammalian neurons (Awatramani et al., 2005).

4.09.2.1.1.(vi) PKA, protein synthesis, and memory reconsolidation after single-trial reward conditioning An interesting observation is that memory reconsolidation after retrieval at 6 h posttraining is both PKA- and protein synthesis-dependent, whereas reconsolidation after retrieval at 24 h depends on protein synthesis but not on PKA activity (Kemenes G et al., 2006) (**Figure 5** and **Table 2**). This finding indicates that, depending on how recent or remote consolidated memory is relative to the time of training, different molecular pathways are activated by memory retrieval and contribute differentially to memory reconsolidation (*See* Chapters 1.24, 4.14). At a more general level, this phase-dependent differential molecular requirement for reconsolidation supports the notion that even seemingly fully consolidated memories undergo further selective molecular maturation processes (the 'lingering consolidation' hypothesis, Dudai and Eisenberg, 2004), which however may only be revealed by analyzing the role of a variety of different specific pathways in memory reconsolidation after retrieval.

A key question concerning the molecular mechanisms of memory reconsolidation is whether or not they are a recapitulation of the processes active during memory consolidation (Nader et al., 2000; Sara, 2000; Dudai, 2002; Nader, 2003; Dudai and Eisenberg, 2004; Morris et al., 2006). If they are, memory retrieval should reactivate the same molecular cascades that were activated by training, and therefore the same amnestic treatments should impede both processes. Direct comparisons of the PKA and protein synthesis dependence of the consolidation of the 6-h and 24-h memory trace and the reconsolidation of memory after retrieval at these two time points (**Figure 5** and **Table 2**) support the notion that reconsolidation is a recapitulation of consolidation, only at a more general molecular level (protein synthesis), but not at the level of a specific signaling molecule (PKA). In fact, it seems that with regard to PKA, the molecular requirements for consolidation and reconsolidation are completely different: consolidation of the 6-h memory trace does not require PKA, but reconsolidation after memory retrieval at 6 h does, whereas reconsolidation after retrieval at 24 h takes place even when PKA activity is inhibited, despite the dependence of the consolidation of the 24-h memory on early posttraining PKA activity (Kemenes G et al., 2005, 2006). It remains to be elucidated if other specific signaling molecules already known to contribute to the consolidation of the 24-h memory trace (MAPK, NO) are also important for the 6-h memory trace and whether or not they are activated by retrieval at these two different time points.

4.09.2.2 Aversive Classical Conditioning of Feeding

Aversive classical conditioning of feeding in *Lymnaea* is based on pairing sucrose as a CS with an aversive chemical US such as KCl, which inhibits feeding and evokes a withdrawal response (conditioned taste aversion, CTA). After eight or more trials, trained animals showed a significantly weaker feeding response to sucrose than did controls, and this associative memory lasted for over 1 month (Kojima et al., 1996; Ito et al., 1999).

A neural analysis of CTA was carried out on isolated brains dissected from conditioned and control animals (Kojima et al., 1997, 2001). Like reward chemical conditioning, aversive chemical conditioning leads to specific changes in the feeding network, described in another chapter (*See* Chapter 1.30) and previous reviews (Ito et al., 1999; Benjamin et al., 2000; Lukowiak et al., 2003a).

4.09.2.2.1 PKA, CREB, and LTM after aversive conditioning

The transcription and translation dependence of aversive behavioral LTM or the necessity of the activation of specific molecular cascades for its consolidation have not been tested in intact *Lymnaea,* but *in vitro* experiments were performed to

investigate the role of the transcription factor CREB and its upstream activators in synaptic plasticity that may be linked to CTA. The injection of cAMP or PKA into the soma of the CGCs in isolated nervous system preparations led to a long-term enhancement of the synapse between the CGC and a follower motor neuron, B1 (Nakamura et al., 1999). The injection of a CRE oligonucleotide into the CGCs prevented this cAMP-induced long-lasting synaptic plasticity (Sadamoto et al., 2004). These *in vitro* experiments showed that one of the mechanisms of the previously described enhancement in the CGC's synaptic output induced by CTA learning could be the activation of the cAMP/PKA/CREB cascade. However, synaptic plasticity induced by CTA learning in the CGCs could depend on molecular mechanisms other than cAMP-dependent cascades (e.g., CaMKII), and cAMP/PKA and CREB-mediated synaptic plasticity in the CGCs could be involved in the formation of a variety of different memory traces arising from different training paradigms using food stimuli (e.g., visual conditioning (Andrew and Savage, 2000)). Thus, unlike LTM forming after reward conditioning, CTA has not yet been conclusively linked to PKA or the transcription factor CREB in *Lymnaea*.

4.09.2.2.2 C/EBP and LTM after aversive conditioning

Unlike in the case of PKA and CREB, a link has been found between CTA in intact *Lymnaea* and another conserved transcription factor, CCAAT/enhancer binding protein (C/EBP), and this was shown in the buccal ganglia and, specifically, the B2 gut motor neuron (Hatakeyama et al., 2006). Both the phosphorylated and total levels of the *Lym-C/EBP* protein increased in the buccal ganglia and neuron B2 during CTA consolidation, although *Lym-C/EBP* mRNA levels were reduced in the same time window (1 h posttraining) when the increases in protein levels were measured. One explanation for this paradoxical observation could be that the existing pool of *Lym-C/EBP* mRNA is rapidly translated and degraded early after CTA learning, resulting in fast turnover of newly transcribed mRNA, which may be required for a prolonged *de novo* synthesis of large amounts of *Lym-C/EBP* necessary for long-term memory after CTA learning. A more detailed analysis of the time course of changes in *Lym-C/EBP* mRNA and protein levels will be necessary to elucidate the relationship between *Lym-C/EBP* gene transcription, mRNA turnover, and protein synthesis in this system.

Although the CRE element upstream of *Lym-C/EBP* has not been investigated, based on data from *Aplysia, Helix,* and mammals (Niehof et al., 1997; Alberini, 1999; Grinkevich, 2002), the expression of *Lym-C/EBP* is likely to be regulated by *Lymnaea* CREB. It is not known which genes are targeted by C/EBP in *Lymnaea*. However, likely candidate downstream targets of C/EBP are the *Lym-nNOS* genes (Korneev et al., 2005). *Lym-C/EBP* and *Lym-nNOS* are colocalized in the B2 motor neurons (Hatakeyama et al., 2006), and in addition, *Lym-nNOS* genes have three putative *Lym-C/EBP* binding sites (Korneev et al., 2005), providing the necessary structural conditions for the interaction of C/EBP with NOS genes in the *Lymnaea* feeding network.

An interesting but so far unanswered question concerns the differences in the molecular mechanisms underlying reward and aversive conditioning of feeding. Plastic changes after both types of conditioning were found in the CGCs (Kojima et al., 1997; Kemenes I et al., 2006), which are therefore regarded as key neurons for both reward and aversive conditioning. In the case of reward conditioning, the plastic change (a persistent somal depolarization) is nonsynaptic in nature and increases the probability of a feeding response to the CS by recruiting feeding command-like neurons into the network of cells activated by the CS (Kemenes I et al., 2006). In the case of aversive conditioning, the plastic change increases the amplitude of a CGC-driven inhibitory synaptic input to the N1M-type CPG neurons (Kojima et al., 1997), whose inhibition suppresses feeding (Kemenes et al., 2001). It will be important to determine what molecular differences underlie the different cellular changes induced in the same neuron by reward versus appetitive conditioning and contributing either to the activation or suppression of the same behavior after classical conditioning.

4.09.2.3 Operant Conditioning of the Suppression of Aerial Respiration

The aerial respiratory behavior of *Lymnaea stagnalis* has been used in a series of experiments investigating the behavioral, neuronal, and molecular mechanisms of operant conditioning. The respiratory behavior and underlying neuronal circuitry are extremely well characterized and are reviewed in another chapter (*See* Chapter 1.30) as well as several previous reviews (Lukowiak, 1991, 2001; Lukowiak and Syed, 1999; Benjamin et al., 2000; Lukowiak et al., 2003b, 2006b). While single-trial classical conditioning has

provided detailed information on specific molecular mechanisms of LTM, work based on the operant conditioning of the suppression of aerial respiration has provided comprehensive information on the general molecular requirements for different memory phases (intermediate-term memory (ITM) and LTM) and active processes related to associative memory, such as forgetting, extinction, and reconsolidation.

The biological basis for operant conditioning in *Lymnaea* lies in the fact that these pond snails are bimodal breathers; they can breathe both through the skin (cutaneous respiration) and via a simple lung (aerial respiration), which is supplied with air through a respiratory orifice called the pneumostome (**Figure 2**). Hypoxia triggers pneumostome opening, the CPG-driven motor mechanism of aerial respiration (**Figure 2**). Tactile stimulation of the pneumostome area evokes reflexive pneumostome closure and thus suppresses aerial respiratory behavior. In an operantly trained group, a tactile stimulus was applied to the pneumostome area each time aerial respiration was attempted by the animal or semi-intact preparation in an artificially created hypoxic environment (Lukowiak et al., 1996). Suitable yoked and hypoxic control groups were also used. The number of openings, latency to first opening, and total breath durations were recorded in pre- and posttraining periods. Only the operantly conditioned group showed significant changes between the pre- and posttraining behaviors, with significant reductions in openings and total breathing time and significant increases in the latency to first breath. A memory for the operantly conditioned suppression of aerial respiration could persist for at least 4 weeks (Lukowiak et al., 1998), indicating the formation of LTM.

4.09.2.4 Intermediate and Long-Term Memory, Reconsolidation, and Extinction after Operant Conditioning

At the behavioral level, both ITM and LTM have been described based partly on the length of time the memory persists (Lukowiak et al., 2000) but also on the sensitivity to the protein and mRNA synthesis blockers ANI and Act-D, respectively (Sangha et al., 2003c). ANI prevents the formation of both ITM and LTM, whereas Act-D only prevents LTM. Both reconsolidation and extinction have been studied following operant conditioning, and both have been shown to be dependent on new RNA and protein synthesis (Sangha et al., 2003b,d). Extinction is viewed as a new type of associative memory that temporarily masks but does not replace the original memory. Thus following extinction trials, the loss of memory at 2 h is followed by full spontaneous recovery at 24 h.

4.09.2.4.1 Inhibition of macromolecular synthesis and dynamics of memory consolidation and forgetting after operant conditioning

In a series of intriguing experiments, Ken Lukowiak and colleagues showed that cooling, which inhibits macromolecular synthesis, can be used as a tool to prevent not only memory consolidation, but also forgetting, which is thought to be an active process itself, requiring both new learning and memory. When snails were kept at room temperature after operant conditioning, LTM was absent 7 days after training (i.e., forgetting occurred) (Sangha et al., 2005). However, when snails were placed into 4 °C water 1 h after the end of training and kept there for 7 days, LTM was preserved. Thus, unlike cooling for 1 h immediately after training, which impedes LTM (Sangha et al., 2003a), delayed and prolonged post-training cooling impeded forgetting instead (Sangha et al., 2005). Another interesting observation was that ITM can be boosted into LTM by cooling snails immediately after the first bout of a training protocol (two 30-min operant conditioning training sessions in hypoxic water separated by a 30-min rest interval in water with normal oxygen levels) that normally only results in ITM, but not LTM (Parvez et al., 2005).

4.09.2.4.2 Single-neuronal contribution to LTM, forgetting, extinction, and reconsolidation after operant conditioning

Neural changes associated with associative memory have been identified in the isolated central nervous system derived from operantly conditioned animals (Spencer et al., 1999; Spencer et al., 2002). For example, a higher percentage of right pedal dorsal 1 (RPeD1) CPG interneurons, which are important in the onset of the respiratory cycle (**Figure 2**), were silent in conditioned versus control preparations. This neuron became the main focus of work aimed at understanding the molecular processes involved in LTM, forgetting, extinction, and reconsolidation at the level of single identified neurons.

Evidence for the role of molecular processes active in the nucleus and somal cytoplasm of RPeD1 during memory formation came from both somal ablation experiments in intact animals

(Scheibenstock et al., 2002) and spike activity perturbation experiments in semi-intact preparations, where LTM formation was shown *in vitro* (Lowe and Spencer, 2006). Removal of the soma 2 h prior to conditioning of intact snails prevented LTM but had no effect on ITM, suggesting that the RPeD1 soma was necessary for LTM formation (Scheibenstock et al., 2002). Removal of the RPeD1 soma 1 h after conditioning had no effect on LTM, indicating that the effects of soma ablation were not related to memory access or retrieval. In semi-intact preparations, preventing RPeD1 spike activity between training sessions can directly augment memory formation (Lowe and Spencer, 2006), again emphasizing the important role this respiratory CPG neuron plays in memory consolidation.

Interestingly, forgetting, extinction, and reconsolidation also require the presence of the soma of RPeD1 (Sangha et al., 2003b,d, 2005), indicating both that these are all active processes and that RPeD1 is involved in all of them. The observations regarding the role of macromolecular synthesis and RPeD1 are summarized in **Table 3**.

Recent work has shown that snails with axotomized and subsequently regenerated RPeD1 axons can both form new LTM and retain already existing LTM (Lukowiak et al., 2006a). An important implication of this observation is that, despite the fact that similar second messenger cascades are utilized to elicit gene activity in both memory consolidation and regeneration (Feng et al., 1997; Zhang and Ambron, 2000; Carew and Sutton, 2001; cited in Lukowiak et al., 2006a), the effect of the complex molecular cascades activated during regeneration does not abolish the molecular processes necessary for memory consolidation or maintenance.

Table 3 Both macromolecular synthesis and the presence of the soma of RPeD1 (a CPG neuron of the respiratory network) are required for a variety of LTM-related processes after operant conditioning in *Lymnaea*

Memory-related process	*Protein/RNA synthesis required*	*RPeD1 soma required*
Consolidation of LTM	Yes	Yes
Reconsolidation of LTM	Yes	Yes
Forgetting of LTM	Yes	Yes
Extinction of LTM	Yes	Yes
Boosting ITM into LTM	Yes	Yes

4.09.3 Conclusions

Studies based on the associative conditioning paradigms described in this article have yielded valuable information on a variety of general and specific molecular mechanisms contributing to memory consolidation, reconsolidation, forgetting, and extinction. Reconsolidation and extinction in operant conditioning have been shown to have similar general molecular requirements to memory consolidation. Memory consolidation after classical conditioning and reconsolidation after retrieval also share the same general molecular requirement (synthesis of new proteins), but the requirement for specific signaling molecules (such as PKA) for reconsolidation depends on how recent or remote the consolidated memory is relative to the time of training.

Studies of LTM in classical conditioning have emphasized the importance of regulation of gene expression by transcription factors such as CREB and C/EBP and the role of the PKA and MAPK signaling pathways, with the most detailed information gained from experiments using the single-trial classical conditioning paradigm. The importance of these molecular pathways in *Lymnaea* provides further evidence for the generality of these highly conserved mechanisms in learning, both across phylogenetic groups and across learning paradigms (nonassociative or associative, single- or multi-trial,

aversive or reward, operant or classical). NO has been shown to be important for memory consolidation in classical reward conditioning, and this appears to involve regulation of nNOS gene expression in a specific modulatory cell type, the CGCs. Work using *Lymnaea* as an experimental model has thus both provided important insights into the molecular mechanisms of associative learning and memory at the behavioral level and linked these mechanisms to learning-induced cellular and molecular changes in single identified neurons, hallmarks of a successful top-down approach to the study of the molecular mechanisms of associative memory.

Acknowledgments

GK's original research into the associative memory mechanisms of *Lymnaea* was funded by the Wellcome Trust, MRC, BBSRC, and Royal Society (UK). I am also grateful to Dr. Ildikó Kemenes for her help with the preparation of the manuscript and for kindly providing the *Lymnaea* photograph shown in **Figure 2**.

Dedicated to the memory of my father.

4.10 Cellular Mechanisms of Associative Learning in *Aplysia*

F. D. Lorenzetti and J. H. Byrne, The University of Texas Medical School at Houston, Houston, TX, USA

4.10.1 *Aplysia* Classical Conditioning and Operant Conditioning

The simple nervous system and the relatively large identifiable neurons of the marine mollusk *Aplysia* provide a useful model system to examine the cellular and molecular mechanisms of the two major forms of associative learning, classical conditioning and operant (instrumental) conditioning. The ability to associate a predictive stimulus with a subsequent salient event (i.e., classical conditioning) and the ability to associate an expressed behavior with the consequences (i.e., operant conditioning) allow for a predictive understanding of a changing environment. Although operationally distinct, there has been considerable debate whether at some fundamental level classical and operant conditioning are mechanistically distinct or similar (e.g., Rescorla and Solomon, 1967; Gormezano and Tait, 1976; Dayan and Balleine, 2002). Studies utilizing the defensive withdrawal reflexes of *Aplysia* have provided much information on the mechanisms underlying classical conditioning. Recent studies utilizing the feeding behavior of *Aplysia* are providing for a comparative analysis of the mechanisms underlying classical and operant conditioning, using the same behavior and studying the same neuron. This comparative analysis can help to resolve the issue of whether similar or different mechanisms underlie these two forms of associative learning.

4.10.2 Classical Conditioning

4.10.2.1 Behavioral Studies

The initial studies of classical conditioning in *Aplysia* focused on defensive reflex behaviors and used aversive conditioning procedures. A tactile or electrical stimulus delivered to the siphon of the animal resulted in a reflex withdrawal of the gill and siphon, a reaction which presumably protects sensitive structures from harmful stimuli. Aversive classical conditioning in this species can be demonstrated by presenting a conditioned stimulus (CS), a brief, weak tactile stimulus to the siphon which produced a small siphon withdrawal, and an unconditioned stimulus (US), a short-duration noxious electric shock to the tail which produced a large withdrawal of the siphon (the unconditioned response, UR). After repeated pairings of the CS and US, the CS alone produced a large siphon withdrawal (the conditioned response, CR). This withdrawal was enhanced beyond that produced by the US alone (sensitization control) or unpaired or random presentations of the CS or the US (Carew et al., 1981), and this conditioning persisted for as long as 4 days. Carew et al. (1983) also found that this reflex exhibited differential classical conditioning. CS (tactile stimulation) were delivered to either the siphon or to the mantle region. One CS (the CS^+) is paired with the US (electric shock to the tail) and the other is explicitly unpaired (the CS^-). After conditioning, the CS^+ produced a greater withdrawal than the CS^-.

In addition to the classical conditioning of defensive reflexes, classical conditioning can also be applied to feeding behavior. *Aplysia* feed by protracting a toothed structure called the radula into contact with seaweed. The radula grasps seaweed by closing and retracting, which results in the ingestion of the seaweed. Inedible objects can be rejected if the radula protracts while closed (grasping the object) and then opens as it retracts to release the object. Thus, the timing of radula closure determines which behavior will occur. Feeding behavior can be classically conditioned with an appetitive protocol (Colwill et al., 1997; Lechner et al., 2000a). This appetitive protocol (Lechner et al., 2000a) consisted of tactile stimulation of the lips with a fine-tipped paint brush (CS), and the US was a small piece of seaweed, which the animals were allowed to eat. The animals were trained by repeatedly pairing the CS and the US. After training, presentation of the CS elicited an increase in ingestive behavior (CR).

4.10.2.2 Neural Mechanisms of Aversive Classical Conditioning in *Aplysia*

A cellular mechanism called activity-dependent neuromodulation contributes to associative learning in *Aplysia* (Hawkins et al., 1983; Walters and Byrne, 1983; Antonov et al., 2001). A general cellular scheme of activity-dependent neuromodulation is illustrated in **Figure 1**. Two sensory neurons (SN1 and SN2) constitute the pathways for the conditioned stimuli (CS^+ and CS^-) and make weak subthreshold connections to a motor neuron. Delivering a reinforcing stimulus or US alone has two effects. First, the US activates the motor neuron and produces the UR. Second, the US activates a diffuse modulatory system that nonspecifically enhances transmitter release from all the sensory neurons. This nonspecific enhancement contributes to sensitization. Temporal specificity, which is characteristic of associative learning, occurs when there is pairing of the CS (spike activity in SN1) with the US, which causes a selective amplification of the modulatory effects in SN1. Unpaired activity does not amplify the effects of the US in SN2. The amplification of the modulatory effects in SN1 leads to an enhancement of the ability of SN1 to activate the motor neuron and produce the CR.

A reduced preparation for the siphon-withdrawal reflex was developed that consists of the isolated tail, siphon, and central nervous system (CNS) of the animal (Antonov et al., 2001). A classical conditioning

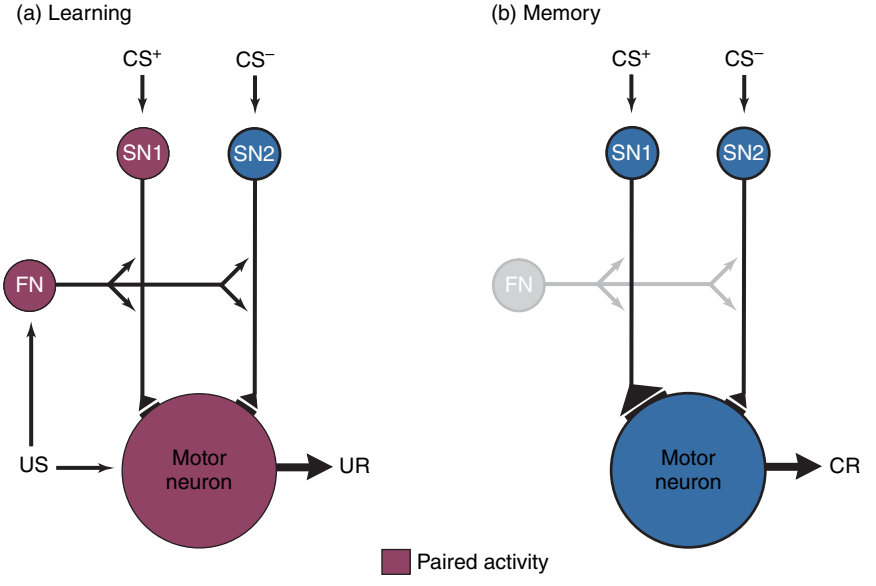

Figure 1 General model of activity-dependent neuromodulation. (a) Learning. A motivationally potent reinforcing stimulus (US) activates a motor neuron to produce the unconditioned response (UR) and a facilitatory neuron (FN) or modulatory system that regulates the strength of the connection between sensory neurons (SN1 and SN2) and the motor neuron. Increased spike activity in one sensory neuron (SN1) immediately before the modulatory signal amplifies the degree and duration of the modulatory effects, perhaps through the Ca^{+2} sensitivity of the modulatory evoked second messenger, with contributions from the postsynaptic neuron. The unpaired sensory neuron (SN2) does not show an amplification of the modulatory effects. (b) Memory: The amplified modulatory effects cause increases in transmitter release and/or excitability of the paired neuron, which in turn strengthens the functional connection between the paired sensory neuron (SN1) and the motor neuron. The associative enhancement of synaptic strength represents the conditioned response (CR).

training protocol was performed with tactile stimulation of the siphon as the CS and an electric shock to the tail as the US. Paired training significantly increased the amplitude of the siphon withdrawal, indicating successful conditioning. The classical conditioning protocol also produced a pairing-specific increase in the strength of the sensorimotor neuron synapse.

Experimental analyses of sensitization of defensive reflexes in *Aplysia* have shown that the neuromodulator released by the reinforcing stimulus, which is believed to be serotonin, activates the enzyme adenylyl cyclase in the sensory neuron. The activation of adenylyl cyclase increases the synthesis of the second messenger cyclic adenosine monophosphate (cAMP), which activates the cAMP-dependent protein kinase, and the subsequent protein phosphorylation leads to a modulation in several properties of the sensory neurons. These changes include modulation of membrane conductances and other processes which facilitate synaptic transmission. This facilitation results in the increased activation of the motor neuron and the sensitization of the reflex. The pairing specificity of the associative conditioning is at least partly due to an increase in the level of cAMP beyond that produced by serotonin alone (Ocorr et al., 1985; Abrams and Kandel, 1988). The influx of Ca^{+2} associated with the CS (spike activity) amplifies the US-mediated modulatory effect by interacting with a Ca^{+2}-sensitive component of the adenylyl cyclase (Abrams and Kandel, 1988). A critical role for Ca^{+2}-stimulated cyclase is also suggested by studies of *Drosophila* showing that the adenylyl cyclase of a mutant deficient in associative learning exhibits a loss of Ca^{+2}/calmodulin sensitivity.

The postsynaptic cell (i.e., motor neuron) also contributes to the plasticity of the synapse (Murphy and Glanzman, 1997; Bao et al., 1998). The postsynaptic membrane of the motor neuron contains *N*-methyl-D-aspartate (NMDA)-like receptors. If these receptors are blocked, then the associative modification of the synapse is disrupted. NMDA receptors require concurrent delivery of glutamate and depolarization in order to allow the entry of calcium. Activity in the sensory neuron (CS) provides the glutamate, and the US depolarizes the cell. The subsequent increase in intracellular Ca^{+2} may release a retrograde signal from the postsynaptic cell to the presynaptic terminal. This retrograde signal would then act to further enhance the cAMP cascade in the sensory neuron. Presynaptically blocking protein kinase A (PKA) by injecting a peptide inhibitor into the sensory neuron, or postsynaptically blocking Ca^{+2} by injecting BAPTA (1,2-bis-(o-aminophenoxy)-ethane-N,N,N′,N′-tetraacetic acid) into the motor neuron, also blocked the pairing-specific strengthening of the sensorimotor neuron synapse (Antonov et al., 2003) using the simplified preparation for classical conditioning mentioned earlier. The plasticity in the sensorimotor neuron synapse can be blocked by an injection to the postsynaptic motor neuron alone, suggesting that a retrograde signal is an integral part of the process.

This mechanism for associative learning appears to be an elaboration of a process already in place that mediates sensitization, which is a simpler form of learning (*See* Chapters 4.02, 4.03 for a review of the mechanisms of sensitization). This finding raises the interesting possibility that even more complex forms of learning may use simpler forms as building blocks, an idea that has been suggested by psychologists for many years but has only recently become testable at the cellular level.

4.10.2.3 Neural Mechanisms of Appetitive Classical Conditioning in *Aplysia*

The feeding system of *Aplysia* has many advantages. For example, much of the cellular circuitry controlling feeding behavior has been identified, so it is possible to study neurons with known behavioral significance. The *in vivo* training protocol for classical conditioning (Lechner et al., 2000a) has been used to examine correlates of classical conditioning in several neurons that are important for the expression of feeding behavior. Classical conditioning led to the pairing-specific strengthening of the CS-evoked excitatory synaptic input to pattern-initiating neuron B31/32, although no changes were observed in the membrane properties, such as input resistance or the threshold for bursting (Lechner et al., 2000b). If B31/32 receives a greater excitatory input from the CS, then this neuron would be more likely to initiate a feeding motor pattern, and the feeding motor patterns evoked by the CS would be mostly ingestive (Lechner et al., 2000b). However, B31/32 promotes the initiation of feeding motor patterns without defining which type of pattern (i.e., ingestive or egestive) is expressed (Hurwitz et al., 1996). Thus, the pairing-specific increase in excitatory input to B31/32 alone cannot account for the specific increase in the ingestive behavior that is observed following *in vivo* classical conditioning (Lechner et al., 2000a).

Correlates of classical conditioning were measured in neuron B51 following the *in vivo* classical

conditioning protocol (Lorenzetti et al., 2006). Neuron B51 is pivotal for the expression of ingestive motor patterns, and B51 exhibits a characteristic all-or-nothing sustained level of activity (i.e., plateau potential; Plummer and Kirk, 1990) during ingestive motor patterns (Nargeot et al., 1999a). Classical conditioning induced a significant pairing-specific increase in the CS-evoked excitatory synaptic input to B51, as well as an increase in the number of CS-elicited plateau potentials. The pairing-specific strengthening of the excitatory synaptic input can increase the likelihood that B51 is recruited into a motor pattern, which can contribute to the pairing-specific increase in the number of CS-evoked plateau potentials. An increase in the recruitment of B51 should bias the feeding central pattern generator (CPG) toward the expression of ingestive motor patterns (Nargeot et al., 1999b). Thus, the effects produced by classical conditioning appear to be distributed among elements of the feeding CPG such as B31/32 and B51, with the pairing-specific plasticity in B31/32 contributing to the increased number of motor patterns, while the pairing-specific plasticity in B51 is biasing the nature of the motor patterns toward ingestion.

In addition to the pairing-specific enhancement of the CS-evoked excitatory synaptic input to B51, classical conditioning can alter the intrinsic biophysical properties of B51. Classical conditioning raised the threshold for eliciting a burst (i.e., plateau potential) in B51 without affecting either the resting membrane potential or input resistance. This result adds to an increasing body of evidence that, in addition to changes in synaptic efficacy, changes in the intrinsic neuronal excitability also contribute to the storage of memory (for reviews see Daoudal and Debanne, 2003; Zhang and Linden, 2003; *See also* Chapter 4.40). The pairing-specific decrease in the excitability would make B51 less likely to be active, whereas the increase in the excitatory synaptic input would facilitate the recruitment of the neuron. However, the training produced more CS-evoked plateau potentials in B51 in the paired group as compared to the unpaired group. Thus, the factors that enhance the recruitment of B51 overpower the diminished excitability and bias B51 toward producing more plateau potentials, resulting in a greater number of ingestive motor patterns. This pairing-specific decrease in the excitability of B51 could be an adaptive mechanism to help shape the CS specificity produced by classical conditioning.

An *in vitro* analog of classical conditioning has been developed for the feeding system of *Aplysia* (Mozzachiodi et al., 2003). This preparation used isolated ganglia from naive animals. Stimulation of the anterior tentacular nerve was chosen as the analog of the CS. Specifically, the fourth branch of the anterior tentacular nerve was used because this branch innervates the lip region, which is the site of stimulation for the *in vivo* CS. Stimulation of the esophageal nerve was used as the analog of the US. The ganglia were trained by repeatedly pairing the CS with the US. After training, the ganglia produced more motor patterns (analogs of the CR) after CS delivery, indicating that conditioning was successful in this reduced analog. The *in vitro* analog of classical conditioning was then performed while monitoring the membrane properties and CS-elicited synaptic input to B31/32, CBI-2 (Mozzachiodi et al., 2003), and B51 (Lorenzetti et al, 2006). The *in vitro* training protocol produced an increase in the CS-elicited synaptic input to both B31/32 and to B51, an increase in the burst threshold of B51, and an increased number of CS-elicited plateau potentials in B51, similar to what was observed following *in vivo* training. In addition, *in vitro* classical conditioning led to a pairing-specific enhancement of the CS-elicited synaptic input to CBI-2 (Mozzachiodi et al., 2003), which is one of the command-like interneurons controlling the activity of the feeding CPG (Rosen et al., 1991). Synergism among these effects can help produce the pairing-specific increase in the number of CS-evoked bites observed following *in vivo* classical conditioning.

These results provide further support that memory can be distributed among multiple sites of plasticity, similar to what has been observed with other animal model systems. In *Lymnaea*, appetitive classical conditioning strengthened the CS-evoked excitatory synaptic drive to feeding motor neurons (Staras et al., 1999) and induced a persistent depolarization in the modulatory neuron CV1a (Jones et al., 2003). In *Aplysia*, empirical studies (e.g., Trudeau and Castellucci, 1993; for review see also Cleary et al., 1995) and theoretical work (White et al., 1993; Lieb and Frost, 1997) on the neural circuits controlling defensive withdrawal reflexes emphasize the role of both sensory neurons and interneurons as sites of learning-related plasticity underlying behavioral sensitization. In vertebrates, the plasticity produced by delay classical conditioning of the eyelid response is distributed between the cerebellar cortex and the deep cerebellar nuclei (for reviews see Raymond et al., 1996; Kim and Thompson, 1997). Trace

classical conditioning of the same reflex can also involve the hippocampus (for review see Christian and Thompson, 2003). Therefore, studies in both invertebrate and vertebrate neural circuits support the concept that multiple sites of plasticity contribute to the storage of information for associative and nonassociative forms of memory.

4.10.3 Operant Conditioning

4.10.3.1 Behavioral Studies

Feeding behavior in *Aplysia* can be modified by pairing feeding with an aversive stimulus. If food is wrapped in a tough plastic net, *Aplysia* bite and attempt to swallow the food. However, netted food cannot be swallowed, and so it is rejected. The inability to consume the food appeared to be an aversive stimulus that modified the feeding behavior, because the trained animals no longer attempted to bite the netted food (Susswein et al., 1986).

Feeding behavior can also be operantly conditioned with an appetitive stimulus (Brembs et al., 2002). The reinforcement signal for the *in vivo* training protocol was a brief shock to the esophageal nerve. The esophageal nerve is believed to be part of the pathway mediating food reward because bursts of activity in this nerve occur when the animal successfully ingests food (Brembs et al., 2002). In addition, lesions to this nerve blocked *in vivo* appetitive classical conditioning (Lechner et al., 2000a). Also, the *in vitro* analog of classical conditioning discussed earlier successfully increased the number of CS-elicited motor patterns when esophageal nerve shock was used as the US (Mozzachiodi et al., 2003). In the operant conditioning paradigm, the contingent reinforcement of biting behavior by a shock to the esophageal nerve produced an increase in the frequency of biting, when measured both immediately after training and 24 h after training, as compared to animals trained with a yoke-control procedure (Brembs et al., 2002).

4.10.3.2 Neural Mechanisms of Appetitive Operant Conditioning in *Aplysia*

We have previously discussed B51 (Plummer and Kirk, 1990) as being implicated in the expression of ingestive behavior and as a correlate of classical conditioning. B51 is active predominantly during the retraction phase (Nargeot et al., 1997), and when B51 is recruited into a pattern, it recruits radula closure motor neurons (see **Figure 2**).

The *in vivo* training protocol for operant conditioning was used to examine correlates in neuron B51 (Brembs et al., 2002). Operant conditioning led to changes in the membrane properties of B51. The input resistance was increased and the threshold for bursting was decreased. These changes increase the likelihood of B51 activation and thereby contribute to the conditioned increase in the ingestive response.

An *in vitro* analog of operant conditioning was developed using only the isolated buccal ganglia, which is responsible for generating the motor patterns involved in feeding (Nargeot et al., 1999a). These motor patterns can either be ingestive or egestive. In this analog of operant conditioning, motor patterns corresponding to ingestion were used as the analog of the behavior. The ingestive motor pattern was selectively reinforced by contingently shocking the esophageal nerve, which was the analog of the reinforcement. The conditioning procedure resulted in an increase in the likelihood of ingestive patterns being produced (Nargeot et al., 1999a). The contingent reinforcement also resulted in the modulation of the membrane properties of neuron B51 (Nargeot et al., 1999a). The input resistance increased and the threshold for eliciting a burst decreased in a manner similar to the *in vivo* operant conditioning protocol. These changes in the membrane properties of B51 make the cell more excitable and more likely to be recruited into a motor pattern, thus helping to explain the increase in the frequency of expression of the ingestive motor patterns following the *in vitro* analog of operant conditioning. Furthermore, these results for the membrane properties of B51 can be replicated when induced electrical activity in B51 was substituted for the analog of the behavior, instead of an ingestive motor pattern, which was then contingently reinforced with a shock to the esophageal nerve (Nargeot et al., 1999b).

The esophageal nerve, which is used to send both a reinforcement signal with operant conditioning and a US signal with classical conditioning, contains dopaminergic processes (Kabotyanski et al., 1998). Esophageal nerve stimulation produced a postsynaptic potential (PSP) in B51 and this PSP was blocked by the dopamine antagonist ergonovine (Nargeot et al., 1999c). This dopamine antagonist also blocked the acquisition of the associative changes induced by *in vitro* analogs of both operant conditioning (Nargeot et al., 1999c) and classical conditioning (Reyes et al., 2005).

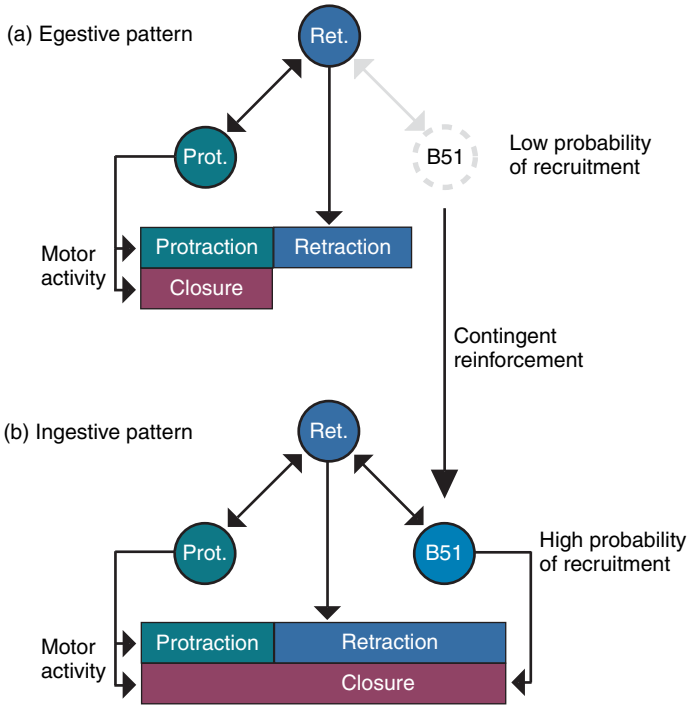

Figure 2 Model of operant conditioning of feeding in *Aplysia*. The cellular network that mediates feeding behavior is represented by the elements in circles. Motor activity comprising two basic feeding patterns is depicted below. (a) At first, the radula protraction-generating element (Prot.) is active, followed by the radula retraction element (Ret.). In the naive state, neuron B51 has a low probability for recruitment and thus does not take part in the feeding motor program. Radula closure occurs during the protraction phase. Consequently, the pattern elicited is egestive. (b) Neuron B51 now has a higher probability for recruitment following contingent reinforcement. B51 is now active during the motor program, leading to radula closure occurring primarily during the retraction phase. Thus, the pattern elicited will now be ingestive.

The analog was further reduced by removing neuron B51 from the ganglia and placing it in culture (Lorenzetti et al., 2000; Brembs et al., 2002). This single, isolated neuron was conditioned by contingently reinforcing induced electrical activity (the analog of behavior) with a direct and temporally discrete application of dopamine (the analog of reinforcement). After conditioning, the input resistance of B51 increased and the threshold for bursting decreased, similar to the *in vivo* and *in vitro* analogs of operant conditioning described above. The membrane properties of B51 were modulated such that the cell was more likely to be active in the future. Such a highly reduced preparation is a promising candidate to study the mechanisms of dopamine-mediated reward and the conditioned expression of behavior at the level of the intracellular signaling cascades.

The operant conditioning of the feeding behavior of *Aplysia* increased the expression of the ingestive responses. The excitability of B51 was also increased by the operant protocol, accounting for the bias in the output of the CPG toward ingestion. However, increasing the excitability of B51 is not likely to increase the total number of patterns expressed. Thus, another site of plasticity is probably induced by the operant protocol. A likely candidate for this additional site of plasticity is in a cell or synapse that is responsible for pattern initiation (e.g., B31). Though these possible sites of plasticity have not yet been explored, it seems likely that both operant and classical conditioning lead to the distribution of memory at multiple sites within the neural circuit.

4.10.4 Conclusions

The feeding system of *Aplysia,* with its relatively simple circuitry, provides a model system for a systematic comparison of the mechanisms underlying classical and operant conditioning. Some interesting similarities as well as differences are beginning to emerge (**Table 1**). One similarity is the nature of the reinforcement pathway and its neurotransmitter. The esophageal nerve mediates the reinforcement signal

Table 1 Comparative analysis between appetitive classical and operant conditioning of feeding in *Aplysia*

	Classical conditioning	*Operant conditioning*
Change in the number of bites	Increase	Increase
Pathway mediating US/reinforcement	Esophageal nerve	Esophageal nerve
Transmitter mediating US/reinforcement	Dopamine	Dopamine
B51 plateau potentials	Increase	Increase
B51 resting membrane potential	No change	No change
B51 input resistance	No change	Increase
B51 burst threshold	Increase	Decrease

for appetitive operant conditioning (Nargeot et al., 1997) and the US pathway for appetitive classical conditioning (Lechner et al., 2000a; Mozzachiodi et al., 2003). Also, this pathway appears to use dopamine as a transmitter, which is consistent with the long-held view that dopamine can mediate the US/reinforcement for appetitive forms of both classical and operant conditioning in both vertebrates and invertebrates (for review see Schultz, 2002).

Appetitive classical conditioning of feeding behavior in *Aplysia* produced two major changes in neuron B51. The synaptic input along the CS pathway into B51 was increased. This increase in the CS pathway suggests that the conditioned sensory pathway receives a preferential boost, while the other sensory pathways could remain unchanged. The second change seen with B51 was an increase in the burst threshold. This change acts on the level of the pattern generation machinery and makes the expression of ingestive feeding responses less likely. Thus, the animal would be less likely to feed unless the CS was present. Identical changes in the properties of B51 were expressed in intact animals trained with a classical conditioning protocol and in an *in vitro* analog of classical conditioning using isolated ganglia (Lorenzetti et al., 2006).

Appetitive operant conditioning of feeding behavior in *Aplysia* also produced two major changes in neuron B51. Both changes were made to the intrinsic membrane properties of the cell. First, the input resistance was increased. Second, the burst threshold was decreased. Both of these changes act in the same direction and would make B51 more likely to be active, thus accounting for the increased expression of the behavior following reinforcement. Identical changes in the membrane properties of B51 were expressed in intact animals trained with an operant conditioning protocol (Brembs et al., 2002), in an *in vitro* analog of operant conditioning using isolated ganglia (Nargeot et al., 1999a,b), and in a single-cell analog consisting of neuron B51 in culture (Brembs et al., 2002).

B51 is a cellular locus for the changes induced by both operant and classical conditioning. No pairing-specific changes in the input resistance were observed following classical conditioning, which was in contrast to the contingent-dependent increase in this parameter measured in B51 following both *in vivo* and *in vitro* operant conditioning. Both operant and classical conditioning modified the threshold level for activation of neuron B51, but in opposite directions, revealing key differences in the cellular mechanisms underlying these two forms of associative learning and suggesting a difference at the molecular level. B51 appears to be a coincidence detector for both the CS–US association (classical conditioning) and the contingency between ingestive behavior and reinforcement (operant conditioning). Because dopamine likely mediates both the US and the reinforcement, a key problem is the elucidation of the mechanisms that lead to the induction of the opposite effects on the burst threshold. One possibility is that the coincidence detector for classical conditioning involves an association between a transmitter released by the CS and dopamine, whereas for operant conditioning it involves an association between the cellular effects of B51 burst activity and dopamine.

4.11 Neural and Molecular Mechanisms of Fear Memory

G. E. Schafe, Yale University, New Haven, CT, USA

J. E. LeDoux, New York University, New York, NY, USA

4.11.1 An Overview of Pavlovian Fear Conditioning

Classical or Pavlovian fear conditioning has long been a tool of behavioral psychology to study simple forms of associative learning in the mammal. In this paradigm, an animal (or human) learns to fear an initially emotionally neutral stimulus (the *conditioned stimulus,* CS) that acquires aversive properties after being paired with a noxious stimulus (the *unconditioned stimulus,* US). First used by J. B. Watson and his colleague Rosalie Rayner in the now infamous studies of "Little Albert" (Watson and Rayner, 2000), fear conditioning is now most widely studied in rodents, where a discrete cue (such as a tone, light, or odor; CS) is paired with a brief electric shock to the feet (US). Before conditioning, the CS does not elicit fearful behavior. After as little as one CS-US pairing, however, the animal begins to exhibit a range of *conditioned responses* (CRs), both to the tone CS and to the context in which conditioning occurs (e.g., the conditioning chamber). In rats, these CRs include 'freezing' or immobility (the rat's species-typical behavioral response to a threatening stimulus), autonomic and endocrine alterations (such as changes in heart rate and blood pressure, defecation, and increased levels of circulating stress hormones), and potentiation of reflexes like the acoustic startle response (Blanchard and Blanchard, 1969; Kapp et al., 1979; LeDoux et al., 1988; Roozendaal et al., 1991; Davis, 1997).

4.11.2 The Amygdala and Fear Conditioning

4.11.2.1 The Neuroanatomy of Fear

There are few associative learning paradigms that have been better characterized at the neuroanatomical level than Pavlovian fear conditioning (see **Figure 1**). This is particularly true for the 'auditory fear conditioning' paradigm, where an animal learns to fear a tone (CS) that is paired with foot shock (US). In this review, we will therefore emphasize the findings from the auditory fear conditioning literature, although similar mechanisms have also been proposed for conditioning to visual stimuli (Davis, 1992, 1997).

Auditory fear conditioning involves transmission of auditory CS and somatosensory US information to the lateral nucleus of the amygdala (LA), an area that lesion and functional inactivation studies have shown to be critical for learning (LeDoux et al., 1990; Helmstetter and Bellgowan, 1994; Campeau and Davis, 1995; Muller et al., 1997; Wilensky et al., 2000). Anatomical tract tracing studies have shown that cells in the LA receive direct glutamatergic projections from areas of the auditory thalamus and cortex, specifically from the medial division of the medial geniculate body and the posterior intralaminar nucleus (MGm/PIN) and cortical area TE3, respectively (LeDoux et al., 1985; LeDoux and

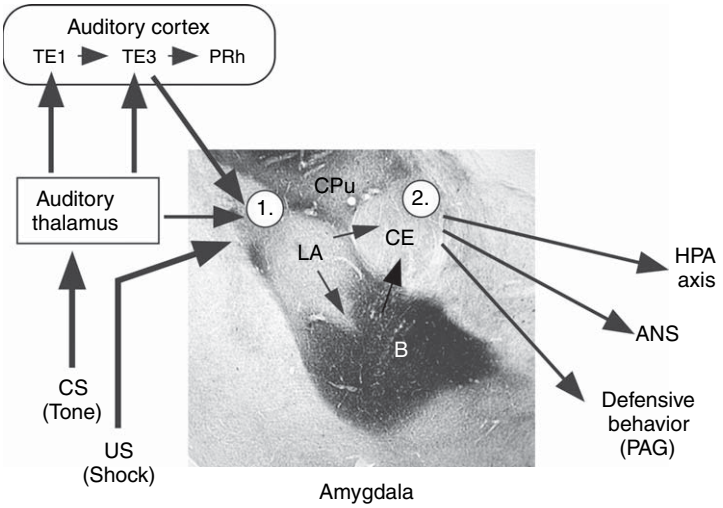

Figure 1 Anatomy of the fear system. (1) Auditory fear conditioning involves the transmission of CS sensory information from areas of the auditory thalamus and cortex to the lateral amygdala (LA), where it can converge with incoming somatosensory information from the foot shock US. It is in the LA that alterations in synaptic transmission are thought to encode key aspects of the learning. (2) During fear expression, the LA engages the central nucleus of the amygdala (CE), which projects widely to many areas of the forebrain and brainstem that control the expression of fear CRs, including freezing, hypothalamic-pituitary-adrenal (HPA) axis activation, and alterations in cardiovascular activity. CPu, caudate/putamen; B, basal nucleus of amygdala; ANS, autonomic nervous system; PRh, perirhinal cortex; PAG, periaqueductal gray.

Farb, 1991; Bordi and LeDoux, 1992; Romanski and LeDoux, 1993; McDonald, 1998; Doron and LeDoux, 1999). Neurophysiological evidence has indicated that inputs from each of these auditory areas synapse onto single neurons in the LA (Li et al., 1996), where they converge with inputs from the somatosensory US (Romanski et al., 1993). Individual cells in the LA are thus well suited to integrate CS and US information during fear conditioning, and it is here, as we will see, that alterations in synaptic transmission are thought to encode key aspects of the memory.

Thalamic and cortical inputs to the LA, while both capable of mediating fear learning (Romanski and LeDoux, 1992a), are believed to carry different types of information to the LA. The thalamic route (often called the 'low road') is believed to be critical for rapidly transmitting crude aspects of the CS to the LA, while the cortical route (known as the 'high road') is believed to carry highly refined information to the amygdala (LeDoux, 2000). Interestingly, while lesions of the MGm/PIN impair auditory fear conditioning (LeDoux et al., 1984, 1986), lesions of the auditory cortex do not (LeDoux et al., 1984; Romanski and LeDoux, 1992b). Thus, the thalamic pathway between the MGm/PIN and the LA appears to be particularly important for auditory fear conditioning. This is not to say, however, that the cortical input to the LA is not involved. Indeed, when conditioning depends on the ability of the animal to make fine discriminations between different auditory CSs, or when the CS is a complex auditory cue such as an ultrasonic vocalization, then cortical regions appear to be required (Jarrell et al., 1987; Lindquist et al., 2004).

During retrieval or expression of a fear memory, the LA, both directly and by way of the adjacent basal nucleus of the amygdala, engages the central nucleus of the amygdala (CE). The CE has traditionally been thought of as the principal output nucleus of the fear learning system, projecting to areas of the forebrain, hypothalamus, and brainstem that control behavioral, endocrine, and autonomic CRs associated with fear learning (Blanchard and Blanchard, 1969; Kapp et al., 1979; LeDoux et al., 1988; Roozendaal et al., 1991; Davis, 1997). Projections from the CE to the midbrain periaqueductal gray, for example, have been shown to be particularly important for mediating behavioral and endocrine responses such as freezing and hypoalgesia (LeDoux et al., 1988; Helmstetter and Landeira-Fernandez, 1990; Helmstetter and Tershner, 1994; De Oca et al., 1998), while projections to the lateral hypothalamus have been implicated in the control of conditioned cardiovascular responses (Iwata et al., 1986; LeDoux et al., 1988). Importantly, while lesions of these individual areas can selectively impair expression of individual CRs, damage to the CE interferes with the expression of all fear CRs (LeDoux, 2000). Thus, the CE acts to coordinate the collection of hard-wired, and typically species-specific, responses that underlie defensive behavior.

4.11.2.2 Synaptic Plasticity in the Amygdala and Fear Conditioning

In addition to being the recipient of CS and US information, the LA is also thought to be a critical site of synaptic plasticity underlying fear learning (LeDoux, 2000; Blair et al., 2001; Maren, 2001). In support of this view, numerous studies have shown that individual cells in the dorsal regions of the LA (LAd) alter their neurophysiological response properties when CS and US are paired during fear conditioning (**Figures 2(a)** and **2(b)**). For example, LAd neurons that are initially weakly responsive to auditory input respond vigorously to the same input after fear conditioning (Quirk et al., 1995, 1997; Rogan et al., 1997; Maren, 2000; Repa et al., 2001; Blair et al., 2003). This change in the responsiveness of LAd cells that occurs as the result of training has contributed to the view that neural plasticity in the LA encodes key aspects of fear learning and memory storage (Fanselow and LeDoux, 1999; Blair et al., 2001; Maren, 2001; Schafe et al., 2001), a topic to which we will return in a later section.

In the next several sections, we will discuss the biochemical and molecular mechanisms that likely underlie plasticity and memory formation at LA synapses. We begin with a discussion of long-term potentiation (LTP), as it has been proposed that this type of synaptic plasticity is the most likely type of mechanism that underlies memory formation in the mammalian brain (Bliss and Collingridge, 1993; Malenka and Nicoll, 1999), including in the LA (Maren, 1999; Blair et al., 2001; Schafe et al., 2001).

4.11.3 LTP as a Mechanism of Fear Learning

4.11.3.1 Why is LTP Important?

The change in the responsiveness of LA cells during fear conditioning suggests that alterations in excitatory synaptic transmission in the LA might be critical for fear conditioning. Accordingly, many of the recent studies that have examined the biochemical

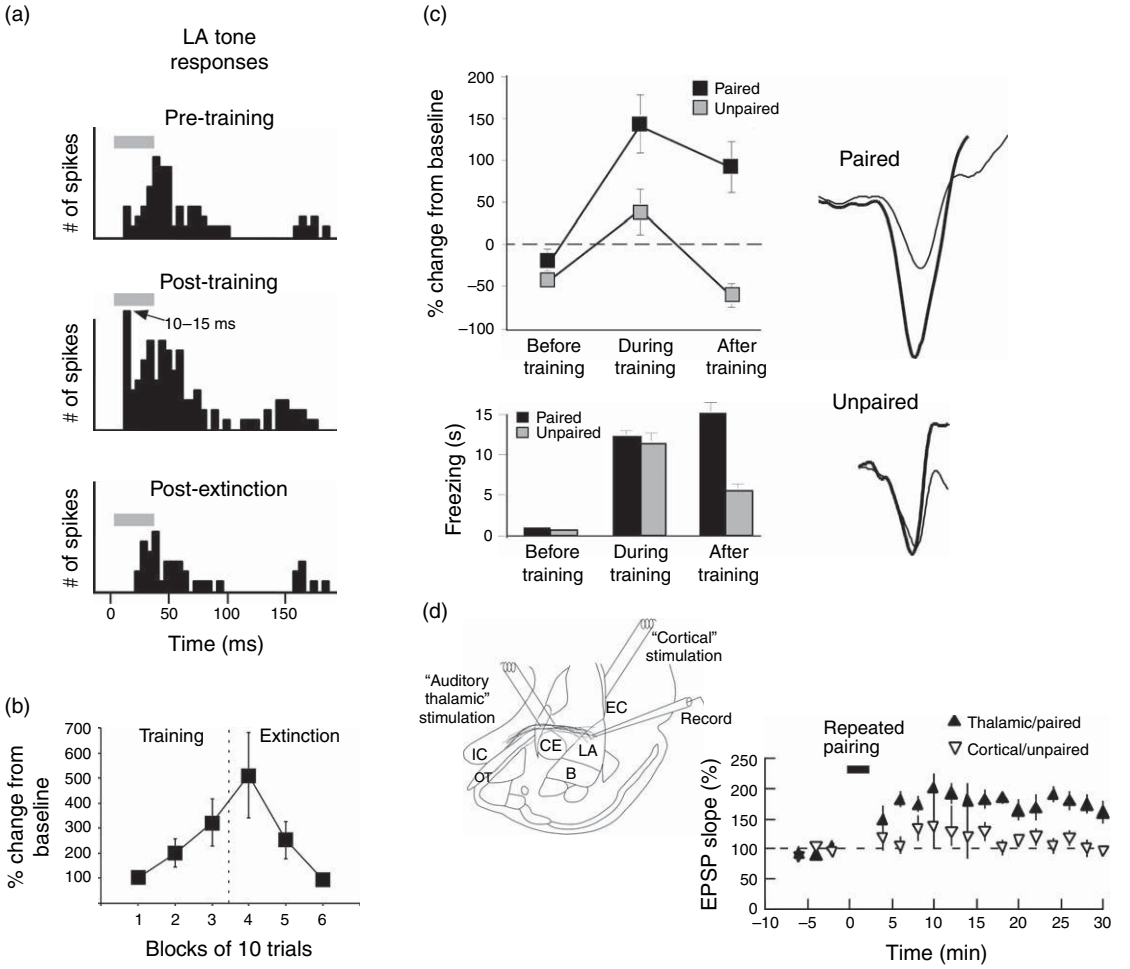

Figure 2 Synaptic plasticity in the lateral amygdala (LA) and fear conditioning. Pairing of CS and US during fear conditioning leads to changes in the responsiveness of LA cells to auditory stimuli, as measured by electrophysiological recording of single cells in the LA. (a) TOP: Prior to auditory fear conditioning, LA cells are weakly responsive to auditory stimuli. MIDDLE: Immediately after conditioning, the same cells respond vigorously, especially in the first few milliseconds of the tone (arrow). BOTTOM: Tone conditioning of LA cells decreases with extinction. In each figure, the onset of the tone stimulus is depicted by a gray bar. (b) Change in firing rate of LA cells over the course of training and extinction. The values represent averaged responses of 16 cells within the first few milliseconds of the tone stimulus and are expressed as percent change from preconditioning firing rates. (c) TOP: Fear conditioning leads to electrophysiological changes in the LA in a manner similar to long-term potentiation (LTP). The figure represents percent change in the slope of the auditory-evoked field potential in the LA before, during, and after conditioning in both paired and unpaired rats. BOTTOM: Freezing behavior across training and testing periods. Note that both paired and unpaired groups show equivalent freezing behavior during training, but only the paired group shows an enhanced neural response. Representative traces can be seen in the inset. (d) LEFT: Associative LTP is induced in the amygdala slice by pairing trains of presynaptic stimulation of fibers coming from the auditory thalamus with depolarization of LA cells. Stimulation of fibers coming from cortical areas serves as a control for input specificity. RIGHT: LTP induced by pairing as measured by the change in the slope of the excitatory postsynaptic potential (EPSP) over time. In this case, the thalamic pathway received paired stimulation, whereas the cortical pathway received unpaired stimulation (i.e., trains and depolarizations, but in a noncontingent manner). The black bar represents the duration of the pairing. IC, internal capsule; OT, optic tract; CE, central nucleus of amygdala; B, basal nucleus of amygdala; EC, external capsule.

basis of fear conditioning have drawn upon a larger literature that has focused on the biochemical events that underlie LTP, an activity-dependent form of synaptic plasticity that was initially discovered in the hippocampus (Bliss and Lømo, 1973). There are several good reasons behind this strategy, including the fact that LTP has been demonstrated in thalamic and cortical auditory input pathways to the

LA (Chapman et al., 1990; Clugnet and LeDoux, 1990; Rogan and LeDoux, 1995; Huang and Kandel, 1998; Weisskopf et al., 1999; Weisskopf and LeDoux, 1999), and that auditory fear conditioning itself has been shown to lead to neurophysiological changes in the LA that resemble artificial LTP induction (McKernan and Shinnick-Gallagher, 1997a; Rogan et al., 1997). Collectively, these findings provide strong support for the hypothesis that an LTP-like process in the LA may underlie fear conditioning (**Figures 2(c) and 2(d)**). This, in turn, suggests that fear memory acquisition and consolidation may share a common biochemical and molecular substrate with LTP.

4.11.3.2 The 'Consolidation' of LTP – E-LTP Versus L-LTP

There are several pharmacologically distinct forms of LTP, most of which have been identified in the hippocampus. One form critically involves the *N*-methyl-D-aspartate receptor (NMDAR), which is normally blocked by Mg^{2+}, but which can be opened following sufficient depolarization of the postsynaptic cell during LTP induction (Malenka and Nicoll, 1993). The other, less widely studied form involves the L-type voltage-gated calcium channel (L-VGCC). Other forms require a combination of both NMDARs and L-VGCCs (Grover and Teyler, 1990; Cavus and Teyler, 1996). Importantly, both NMDAR and L-VGCC-mediated forms of LTP have been discovered in the LA (Weisskopf et al., 1999; Bauer et al., 2002).

Regardless of how it is induced, the hallmark of each form of LTP is the entry of Ca^{2+} into the postsynaptic spine, which initiates a biochemical cascade of events that leads to strengthening of the synapse. Some of these biochemical cascades lead to a transient change in synaptic strength known as early LTP (E-LTP) that is independent of *de novo* RNA and protein synthesis. This type of LTP is thought to involve the activation of protein kinase signaling pathways near the postsynaptic density and the alteration in the conductance of number of a number of key synaptic proteins involved in glutamatergic signaling, including the NMDAR and the closely related alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor (Soderling and Derkach, 2000). Other intracellular cascades lead to a more permanent alteration in cell excitability known as late LTP (L-LTP). Unlike E-LTP, L-LTP requires *de novo* RNA and protein synthesis and different classes of protein kinase signaling cascades that are thought to promote long-term synaptic plasticity by engaging activators of transcription in the nucleus (Nguyen et al., 1994; Nguyen and Kandel, 1996). Thus, the two forms of LTP have features in common with the traditional phases of memory consolidation. L-LTP is conceptually similar to long-term memory (LTM) formation, which is known to be dependent on *de novo* mRNA transcription and protein synthesis, while E-LTP is conceptually similar to short-term memory (STM), which is known to be short-lasting and independent of transcription and translation (Davis and Squire, 1984; Milner et al., 1998; Schafe et al., 2000). This pattern of findings suggests, in turn, that the consolidation process can be represented at the cellular level and understood through studies of LTP (Milner et al., 1998).

An exhaustive review of the biochemical mechanisms underlying LTP is beyond the scope of this chapter (for a more exhaustive review of this topic, see Milner et al., 1998). In the next several sections, however, we will review some of the key membrane-bound receptors and intracellular signaling pathways that have been most widely implicated in LTP and in memory formation of fear conditioning.

4.11.4 Biochemical Mechanisms of Fear Memory Formation and Consolidation

The fact that LTP is characterized by phases that differ as a function of the requirement for transcription and translation suggests that it is an excellent cellular model by which to study the biochemical mechanisms of memory consolidation. Accordingly, inspired by the success of studies that have defined the contribution of different cellular and molecular signaling cascades underlying both E-LTP and L-LTP, a number of recent studies have asked whether these same mechanisms might underlie short- and long-term formation of fear memories in the amygdala. In this section, we will summarize these findings, beginning with recent studies that have focused on glutamatergic signaling pathways and their contribution to fear acquisition and STM formation.

4.11.4.1 Short-Term Fear Memory Formation – Glutamatergic Signaling, CaMKII Activation, and AMPAR Trafficking in the Amygdala

Like E-LTP, STM is a short-lasting form of memory that does not require new protein or RNA synthesis (Milner et al., 1998). While no consistent time frame of STM has been defined in the literature, it is generally tested shortly after training, usually within 1 h. Further, deficits in STM formation are typically assumed to reflect deficits in memory acquisition, although it should be emphasized that acquisition and STM formation are likely subserved by distinct molecular mechanisms (Rodrigues et al., 2004b). In this section, we will examine how glutamatergic transmission, αCaMKII, and AMPA receptor (AMPAR) regulation and trafficking might contribute to fear memory acquisition and STM formation in the LA.

4.11.4.1.1 NMDA receptors

The NMDAR has a long history in the fear conditioning literature. Early pharmacological studies showed that blockade of NMDARs in the LA using the NMDAR antagonist D-2-amino-5-phosphonovaleric acid (APV) reliably impaired fear conditioning (Miserendino et al., 1990; Kim et al., 1991; Campeau et al., 1992), suggesting that an NMDAR-dependent form of synaptic plasticity was critical for fear learning. Later reports, however, indicated that infusion of APV into the LA also impaired the expression of previously acquired fear responses (Maren et al., 1996). These findings are consistent with neurophysiological evidence showing that NMDARs are involved, at least in part, in routine synaptic transmission in the LA (Weisskopf and LeDoux, 1999; Bauer et al., 2002). As such, it has been difficult to conclude unambiguously that NMDARs are required for fear acquisition independently of a role in routine synaptic transmission.

Several years ago, the role of NMDARs in fear conditioning was revisited by examining the effects of selective blockade of the NR2B subunit of the NMDA receptor in the LA. NMDARs are heteromeric complexes composed of several subunits, including the NR1 subunit, which is essential for channel function, as well as a range of NR2 subunits which regulate channel function (Monyer et al., 1992; Nakanishi, 1992). *In vitro* studies have shown that the NR1-NR2B complex exhibits longer excitatory postsynaptic potentials (EPSPs) than the NR1-NR2A complex (Monyer et al., 1992). This characteristic of NR2B-containing NMDARs is thought to provide a longer time window for coincidence detection, which is thought to be especially important during synaptic plasticity (Tsien, 2000). Indeed, recent molecular genetic studies have implicated the NR2B subunit in both synaptic plasticity and memory formation; overexpression of NR2B in the forebrain of mice results in enhanced LTP and memory formation for a variety of tasks, including fear conditioning (Tang et al., 1999).

In the amygdala, blockade of the NR2B by ifenprodil, a selective antagonist of the NR2B subunit of the NMDAR, dose-dependently impairs formation of both STM and LTM of fear conditioning (Rodrigues et al., 2001); that is, memory is impaired both at 1 h and 24 h after infusion and training (**Figures 3(a) and 3(b)**). In contrast, infusions of ifenprodil prior to testing at either time point have no effect on fear expression. These results suggest that ifenprodil lacks the nonspecific effects on routine transmission that are characteristic of the more global NMDAR antagonist APV. In support of this hypothesis, bath application of ifenprodil to amygdala slices also impairs LTP at thalamic inputs to LA neurons but has no effect on routine synaptic transmission (Bauer et al., 2002; **Figure 3(c)**). These results are also consistent with those of a recent study that examined the effects of APV on acquisition of fear-potentiated startle (Walker and Davis, 2000), showing that APV can, under certain circumstances, have selective effects on plasticity. Collectively, findings suggest that the NMDA receptor in the amygdala plays an essential role in both the acquisition and STM of conditioned fear.

4.11.4.1.2 Ca^{2+}/calmodulin-dependent protein kinase

One of the immediate downstream consequences of NMDAR-mediated activity-dependent increases in Ca^{2+} at the time of LTP induction is the activation of Ca^{2+}/calmodulin (CaM)-dependent protein kinase II (CaMKII). The alpha isoform of CaMKII has been widely implicated in synaptic plasticity and memory formation (Fukunaga and Miyamoto, 1999; Soderling and Derkach, 2000; Fink and Meyer, 2002; Lisman et al., 2002), in part for its ability to undergo a rapid 'autophosphorylation,' a state in which this enzyme can remain active in the absence of further Ca^{2+} entry (Soderling and Derkach, 2000). In this state, αCaMKII can phosphorylate and transiently enhance the conductance of a variety of membrane proteins, including AMPARs (Barria et al., 1997;

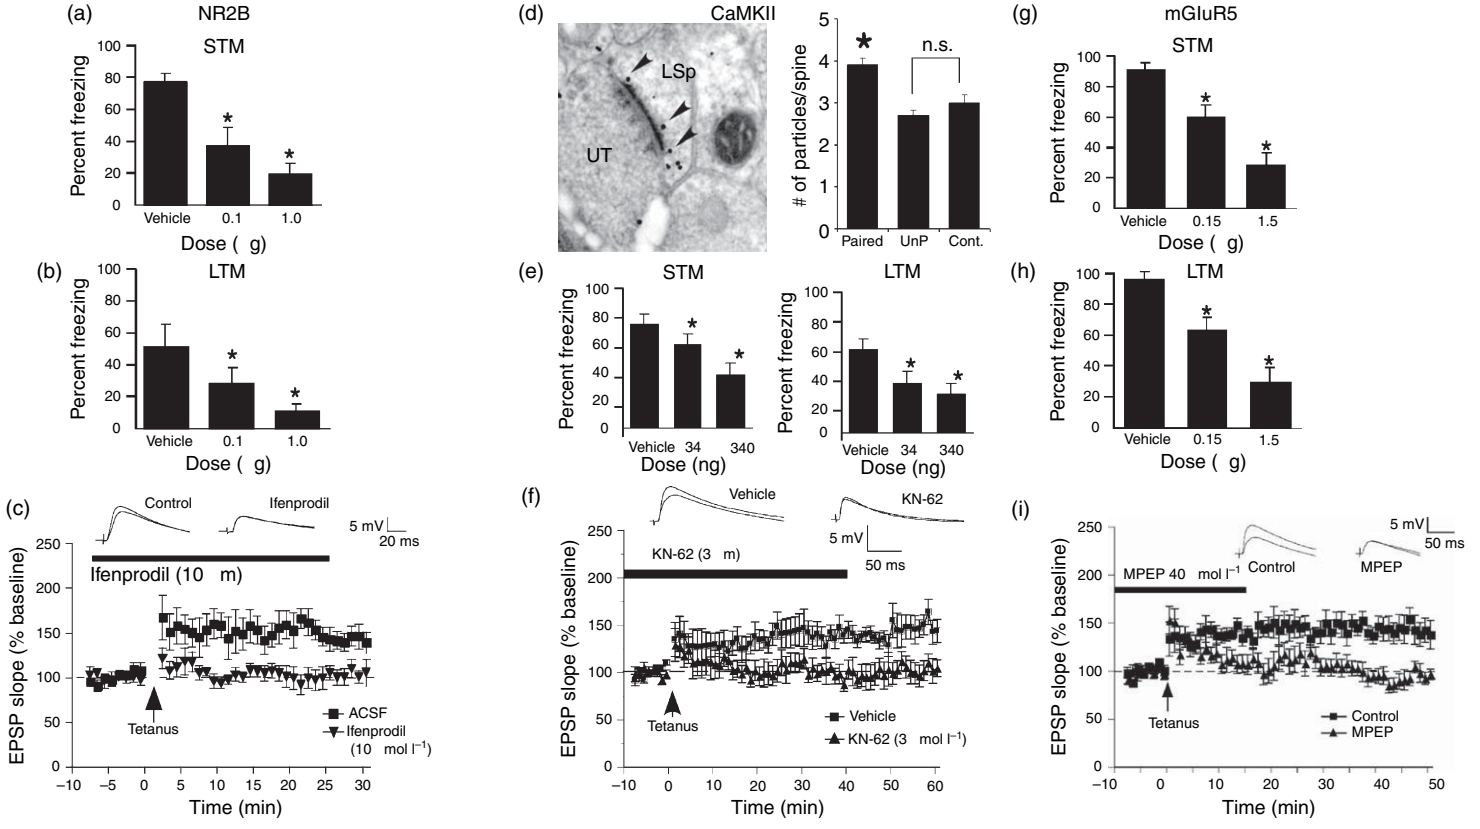

Figure 3 Glutamatergic mechanisms of fear acquisition and STM formation in the LA. (a–b) Both STM and LTM of auditory fear conditioning are dose-dependently impaired by intra-LA infusions of ifenprodil, a selective NR2B antagonist. Adapted from Rodrigues SM, Schafe GE, and LeDoux JE (2001) Intraamygdala blockade of the NR2B subunit of the NMDA receptor disrupts the acquisition but not the expression of fear conditioning. *J. Neurosci.* 21(17): 6889–6896, with permission from the Society for Neuroscience. (c) LTP at thalamic inputs to the LA is also impaired by ifenprodil. Adapted from Bauer EP, Schafe GE, and LeDoux JE (2002) NMDA receptors and L-type voltage-gated calcium channels contribute to long-term potentiation and different components of fear memory formation in the lateral amygdala. *J. Neurosci.* 22: 5239–5249, with permission from the Society for Neuroscience. (d) Fear conditioning results in an increase in autophosphorylated alpha Ca^{2+}/calmodulin-dependent protein kinase II (αCaMKII) in LA spines. Here, rats were conditioned, and activated αCaMKII was detected in LA spines using electron microscopy and an antibody against autophosphorylated αCaMKII at Thr^{286}. The image on the left shows a labeled spine (LSp) in the LA that contains numerous αCaMKII-immunogold labeled particles (arrowheads). The graph on the right shows that paired, but not unpaired (UnP), training leads to significant elevations in αCaMKII-labeled particles in LA spines. UT, unlabeled terminal. $p < .05$. (e) Both STM and LTM of auditory fear conditioning are impaired after intra-LA infusion of KN-62, a CaMKII antagonist. (f) LTP at thalamic inputs to the LA is also impaired by KN-62. (d–f) Adapted from Rodrigues SM, Farb CR, Bauer EP, LeDoux JE, and Schafe GE (2004a) Pavlovian fear conditioning regulates Thr286 autophosphorylation of Ca^{2+}/calmodulin-dependent protein kinase II at lateral amygdala synapses. *J. Neurosci.* 24: 3281–3288, with permission from the Society for Neuroscience. (g–h) Both STM and LTM of auditory fear conditioning are dose-dependently impaired by intra-LA infusions of 2-methyl-6-(phenylethynyl)-pyridine (MPEP), a selective mGluR5 antagonist. (i) LTP at thalamic inputs to the LA is also impaired by MPEP. (g–i) Adapted from Rodrigues SM, Bauer EP, Farb CR, Schafe GE, and LeDoux JE (2002) The group I metabotropic glutamate receptor mGluR5 is required for fear memory formation and long-term potentiation in the lateral amygdala. *J. Neurosci.* 22: 5219–5229, with permission from the Society for Neuroscience.

Mammen et al., 1997; Soderling and Derkach, 2000). Autophosphorylation of αCaMKII on Thr^{286}, for example, promotes the translocation of the kinase to synaptic sites (Shen and Meyer, 1999) and results in phosphorylation of the AMPAR subunit GluR1 on Ser^{831} (Barria et al., 1997; Mammen et al., 1997), an event which increases excitatory current influx into the postsynaptic cell (Derkach et al., 1999) and which is critical for LTP induction (Lee et al., 2000, 2003). Transgenic mice with a deletion of the αCaMKII gene display deficits in hippocampal LTP and hippocampal-dependent spatial memory (Silva et al., 1992a,b). Similarly, pharmacological inhibition of CaMKII blocks the induction of LTP in hippocampal area CA1 (Ito et al., 1991; Stanton and Gage, 1996) and impairs hippocampal dependent learning and memory (Tan and Liang, 1996).

Recent studies have also implicated αCaMKII in fear conditioning. Anatomical studies have shown that αCaMKII is robustly expressed in LA pyramidal neurons (McDonald et al., 2002), where it coexists with NR2B in LA spines postsynaptic to terminals that originate in the auditory thalamus (Rodrigues et al., 2004a). Fear conditioning leads to increases in the autophosphorylated form of αCaMKII at Thr^{286} in spines of LA neurons (**Figure 3(d)**). Further, intra-amygdala infusion or bath application of an inhibitor of CaMKII (KN-62) impairs acquisition and STM formation of fear conditioning and LTP at thalamic inputs to LA neurons, respectively (**Figures 3(e)** and **3(f)**). This latter finding is consistent with molecular genetic experiments indicating that induced overexpression of active αCaMKII by a transgene that replaces Thr^{286} with an aspartate residue in the amygdala and striatum results in a reversible deficit in fear conditioning (Mayford et al., 1996).

4.11.4.1.3 Metabotropic glutamate receptors and protein kinase C

While activation of αCaMKII and resultant GluR1 phosphorylation and receptor trafficking appears to be NMDAR dependent (Hayashi et al., 2000; Fu et al., 2004), it appears that Group I metabotropic glutamate receptors (mGluRs), including mGluR1 and mGluR5, are critical for the potentiation of NMDAR function via the Ca^{2+}/phospholipid-dependent protein kinase (PKC) (Ben-Ari et al., 1992; Kelso et al., 1992). Both mGluR1 and mGluR5, for example, are positively coupled to phospholipase C, activation of which leads to the hydrolysis of phosphatidylinositol 4,5-biphosphate into inositol 1,4,5-trisphosphate (IP3) and diacylglycerol (DAG), two substances that are directly upstream of PKC. In mGluR5 knockout mice, LTP of NMDAR currents in CA1 is absent, but can be rescued by activators of PKC (Jia et al., 1998). Further, an mGluR5 antagonist (CHPG) has been reported to induce a slowly developing, long-lasting potentiation of NMDAR currents via PKC (Doherty et al., 1997). Studies have suggested that two serine residues on the C-terminal domain of the NR2B subunit of the NMDAR, Ser^{1303} and Ser^{1323}, are the critical structural domain for PKC-mediated current potentiation (Liao et al., 2001). However, removal of all the PKC phosphorylation sites on NR1 and NR2 does not alter the PKC-induced potentiation of NMDAR currents (Zheng et al., 1999). Thus, it has been hypothesized that there is an intermediate step between PKC activation and NR2 subunit activation. One hypothesis is that this involves Src kinases (Ali and Salter, 2001; MacDonald et al., 2001). Src is the lead member of a family of protein tyrosine kinases, which also includes Fyn, Lyn, Lck, and Yes. It is thought that these kinases regulate the activity of NMDARs during LTP induction by phosphorylating tyrosine residues that, in turn, are responsible for increased channel conductance (Ali and Salter, 2001; MacDonald et al., 2001). The phosphorylation of NR2B on Tyr^{1472} is increased after tetanic stimulation in area CA1 (Nakazawa et al., 2001), and this appears to be Fyn mediated (Nakazawa et al., 2001, 2002). Further, mice lacking Fyn have impaired LTP in hippocampal area CA1 (Grant et al., 1992).

Several recent studies have examined the role of mGluRs in fear conditioning. Transgenic mice lacking mGluR5 are impaired in fear conditioning tasks (Lu et al., 1997), as are rats injected systemically with the selective mGluR5 antagonist 2-methyl-6-(phenylethynyl)-pyridine (MPEP) prior to fear conditioning (Fendt and Schmid, 2002). In a recent study, Rodrigues et al. showed that mGluR5 was localized in LA spines postsynaptic to auditory thalamic inputs and required for synaptic plasticity at thalamic inputs to LA neurons (Rodrigues et al., 2002). Further, in behavioral experiments, intra-amygdala infusion of MPEP prior to fear conditioning impaired formation of both STM and LTM of fear conditioning (Rodrigues et al., 2002; **Figures 3(g)** amd **3(h)**), and also impaired LTP at thalamic inputs to the LA (**Figure 3(i)**). Similar to the results with the NR2B antagonist ifenprodil, infusion of MPEP prior to training blocked both STM and

LTM, while infusion immediately prior to testing at either time point had no effect.

These findings suggest that mGluRs, and in particular mGluR5, are required for fear conditioning and STM formation in the amygdala. Future experiments, however, will be required to understand the exact mechanisms by which mGluRs contribute to fear conditioning. One attractive hypothesis, suggested by the LTP literature, is that activation of mGluR5 in the amygdala recruits the PKC signaling pathway and leads to modulation and trafficking of NMDARs via tyrosine phosphorylation of NR2B (Doherty et al., 1997; Anwyl, 1999; Liao et al., 2001). The role of PKC or tyrosine kinases in fear acquisition and STM formation has not been explicitly tested, although mice with a specific deletion of the β isoform of PKC have impaired fear conditioning when tested 24 h after training (Weeber et al., 2000). Additional experiments will be necessary to examine the role of mGluR5-mediated signaling in the LA in fear conditioning.

4.11.4.1.4 AMPA receptor regulation and trafficking

Alterations in the conductance properties of glutamatergic receptors are thought to be only one mechanism underlying LTP induction and E-LTP. Ample evidence, for example, has accumulated indicating that new AMPARs and NMDARs are trafficked and inserted into synapses during and after LTP (Grosshans et al., 2002; Malenka, 2003; Malinow, 2003). The insertion of GluR1 into synapses, for example, appears to be αCaMKII dependent, and blockade of αCaMKII-mediated synaptic delivery of GluR1 prevents LTP (Hayashi et al., 2000). Further, activation of PKC has been shown to drive NMDAR subunits into synapses, an effect which is blocked by tyrosine kinase inhibitors (Grosshans et al., 2002). Together with alterations in receptor conductance, these rapid physical alterations in the distribution of AMPARs and NMDARs represent one mechanism by which LTP might persist in the short term.

A recent study by Malinow and colleagues elegantly showed that intra-amygdala expression of a viral vector that prevents GluR1 from being inserted into synaptic sites impairs fear acquisition and synaptic plasticity in the LA (Rumpel et al., 2005). Thus, while additional studies are needed, these findings collectively suggest that activation of αCaMKII during fear acquisition may regulate the insertion of AMPARs at LA synapses and thereby contribute to the formation and maintenance of STM. It is currently unknown how long-lasting this effect is; e.g., whether it persists only over the course of hours or is also evident days after fear learning. Further, no studies have to date examined how fear conditioning might similarly regulate the trafficking of NMDARs. Additional experiments will be critical to examine each of these questions.

4.11.4.2 Long-Term Fear Memory Formation – Protein Kinase Signaling and Transcriptional Regulation in the Amygdala

As its name implies, LTM is a long-lasting phenomenon that can last many hours, days, weeks, or even years (Milner et al., 1998). Accordingly, LTM is typically tested at longer intervals after training, usually starting at 24 h. In this section, we discuss what is known about the mechanisms of LTM formation of fear conditioning in the amygdala. We begin with a discussion of L-VGCCs, as recent work has suggested that these channels play an essential role in promoting LTM formation in the LA.

4.11.4.2.1 L-VGCCs

Recent experiments have shown that LTP at thalamic input synapses to the LA is, under certain conditions, L-VGCC dependent and NMDAR independent (Weisskopf et al., 1999). These experiments used a pairing protocol in which subthreshold presynaptic stimulation of auditory afferents was paired with brief postsynaptic depolarizations (Magee and Johnston, 1997; Markram et al., 1997; Johnston et al., 1999). In this protocol, back-propagating action potentials (BPAPs) originating in the soma are thought to invade the dendrites and interact with EPSPs leading to Ca^{2+} influx through VGCCs (Magee and Johnston, 1997; Johnston et al., 1999; Stuart and Hausser, 2001). Accordingly, LTP induced by pairing in the thalamic pathway is blocked by application of the L-VGCC blockers nifedipine or verapamil (Weisskopf et al., 1999; Bauer et al., 2002).

Until recently, the contribution of L-VGCCs to fear conditioning had not been established. Bauer et al., however, examined the effect of intra-amygdala infusion of the L-VGCC blocker verapamil on the acquisition and consolidation of auditory fear conditioning (Bauer et al., 2002). The findings revealed that blockade of L-VGCCs prior to conditioning selectively impaired LTM formation of fear conditioning at 24 h after training; acquisition and STM, assessed at 1 h, were left intact. These findings,

together with those of studies that examined the role of NMDAR function in fear conditioning discussed earlier, suggest that there are two sources of Ca^{2+} in the LA that are critical for fear memory formation. One, mediated by NMDARs, appears to be selectively involved in fear acquisition and STM formation of fear conditioning (Walker and Davis, 2000; Rodrigues et al., 2001). The second, mediated by L-VGCCs, is selectively involved in LTM formation. While the effects of L-VGCC blockade are not apparent in fear conditioning for many hours after training, it is important to note that this is likely due to interference with a process that is set in motion at the time of CS-US pairing and fear acquisition. Consistent with that notion, recent reports have demonstrated that L-VGCCs play a selective role in signaling to the nucleus and initiating cyclic adenosine monophosphate (cAMP) response element (CRE)-mediated transcription, which is known to be required for long-term synaptic plasticity and memory formation (Dolmetsch et al., 2001). Additional experiments will be necessary to determine the contribution of L-VGCCs to activation of protein kinases and CRE-driven gene expression in the LA following fear conditioning.

4.11.4.2.2 Protein kinase A and mitogen-activated protein kinase

Activity-dependent increases in intracellular Ca^{2+} in LA neurons during fear acquisition is thought to lead, either directly or indirectly, to the activation of both protein kinase A (PKA) and the extracellular signal-regulated kinase/mitogen-activated protein kinase (ERK/MAPK). There has been a great deal of recent interest in each of these kinases, in part because they have been shown to be essential for the late phase of multiple forms of synaptic plasticity and memory (Milner et al., 1998; Sweatt, 2004). Once activated by stimulation that promotes L-LTP, each of these kinases is thought to engage activators of transcription. While PKA is directly capable of regulating transcription, recent evidence suggests that PKA may play a permissive role in transcriptional regulation by promoting the activation and nuclear translocation of ERK/MAPK (Roberson et al., 1999). As a result, it has been suggested that ERK/MAPK may represent a final common pathway through which different upstream kinases regulate transcription, long-term plasticity, and memory formation (Adams and Sweatt, 2002).

Both PKA and ERK/MAPK have also been implicated in fear conditioning. Mice that overexpress an inhibitory form of PKA, R(AB), exhibit impaired L-LTP in hippocampal area CA1 and selective deficits in LTM, but not STM, of contextual fear conditioning (Abel et al., 1997). Similarly, mice that lack *Ras-GRF,* an upstream regulator of ERK/MAPK, have impaired memory consolidation of auditory and contextual fear conditioning, as well as impaired amygdala LTP (Brambilla et al., 1997).

Recent pharmacological experiments have examined the role of PKA and ERK/MAPK in amygdala LTP and in fear conditioning. Huang et al. showed that bath application of inhibitors of PKA or ERK/MAPK to amygdala slices impairs LTP at thalamic and cortical inputs to the LA but has no effect on E-LTP (Huang et al., 2000). Consistent with those findings, infusion of a PKA inhibitor or of a peptide that blocks the association of PKA with the A-kinase anchoring protein (AKAP) in the LA impairs LTM, but not STM of fear conditioning (Schafe and LeDoux, 2000; Moita et al., 2002; **Figure 4(e)**). Further, fear conditioning results in a transient activation of ERK/MAPK in the LA (**Figures 4(a)–4(c)**), and infusion of an inhibitor of MEK, an upstream regulator of ERK/MAPK, into the LA prior to fear conditioning impairs memory consolidation; that is, rats have intact STM and impaired LTM (Schafe et al., 2000; **Figure 4(d)**). Collectively, these findings support the hypothesis that both PKA and ERK/MAPK contribute to fear memory formation by engaging cellular processes, possibly those in the nucleus, that are necessary for long-term synaptic plasticity and memory formation.

4.11.4.2.3 Neurotrophin signaling

In addition to Ca^{2+}-mediated signaling, neurotrophins have been widely implicated in driving protein kinase signaling pathways necessary for long-term synaptic plasticity and memory formation, including fear conditioning. In hippocampal neurons, direct application of brain-derived neurotrophic factor (BDNF) produces a long-lasting, transcription-dependent form of LTP (Kang and Schuman, 1995; Figurov et al., 1996). Further, blockade or genetic deletion of BDNF or its membrane-bound receptor tyrosine kinase, TrkB, impairs L-LTP in the hippocampus (Figurov et al., 1996; Patterson et al., 1996; Korte et al., 1998; Fanselow and LeDoux, 1999), and L-LTP is impaired in hippocampal slices in mice that lack BDNF (Patterson et al., 1996; Korte et al., 1998). Consistent with the importance of ERK/MAPK signaling in long-term synaptic plasticity and memory formation, recent studies have suggested that

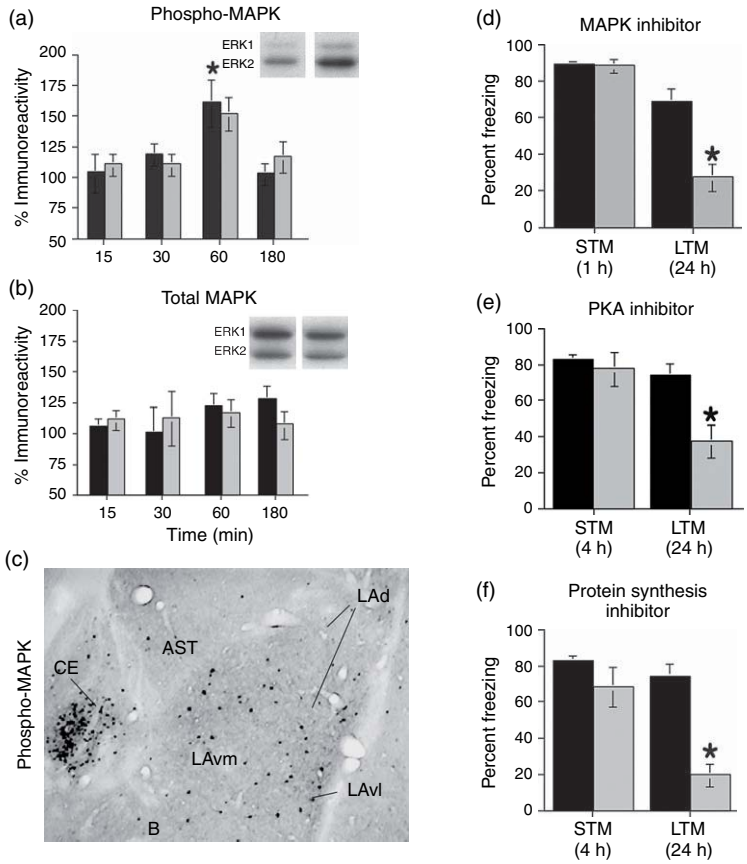

Figure 4 Protein kinase signaling pathways involved in long-term memory (LTM) formation in the lateral amygdala (LA). (a) Fear conditioning leads to an increase in phosphorylated extracellular signal-related kinase 1 (ERK1) and ERK2 at t = 60 min after training. In these experiments, rats were trained and sacrificed at different time points after conditioning, and LA homogenates were probed with antibodies that recognize phosphorylated ERK/mitogen-activated protein kinase (MAPK). ERK1 (black bars) and ERK2 (gray bars) are the two isoforms of ERK/MAPK recognized by the anti-phospho-ERK antibody. $p < .05$. (b) The increase in activated ERK/MAPK is not accounted for by a change in the amount of total (unphosphorylated) ERK/MAPK. (c) Immunocytochemical localization of phosphorylated ERK/MAPK in the LA after fear conditioning. The image shows ERK-labeled cells in three different regions of the LA (dorsal, LAd; ventromedial, LAvm; and ventrolateral, LAvl), with most of the label concentrated in the ventral portions of the LAd and throughout the LAvm and LAvl. Activated ERK/MAPK is also highly expressed in the nearby central nucleus (CE) and the amygdala-striatal transition zone (AST). B, basal nucleus of the amygdala. (a–c) Adapted from Schafe GE, Atkins CM, Swank MW, Bauer EP, Sweatt JD, and LeDoux JE (2000) Activation of ERK/MAP kinase in the amygdala is required for memory consolidation of Pavlovian fear conditioning. *J. Neurosci.* 20: 8177–8187, with permission from the Society for Neuroscience. (d–f) LTM, but not short-term memory (STM), in the LA requires MAPK, protein kinase A (PKA), and protein synthesis. In these studies, rats received intra-amygdala infusions of (d) U0126 (a MEK inhibitor, which is an upstream regulator of ERK/MAPK activation), (e) Rp-cAMPS (a PKA inhibitor), or (f) anisomycin (a protein synthesis inhibitor) at or around the time of training and were assayed for both STM (1–4 h later) and LTM (24 h later) of auditory fear conditioning. In each figure, vehicle-treated rats are represented by the gray bars, while drug-treated animals are represented by the black bars. $^{*}p < .05$ relative to vehicle controls. (d–f) Adapted from Schafe GE and LeDoux JE (2000) Memory consolidation of auditory Pavlovian fear conditioning requires protein synthesis and protein kinase A in the amygdala. *J. Neurosci.* 20: RC96, with permission from the Society for Neuroscience.

BDNF-TrkB-mediated signaling promotes long-term synaptic plasticity by engaging the ERK/MAPK signaling pathway (Patterson et al., 2001). Application of BDNF potently activates ERK/MAPK in hippocampal neurons (Ying et al., 2002), and treatment with an inhibitor of ERK/MAPK activation impairs BDNF-induced LTP (Ying et al., 2002). Collectively, these findings suggest that BDNF-induced ERK signaling plays an essential role in long-term synaptic plasticity.

A recent study has shown that BDNF-mediated signaling in the amygdala is critical to fear learning

(Rattiner et al., 2004, 2005). In that study, fear conditioning led to increases in both TrkB receptor phosphorylation and decreases in TrkB receptor immunoreactivity in the LA during the consolidation period, which is typically indicative of bound BDNF. Further, disruption of TrkB receptor signaling in the amygdala using either a Trk receptor antagonist or lentiviral overexpression of a dominant negative TrkB isoform impaired fear memory formation (Rattiner et al., 2004). While this study did not distinguish between acquisition and consolidation phases of fear learning, the assumption is that BDNF signaling in the LA plays a critical role in the establishment of long-term fear memories, possibly by promoting the activation and nuclear translocation of protein kinases such as ERK (Patterson et al., 2001; Ying et al., 2002). Additional experiments will be necessary to define the signaling pathways through which BDNF acts during fear learning.

4.11.4.2.4 Transcriptional regulation and macromolecular synthesis

Both L-LTP in the LA (Huang and Kandel, 1998; Huang et al., 2000) and LTM of fear conditioning (Bailey et al., 1999; Schafe and LeDoux, 2000) are known to require new RNA and protein synthesis in the LA (**Figure 4(f)**). The requirement for *de novo* RNA synthesis is particularly important, because it suggests that a nuclear event is required for the transition between short- and long-term memory formation.

As previously discussed, signaling via ERK/MAPK plays a critical role in memory formation by engaging activators of transcription in the nucleus. ERK/MAPK is thought to promote transcription by binding to and activating transcription factors, including, by way of the Rsk and MSK1 signaling pathways (Xing et al., 1996; Adams and Sweatt, 2002), the cAMP-response-element binding protein (CREB) (Impey et al., 1996, 1998a). It is the activation of CREB and CRE-mediated genes that ultimately leads to the protein and RNA synthesis-dependent functional and/or structural changes that are thought to underlie L-LTP (Frank and Greenberg, 1994; Yin and Tully, 1996; Silva et al., 1998; Stevens, 1998; Holt and Maren, 1999). While many of these genes and their functional roles remain to be elucidated, it has been suggested that the regulation of a number of CRE- and serum response element (SRE)-mediated immediate early genes (IEGs) plays a critical intermediate role in regulating the expression of late-response genes. These have included *Zif-268,* and its protein product EGR-1, and the activity-regulated cytoskeletal-associated protein (Arc). Importantly, each of these IEGs is known to be regulated by hippocampal LTP (Richardson et al., 1992; Abraham et al., 1993; Worley et al., 1993; Link et al., 1995) and required for hippocampal-dependent LTM formation (Guzowski et al., 2000; Jones et al., 2001).

Several transcription factors have been implicated in long-term synaptic plasticity and in memory formation, but CREB is perhaps the best studied. CREB is a family of transcription factors consisting of several functionally distinct isoforms. Some, known as activator isoforms, bind to DNA at CRE promoter regions and promote transcription. Others, known as repressor isoforms, compete with the binding of activator isoforms to DNA (Bartsch et al., 1995; Abel et al., 1998; Silva et al., 1998). CREB is an attractive candidate molecule for memory consolidation because it has direct interaction with the transcriptional machinery and also contains phosphorylation sites for the major protein kinase signaling pathways that are known to be involved in memory formation, including PKA, ERK/MAPK, and CaMKII (Silva et al., 1998).

The first evidence that suggested CREB might be involved in memory consolidation came from a study employing a Pavlovian conditioning task in *Drosophila.* Overexpression of a dominant negative (repressor) isoform of CREB in flies impaired LTM formation in a conditioned odor aversion task (Yin et al., 1994). Conversely, overexpression of an activator isoform of CREB facilitated LTM; that is, behavioral training that would normally produce only STM was effective at producing LTM (Yin et al., 1995).

CREB has also been implicated in fear conditioning. Mice lacking two critical isoforms of CREB, the α and δ, have impaired hippocampal L-LTP and memory consolidation for auditory and contextual fear conditioning; that is, LTM is impaired, while STM is intact (Bourtchuladze et al., 1994). Further, induced overexpression of a dominant negative isoform of CREB in the forebrain impairs LTM formation of fear conditioning (Kida et al., 2002). Conversely, overexpression of the transcription factor CREB in the LA facilitates fear memory formation (Josselyn et al., 2001). In the latter study, CREB was overexpressed locally in the LA, using viral transfection methods. Consistent with the role of CREB in long-term synaptic plasticity and memory formation, overexpression of CREB in the LA

facilitated LTM of fear conditioning, but had no effect on STM.

While CRE-mediated transcription clearly supports the development of long-term plasticity and memory, the downstream targets of CREB have remained largely unknown. However, a number of studies have shown that fear conditioning induces the expression of both IEGs (Beck and Fibiger, 1995; Rosen et al., 1998; Malkani and Rosen, 2000; Scicli et al., 2004) and downstream genes (Stork et al., 2001; Ressler et al., 2002; Rattiner et al., 2004) in the LA. While the specific contributions of many of these genes to fear conditioning is still unclear, it is widely believed that learning-induced gene expression ultimately contributes to changes in cell (especially synaptic) structure that stabilizes memory (Bailey and Kandel, 1993; Woolf, 1998; Rampon et al., 2000; Sweatt, 2004), presumably by altering the actin cytoskeleton underlying synaptic organization (van Rossum and Hanisch, 1999; Matus, 2000; Kasai et al., 2003). Such changes in synaptic structure have been well documented in invertebrates, where stimulation that promotes long-term synaptic plasticity has been shown to lead to an increase in new synaptic contacts (Bailey et al., 1992, 1994; Bailey and Kandel, 1993). Further, both learning and LTP result in a number of structural changes in the hippocampus and cortex, including an increase in spine head volume and widening and shortening of the spine neck (Van Harreveld and Fifkova, 1975; Fifkova and Van Harreveld, 1977; Fifkova and Anderson, 1981), spine perforation (Toni et al., 1999), and an increase in the total number of spines (Engert and Bonhoeffer, 1999; Leuner et al., 2003).

Recent studies have suggested that fear conditioning leads to alterations in cytoskeletal proteins and to new spine formation in the LA. Fear conditioning, for example, leads to the transcription of genes involved in cytoskeletal remodeling, including the CRE-mediated gene neurofilament-light chain (NF-l) (Ressler et al., 2002). Further, interference with molecular pathways known to be involved in structural plasticity during early development, such as the Rho GTPase (GTP: guanosine triphosphate) activating protein (Rho-GAP) signaling pathway, disrupts memory formation (Lamprecht et al., 2002), and fear conditioning drives actin cytoskeleton-regulatory proteins, such as profilin, into amygdala spines shortly after training (Lamprecht et al., 2006). Finally, a recent morphological study has suggested that fear conditioning leads to an increase in spinophilin-immunoreactive dendritic spines in the LA (Radley et al., 2006).

4.11.4.3 A Presynaptic Component to Fear Learning?

As outlined, most recent studies have focused on postsynaptic mechanisms and their role in amygdala LTP and memory formation (for review, see Schafe et al., 2001). There is growing evidence, however, that suggests that synaptic plasticity and memory formation in the LA involves a presynaptic process. McKernan and Shinnick-Gallagher (1997), for example, showed that auditory fear conditioning occludes paired-pulse facilitation (PPF) at cortical inputs to the LA, a type of short-term plasticity that is largely believed to be presynaptic. Similarly, Huang and Kandel (1998) observed that LTP at cortical inputs to the LA occludes PPF in this pathway. Further, bath application, but not postsynaptic injection, of a PKA inhibitor impairs LTP in LA neurons (Huang and Kandel, 1998). Conversely, bath application of forskolin, a PKA activator, in the presence of antagonists of postsynaptic NMDAR and AMPAR receptors, induces LTP and occludes PPF at cortical inputs (Huang and Kandel, 1998), suggesting that the presynaptic component of LTP in this pathway is PKA dependent. More recently, Tsvetkov et al. showed that auditory fear conditioning itself, in addition to LTP, occludes PPF at cortical inputs to LA (Tsvetkov et al., 2002). It is thus clear from the available evidence that a complete understanding of memory formation and synaptic plasticity in the LA will require attention to both sides of the synapse.

4.11.4.3.1 Nitric oxide signaling and fear learning

Recent evidence has suggested that nitric oxide (NO) signaling in the LA is critical to fear memory formation (Schafe et al., 2005) and may represent a mechanism whereby postsynaptic induction of plasticity induced by fear conditioning in LA neurons may engage accompanying presynaptic changes. NO is a highly soluble gas generated by the conversion of L-arginine to L-citrulline by the Ca^{2+}-regulated enzyme nitric oxide synthase (NOS) (Bredt and Snyder, 1992). In other memory systems, NO is thought to serve as a 'retrograde messenger' that engages aspects of presynaptic plasticity (Schuman and Madison, 1991; Zhuo et al., 1994; Arancio et al.,

1996; Doyle et al., 1996; Son et al., 1998; Ko and Kelly, 1999; Lu et al., 1999) and memory formation (Chapman et al., 1992; Bohme et al., 1993; Bernabeu et al., 1995; Holscher et al., 1996; Suzuki et al., 1996; Zou et al., 1998). One immediate downstream effector of NO, for example, is soluble guanylyl cyclase (Bredt and Snyder, 1992; Son et al., 1998; Denninger and Marletta, 1999; Arancio et al., 2001). This enzyme directly leads to the formation of cyclic guanosine monophosphate (cGMP) and in turn to the activation of the cGMP-dependent protein kinase (PKG). PKG, in turn, can have a number of effects, including targeting and mobilization of synaptic vesicles in the presynaptic cell, leading to enhanced transmitter release (Hawkins et al., 1993, 1998). In the hippocampus, pharmacological inhibition of NOS activation, guanylyl cyclase, or PKG impairs LTP in CA1 (Zhuo et al., 1994; Doyle et al., 1996; Son et al., 1998; Lu et al., 1999; Monfort et al., 2002). Conversely, bath application of exogenous NO or pharmacological activators of cGMP or PKG combined with weak tetanic stimulation, which would not produce LTP alone, induces long-lasting LTP (Zhuo et al., 1994; Son et al., 1998; Lu et al., 1999; Lu and Hawkins, 2002). Inhibition of NOS activity is equally effective at impairing LTP, whether the NOS inhibitor is injected directly into the postsynaptic cell or perfused over the entire slice, suggesting that the critical activation of NOS occurs postsynaptically (Schuman and Madison, 1991; Arancio et al., 1996; Ko and Kelly, 1999). However, NO is thought to act presynaptically, at least in part, because bath application of membrane-impermeable scavengers of NO also impairs LTP in CA1 (Schuman and Madison, 1991; Ko and Kelly, 1999). Collectively, this pattern of findings supports the notion that LTP in area CA1 is induced postsynaptically, but maintained or expressed presynaptically, at least in part, by an NO-dependent mechanism.

In our recent experiments, we showed that neuronal nitric oxide synthase (nNOS) is localized in LA spines (**Figure 5(a)**). Further, PPF was occluded by LTP at thalamic inputs to the LA, and bath application of either a NOS inhibitor or a membrane impermeable scavenger of NO impaired LTP at thalamo–LA synapses (**Figures 5(b)–5(d)**). Finally, intra-amygdala infusion of both compounds impaired fear memory consolidation; that is, LTM was impaired, while STM was intact (Schafe et al., 2005; **Figures 5(e)** and **5(f)**). While additional studies will be necessary, these are among the first to define a role for NO signaling in fear memory formation in the LA.

4.11.5 Is the Lateral Amygdala an Essential Locus of Fear Memory Storage?

In the previous sections, we have discussed the findings of lesion, neurophysiological, pharmacological, and biochemical studies. Collectively, these findings suggest that fear memory formation and consolidation involve alterations in synaptic transmission at LA synapses via an LTP-like mechanism. But is the LA really a site of fear memory storage? This question has proven extremely difficult to address experimentally. Recent findings, however, have provided a fresh look at this question and provide a new strategy for revealing the location of the fear engram.

4.11.5.1 An Alternative View of the Amygdala and Fear Conditioning

While an ever-increasing number of studies using lesion, neurophysiological, and most recently, pharmacological/biochemical techniques have suggested that the LA is an essential site of fear memory formation and storage, an alternative view has offered alternative interpretations of each of the aforementioned findings (Cahill et al., 1999). One obvious way to ask whether a brain structure might be involved in permanent storage of a memory is to lesion that structure at different time points after training (e.g., 1 day later, 1 week later, 1 year later). If memory is impaired as the result of the lesion at each of these time points it suggests that some type of permanent storage has occurred there, *provided that* the area of interest is not involved in some way in the expression of that type of learning. In support of the memory storage hypothesis, lesions of the amygdala impair fear learning even if given years after the initial training event (Gale et al., 2004). The conclusions drawn from these studies, however, have long been called into question due to the fact that the LA and its connections with the CE are also critical for fear expression (Cahill et al., 1999, 2001). Accordingly, lesion studies alone cannot unambiguously distinguish a role for the LA in fear acquisition from that of fear expression.

Neurophysiological and pharmacological studies supporting a role for the amygdala in memory storage have also been called into question. It has been pointed out, for example, that the LA is not unique but rather one of many regions of the wider fear network to exhibit training-related neurophysiological changes during and after fear conditioning.

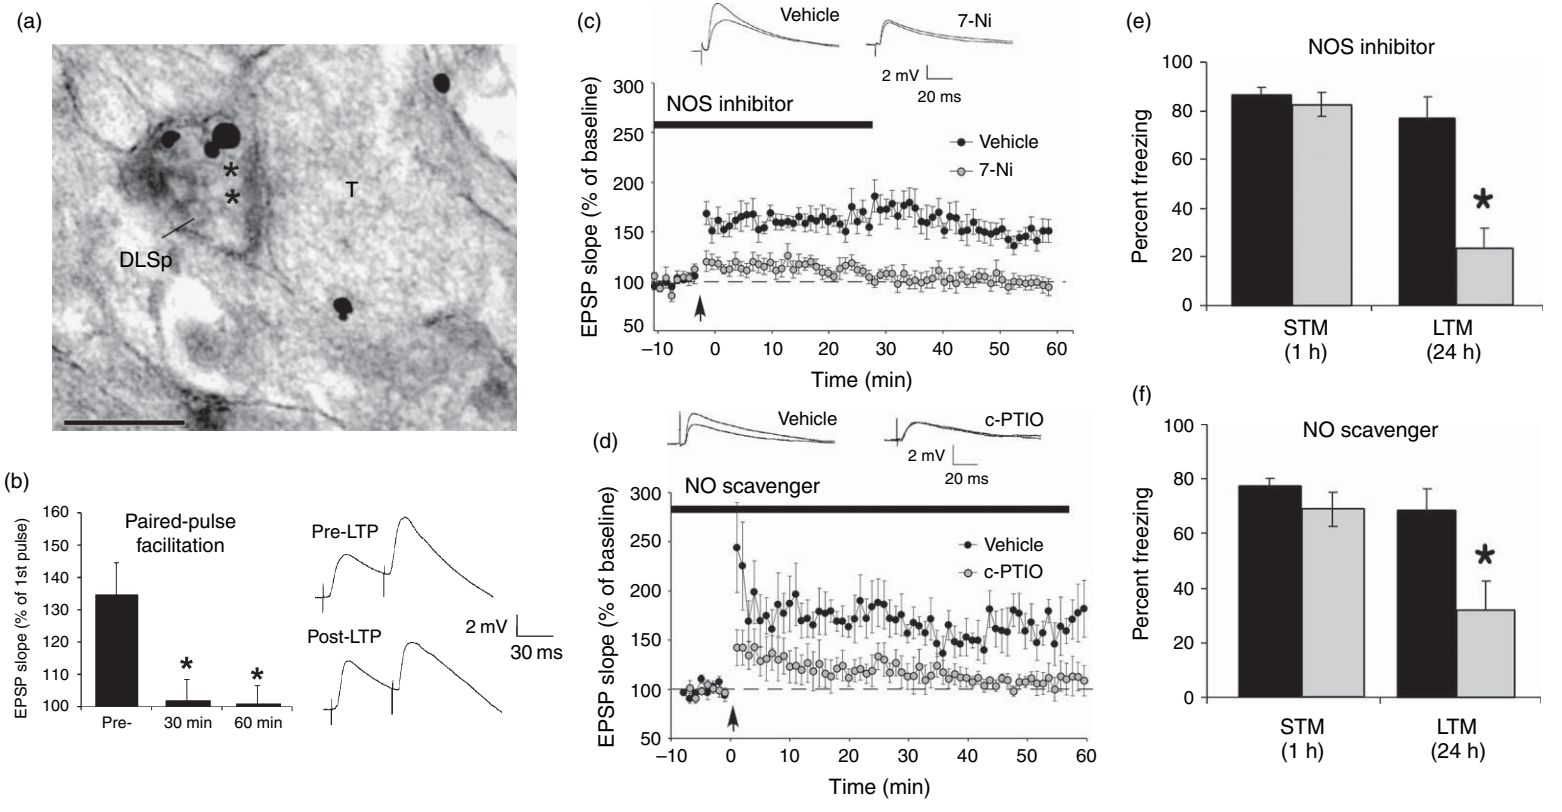

Figure 5 Nitric oxide (NO) signaling and fear memory formation. (a) Localization of neuronal NOS (nNOS) in LA spines. A terminal (T) forms an asymmetric synapse (asterisks) onto a nNOS- and αCaMKII-immunoreactivity dually labeled spine (DLSp) in the LA. The immunogold particles represent labeling of αCaMKII, while the peroxidase represents labeling of nNOS. (b) Paired-pulse facilitation at thalamic inputs to the LA before (Pre-) and 30 and 60 min after LTP induction. Each cell was given two stimulations that were spaced 50 ms apart, and the second pulse was expressed as a percentage of the first pulse. Representative traces can be seen at the right. (c–d) LTP at thalamic inputs to the LA is impaired by bath application of either (c) an inhibitor of nNOS (7-nitroindazole, 7-Ni) or (d) a membrane impermeable scavenger of NO (carboxy-PTIO, c-PTIO). (e–f) Fear memory consolidation is also impaired by 7-Ni and carboxy-PTIO. In both cases, STM is intact, while LTM is impaired. All figures adapted, with permission, from Schafe GE, Bauer EP, Rosis S, Farb CR, Rodrigues SM, and LeDoux JE (2005) Memory consolidation of Pavlovian fear conditioning requires nitric oxide signaling in the lateral amygdala. *Eur. J. Neurosci.* 22: 201–211. Copyright by Blackwell Publishing.

Auditory fear conditioning, for example, induces associative alterations in the activity of neurons not only in the LA, but also in the auditory cortex (Bakin and Weinberger, 1990; Edeline and Weinberger, 1993) and the auditory thalamus (Gabriel et al., 1975; Weinberger, 1993). Consequently, it has been difficult to argue with certainty that training-induced changes in the LA are of local origin rather than the result of a passive reflection of plasticity in these upstream regions (Cahill et al., 1999). This has been especially true of training-induced changes in the auditory thalamus (MGm/PIN), which are of short enough latency (e.g., 5–7 ms) to account for the shortest observed changes in the LA (e.g., 12–15 ms). Finally, rather than indicating that the LA is a site of storage of fear memories, it has been suggested that memory deficits observed after pharmacological manipulations may instead indicate that the LA is essential for triggering or modulating the strength of plasticity and memory storage in other regions of the wider fear network (Cahill et al., 1999). In support of this notion, recent studies have suggested that the acquisition of training-induced plasticity in the auditory thalamus is dependent on the amygdala (Maren et al., 2001; Poremba and Gabriel, 2001). Accordingly, one may argue that pharmacological manipulations of the LA that are aimed at disrupting synaptic plasticity may be doing so by modulating the strength of plasticity in regions of the wider fear network, such as the MGm/PIN, which is in turn reflected back to the LA.

4.11.5.2 A New Strategy for Tracking the Fear Engram

Recognizing that neurophysiological or pharmacological methods alone are unlikely to be able to answer the question of where fear memories are stored, a recent study from our lab has taken a new approach. In our studies, we combined simultaneous neurophysiological recordings from both LA and MGm/PIN with intra-LA infusion of the MAP kinase kinase (MEK) inhibitor U0126 (**Figure 6**). We reasoned that if local synaptic plasticity in the LA was necessary for fear memory formation and storage via an ERK/MAPK dependent mechanism, then local inhibition of MEK in the LA should selectively impair training-induced plasticity in the LA rather than the MGm/PIN. The findings showed that MEK inhibition in the LA impaired both memory consolidation of auditory fear conditioning (**Figures 6(a) and 6(b)**), and also the consolidation of training-induced synaptic plasticity in the LA (**Figures 6(c)–6(e)**). That is, acquisition and short-term retention of fear learning and cellular changes were intact, whereas long-term retention was impaired. Intra-LA infusion of the MEK inhibitor had no effect, however, on training-induced neurophysiological changes in the MGm/PIN (**Figures 6(f)–6(h)**).

Together, these findings strongly indicate that ERK/MAPK-mediated signaling in the LA is required for memory consolidation of fear conditioning as well as for consolidation of conditioning-induced synaptic plasticity in the LA. Further, our findings rule out the possibility that MEK inhibition in the LA may be impairing to fear memory formation by influencing synaptic plasticity (either short- or long-term) in the MGm/PIN. Further, these findings suggest that conditioned enhancement of CS responses in the auditory thalamus is not sufficient to support memory storage of fear conditioning, whereas ERK-dependent conditioned enhancement of CS responses in LA is necessary, at least in part, for memory storage. Importantly, it should be emphasized that these recent findings do not diminish the potential importance of the auditory thalamus and other structures in the encoding of different components of the whole fear memory trace, nor do they suggest, as we will see later, that the amygdala plays no role in modulating certain types of memory storage. However, these recent findings provide strong support to the notion that long-term storage of an emotional memory trace relies, in part, on local synaptic plasticity in the LA.

4.11.6 Distributed Versus Local Plasticity in the Amygdala

While the LA clearly appears to be a critical locus of synaptic plasticity, fear memory acquisition, and storage, it should not be assumed that LA synapses are the only critical synapses in the amygdala which undergo changes that are essential to fear memory formation and/or consolidation. Several recent studies, for example, have suggested that a distributed, rather than localized, network of plasticity in the amygdala underlies fear learning (Medina et al., 2002; Paré et al., 2004).

4.11.6.1 Distributed Plasticity within the LA

The distributed view of plasticity underlying fear learning begins in the LA itself, where plasticity at two sets of synapses has been linked to fear learning,

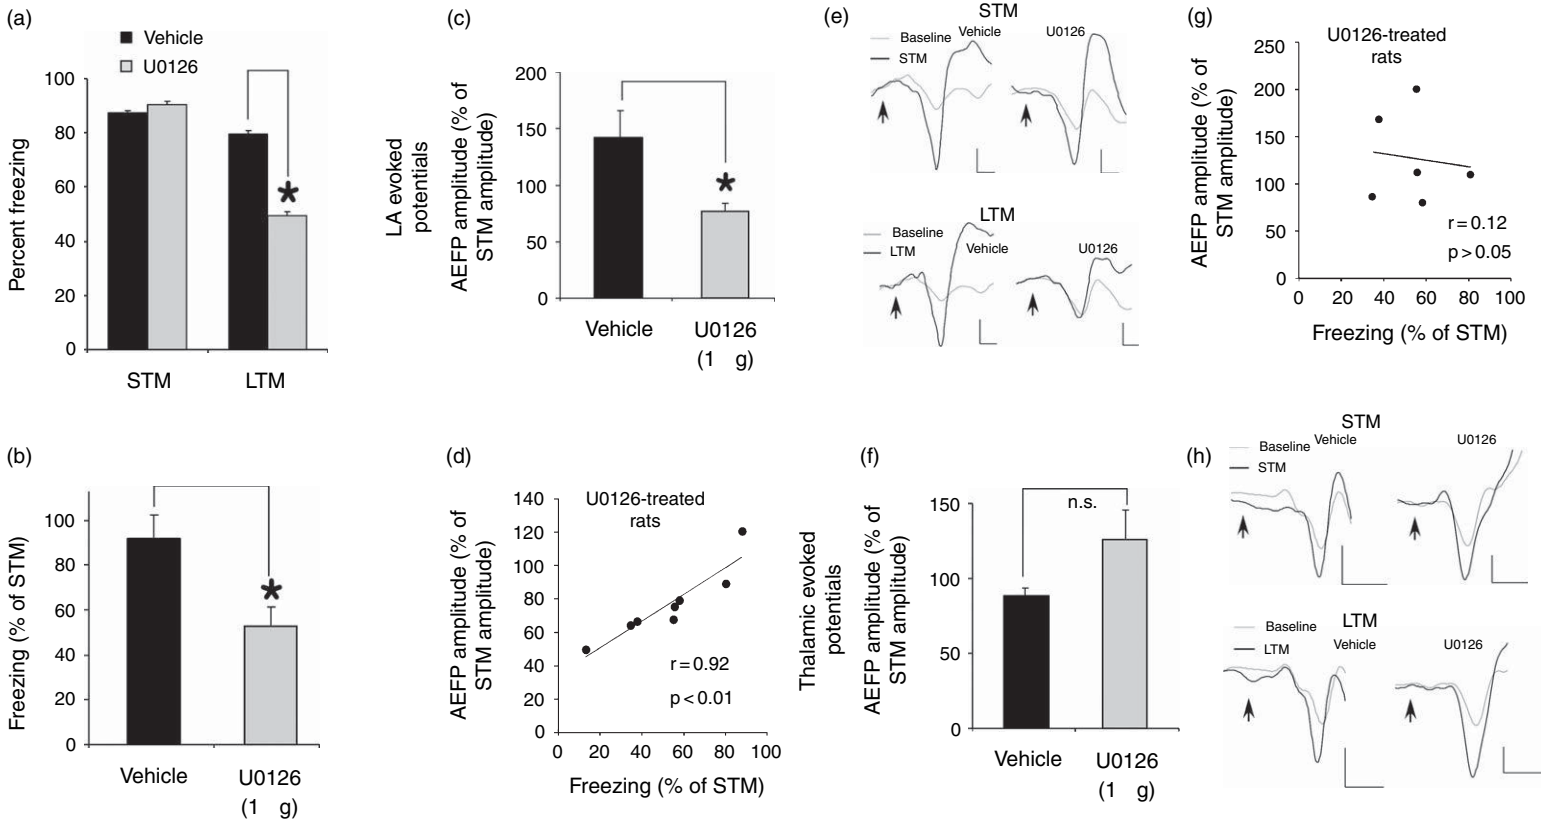

Figure 6 Local synaptic plasticity is required for fear memory consolidation in the lateral amygdala (LA). (a) Impaired fear memory in rats receiving intra-LA infusions of U0126 while neurophysiological recordings were made from both LA and the medial geniculate body and the posterior intralaminal nucleus (MGm/PIN). Mean (± SEM) percent freezing expressed during STM and LTM tests in rats treated with 50% dimethyl sulfoxide vehicle (black bars) or 1 μg U0126 (ray bars). (b) Mean (± SEM) retention of freezing in both groups; freezing during LTM is expressed as a percentage of that observed during the STM test. (c) Mean (± SEM) changes in the amplitude of LA auditory-evoked field potentials (AEFPs) during the LTM test, expressed as a percentage of that obtained during the STM test. (d) Correlation between freezing scores and LA AEFP amplitudes in U0126-treated rats (each expressed as a percentage of STM). (e) Representative AEFPs in the LA for each group (vehicle, U0126) during baseline, STM, and LTM tests. Scale = 20 μs, 5 ms. (f) Mean (± SEM) changes in the amplitude of MGm/PIN AEFPs during the LTM test, expressed as a percentage of that obtained during the STM test. (g) Correlation between freezing scores and LA AEFP amplitudes in U0126-treated rats (each expressed as a percentage of STM). (h) Representative AEFPs in the MGm/PIN for each group (vehicle, U0126) during baseline, STM, and LTM tests. Scale = 20 μs, 5 ms. Adapted from Schafe GE, Doyère V, LeDoux JE (2005b) Tracking the fear engram: The lateral amygdala is an essential locus of fear memory storage. *J. Neurosci.* 25: 10010–10015, with permission from the Society for Neuroscience.

and in unique ways. While most studies that have documented training-induced alterations in synaptic plasticity have focused on cells in the LAd (Quirk et al., 1995, 1997; Rogan et al., 1997; Maren, 2000; Blair et al., 2003), a relatively recent study has documented plastic changes in two populations of cells in the LA (Repa et al., 2001; **Figure 7**). The first is the traditionally studied dorsal population in the LAd that shows enhanced firing to the CS in the initial stages of training and testing and is sensitive to fear extinction. These so-called 'transiently plastic cells' exhibit short-latency changes (within 10–15 ms after tone onset) that are consistent with the involvement of rapid, monosynaptic thalamic input (**Figure 7(b)**). The second population of cells occupies a more ventral position in the LA. In contrast to the transiently plastic cells, these more ventral cells exhibit enhanced firing to the CS throughout training and testing and do not appear to be sensitive to extinction (**Figure 7(c)**). Further, these 'long-term plastic cells' exhibit longer latencies (within 30–40 ms after tone onset), indicative of a polysynaptic pathway. Thus, it has been hypothesized that a network of neurons within the LA is responsible for triggering and storing fear memories (Repa et al., 2001; Medina et al., 2002).

Interestingly, the cells that express activated ERK/MAPK after fear conditioning occupy a more ventral position in the LA, in the same anatomical location of cells that exhibit long-term plasticity during and after fear conditioning (Schafe et al., 2000; Repa et al., 2001; **Figure 7(d)**). In fact, very little activated ERK is observed in the dorsal region of the LA, the site of the majority of CS-US convergence and of cells that exhibit rapid, and transient, plastic changes during fear conditioning (Romanski et al., 1993; Repa et al., 2001). This pattern of findings is consistent with the hypothesis that fear conditioning induces long-term plastic change and memory formation in a ventral population of cells in the LA via the ERK/MAPK signaling cascade. It remains unknown whether this involves a rapid 'transfer' of plasticity between dorsal and ventral cells in the LA during fear conditioning, or an independent, parallel process.

4.11.6.2 Distributed Plasticity within Amygdala Nuclei

Recently, interest has also grown in the idea that distributed plasticity *between* amygdala nuclei may be critical for fear learning. This has been sparked, in part, by a recent study showing that the central nucleus of the amygdala may also be an important locus of fear memory acquisition and consolidation (Wilensky et al., 2006). In that study, functional inactivation restricted to *either* the LA or the CE impaired acquisition of auditory fear conditioning. Further, infusion of the protein synthesis inhibitor anisomycin into the CE impaired fear memory consolidation; that is, rats had intact STM but impaired LTM (Wilensky et al., 2006). These findings suggest that the CE plays an important role not only in fear expression, as has been previously thought, but also in the acquisition and consolidation of fear learning.

How might the CE participate in fear memory acquisition and consolidation? Since the CE, and particularly the medial division of the CE (CEm), also appears to be a recipient of somatosensory (Bernard and Besson, 1990; Jasmin et al., 1997) and possibly also auditory (LeDoux et al., 1987; Turner and Herkenham, 1991; Frankland et al., 1998; Linke et al., 2000) information, one possibility is that the CE encodes in parallel the same type of association that is encoded in the LA. In support of this possibility, a recent study showed that high-frequency stimulation of the auditory thalamus induces an NMDAR-dependent LTP in CEm neurons (Samson and Paré, 2005). If the CE were encoding memory in parallel to the LA, however, this would suggest that the CE should readily be capable of mediating fear learning when the LA is compromised, a finding which is not supported by the literature. Another possibility is that plasticity in the LA and the CE proceeds in a serial manner, such that plasticity and memory formation in the CE depends on plasticity in the LA. This view has been advocated in a recent model that proposes that plasticity in the LA enables CEm neurons to encode plasticity that is essential for fear conditioning, resulting in distributed plasticity and memory formation throughout the amygdala (Paré et al., 2004). The mechanism by which this distributed plasticity between the LA and the CE occurs is at present unknown, but likely involves projections from the LA to CEm neurons via the nearby intercalated cell masses which lie between the LA and the CE (Paré and Smith, 1993; Royer et al., 1999). Additional experiments employing single-unit recording techniques in both the LA and the CEm will be required to determine how these two regions influence one another during fear conditioning.

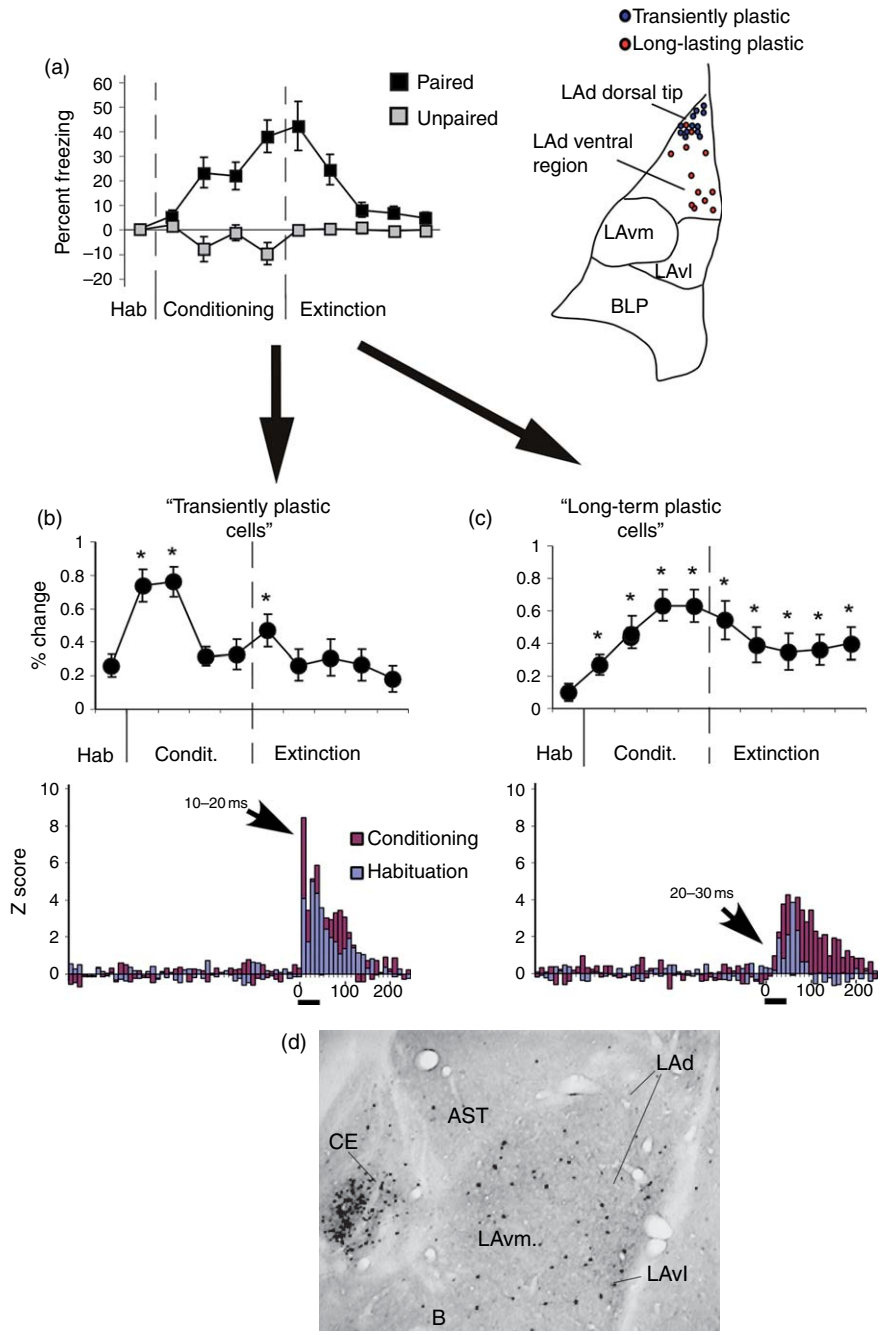

Figure 7 Distributed plasticity in the LA during fear conditioning. Pairing of CS and US during fear conditioning leads to changes in fear behavior (a) and also to changes in the responsiveness of single LA cells to auditory stimuli. During fear conditioning, there are two populations of cells that undergo plastic change. (b) 'Transiently plastic cells' are generally short latency and show enhanced firing shortly after training and during the initial phases of extinction, but not at other times. (c) 'Long-term plastic cells' are generally longer latency and show enhanced firing throughout training and extinction. INSET: 'Transiently plastic cells' are generally found in the dorsal tip of the LAd, where they may serve to trigger the initial stages of memory formation. 'Long-term plastic cells,' on the other hand, are found in the ventral regions of the LAd and may be important for long-term, extinction-resistant memory storage. (d) Location of cells expressing phospho-ERK following fear conditioning. Note the location of ERK-positive cells relative to 'long-term plastic cells.' CE, central nucleus of the amygdala; regions of the LA: LAd, dorsal; LAvm, ventromedial; LAvl, ventrolateral; AST, amygdala-striatal transition zone; B, basal nucleus of amygdala. 4.11.7 Summary: A Model of Fear Memory Acquisition and Consolidation in the Amygdala

In summary, the converging evidence from a number of recent studies supports a model of fear conditioning in which CS and US inputs converge onto individual LA neurons and initiate changes in synaptic function and/or structure (Blair et al., 2001; **Figure 8**). The convergence of CS and US inputs onto LA principal cells during training leads to Ca^{2+} influx through both NMDARs (Miserendino et al., 1990; Kim et al., 1991; Campeau et al., 1992; Walker and Davis, 2000; Rodrigues et al., 2001) and also L-VGCCs (Bauer et al., 2002). The NMDAR-mediated increase in intracellular Ca^{2+}, together with mGluR5 (Rodrigues et al., 2002), leads to the activation of a variety of local protein kinases at the postsynaptic density (PSD), including αCaMKII (Rodrigues et al., 2004a) and likely PKC, that promote STM formation by targeting and modulating the conductance and trafficking of glutamate receptors at LA synapses (Barria et al., 1997; Benke et al., 1998; Rumpel et al., 2005). The combined entry of Ca^{2+} through both NMDARs and L-VGCCs, together with signaling via the BDNF-TrkB pathway, however, may promote the activation of PKA and ERK/MAPK (Schafe et al., 2000; Schafe and LeDoux, 2000). These kinases, and particularly ERK/MAPK, appear to be exclusively involved in the formation of LTM, possibly via translocation to the cell nucleus and activation of transcription factors such as CREB (Josselyn et al., 2001). The activation of CREB by ERK/MAPK promotes CRE-mediated gene transcription (Bailey et al., 1999; Ressler et al., 2002) and the synthesis of new proteins (Schafe and LeDoux, 2000), which likely promotes LTM formation by leading to alterations in the structure of LA synapses (Lamprecht et al., 2002; Ressler et al., 2002; Radley et al., 2006). Intracellular signaling in the postsynaptic neuron, alone, however, does not appear to be sufficient for fear memory formation (McKernan and Shinnick-Gallagher, 1997b; Huang and Kandel, 1998; Tsvetkov et al., 2002). Modifications in presynaptic signaling, possibly engaged by retrograde signaling in the LA via NO and its downstream targets, also appears to be critical

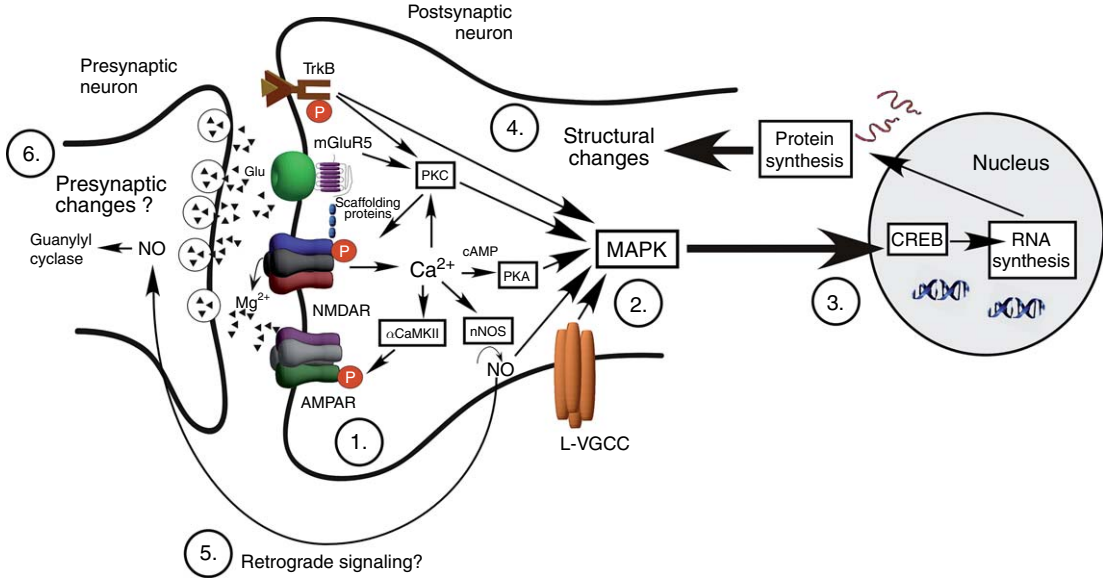

Figure 8 A model of fear memory consolidation in the amygdala. See text for details. (1) Acquisition and STM formation of fear conditioning requires events at the postsynaptic density, including activation of NMDARs, mGluR5, αCaMKII, and possibly PKC. Both αCaMKII and PKC may contribute to STM by influencing the conductance of NMDARs and AMPARs. (2) LTM formation of fear conditioning requires the activation of TrkB receptors, L-type VGCCs, and the cAMP-PKA signaling pathway. These pathways are thought to converge on ERK, which is thought to promote LTM and synaptic plasticity by translocating to the nucleus to influence gene expression. (3) CREB and CRE-mediated transcription are both required for LTM of fear conditioning. (4) The translation of CRE-mediated genes into proteins may lead to structural changes at LA spines that contribute to the permanence of LTM formation. (5) The activation of nNOS in LA neurons may promote retrograde signaling by NO and structural and/or functional changes on the presynaptic side of the synapse (6).

(Schafe et al., 2005). Finally, recent findings emphasizing a distributed network of plasticity in the amygdala have suggested that attention to synaptic plasticity at one synapse, or even one amygdala nucleus, will not be sufficient for a full understanding of how fear memories are acquired or consolidated (Repa et al., 2001; Paré et al., 2004). Accordingly, future experiments will need to consider not only how intracellular signaling mechanisms contribute to fear learning, but also how plasticity across amygdala synapses might be involved in fear memory formation.

4.11.8 Beyond 'Simple' Fear Conditioning

While great strides have been made in identifying the neural and molecular mechanisms that underlie auditory fear conditioning, we have also begun to learn a great deal about more complex aspects of fear learning. In this section, we will explore what is known regarding contextual fear learning, fear extinction, 'reconsolidation' of fear, instrumental fear learning, and memory modulation by the brain's fear system.

4.11.8.1 Contextual Fear Conditioning

In a typical auditory fear conditioning experiment, the animal not only learns to fear the tone that is paired with the foot shock, but also the context in which conditioning occurs. Contextual fear may also be induced by the presentation of foot shocks alone within a novel environment. In the laboratory, fear to the context is measured by returning the rat to the conditioning chamber on the test day and measuring freezing behavior (Blanchard et al., 1969; Fanselow, 1980).

In comparison to auditory fear conditioning, much less is known about the neural system underlying contextual fear. Much of the work examining the neuroanatomical substrates of contextual fear has relied exclusively on lesion methods, and, as in auditory fear conditioning the amygdala appears to play an essential role. For example, lesions of the amygdala, including the LA and basal nucleus, have been shown to disrupt both acquisition and expression of contextual fear conditioning (Phillips and LeDoux, 1992; Kim et al., 1993; Maren, 1998), as has reversible functional inactivation targeted to the LA (Muller et al., 1997). Contextual fear conditioning is also impaired by infusion of antagonists to NMDARs, mGluR5, and CaMKII into the LA, as well as inhibitors of PKA/PKC, RNA, and protein synthesis (Kim et al., 1991; Bailey et al., 1999; Goosens et al., 2000; Rodrigues et al., 2001, 2002, 2004a). Further, a recent study showed that memory consolidation for contextual fear is impaired by infusion of antisense oligonucleotides directed against EGR-1 (Malkani et al., 2004). Collectively, these findings suggest that essential aspects of the memory are encoded and stored in the amygdala via alterations in some of the same intracellular signaling mechanisms that underlie acquisition and consolidation of auditory fear conditioning. At this time, however, there are few data that allow us to distinguish between the involvement of different amygdala subnuclei in contextual fear, although recent lesion evidence suggests that the LA and anterior basal nuclei are critical, but not the posterior basal nucleus (Goosens and Maren, 2001). The CE is, of course, essential for the expression of contextual fear, as it is for auditory fear conditioning (Goosens and Maren, 2001). It remains unknown, however, whether the CE is also required for the acquisition and/or consolidation of contextual fear, or whether distributed plasticity in the LA underlies contextual fear learning.

The hippocampus has also been implicated in contextual fear conditioning, although its exact role has been difficult to define. A number of studies have shown that electrolytic and neurotoxic lesions of the hippocampus disrupt contextual, but not auditory, fear conditioning (Kim and Fanselow, 1992; Phillips and LeDoux, 1992; Kim et al., 1993; Maren et al., 1997). Posttraining lesions appear to be the most effective; pretraining lesions of the hippocampus have occasionally been shown to be without effect (Maren et al., 1997). This is presumably because the animal uses a nonhippocampal strategy to acquire fear to the contextual cues of the environment in the absence of an intact hippocampus during training. Posttraining hippocampal lesions, however, are only effective at impairing contextual fear if given shortly after training. If rats are given hippocampal lesions 28 days after training, there is no memory impairment (Kim and Fanselow, 1992). This 'retrograde gradient' of recall suggests that hippocampal-dependent memories are gradually transferred, over time, to other regions of the brain for permanent storage, an idea that is consistent with the findings of hippocampal-dependent episodic memory research in humans (Milner et al., 1998). The exact mechanism whereby these 'remote' contextual fear memories are consolidated remains unknown, but is thought to involve LTP-like changes in signaling between the

hippocampus and regions of the cortex that make up the individual elements of the contextual representation (Frankland et al., 2001).

What role does the hippocampus play in contextual fear? One prominent view is that it is necessary for forming a representation of the context in which conditioning occurs and for providing the amygdala with that information during training and CS-US integration (Phillips and LeDoux, 1992; Young et al., 1994; Frankland et al., 1998). In support of this view, the hippocampal formation has been shown to project to the basal nucleus of the amygdala (Canteras and Swanson, 1992). This pathway has been shown to exhibit LTP (Maren and Fanselow, 1995), thus providing a potential neuroanatomical substrate through which contextual fear associations can be formed (Maren and Fanselow, 1995). Further, it has recently been shown that intrahippocampal infusions of the protein synthesis inhibitor anisomycin impair the ability of the hippocampus to form a contextual representation, but not the ability of the animal to form a context-shock association (Barrientos et al., 2002). In these experiments, the 'immediate shock deficit' paradigm was used to tease apart the contribution of the hippocampus to learning about a context and learning to fear one. Normally, immediate shock (i.e., that which is given soon after introduction to the conditioning chamber) is not sufficient to support contextual fear conditioning, presumably because it takes time for the hippocampus to form a representation of the context in which the animal finds itself. However, if the animal is *preexposed* to the conditioning chamber briefly on the day before training, it can subsequently acquire contextual fear following immediate shock, presumably because the animal now enters the training situation with a contextual representation already intact (Fanselow, 1980). In the Barrientos et al. study (2002), rats were given an infusion of anisomycin or vehicle into the dorsal hippocampus immediately after exposure to a novel context on the day before they received immediate shock, or immediately after receiving immediate shock on the day after they received preexposure. The findings showed that intrahippocampal anisomycin resulted in impaired contextual learning only in the first group (Barrientos et al., 2002). This important finding suggests that the protein synthesis in the hippocampus is necessary for learning about contexts, but not for contextual fear conditioning. A similar finding has recently been reported by Frankland and colleagues using manipulations of NMDARs, CaMKII, and CREB in the hippocampus (Frankland et al., 2004).

It is clear, however, that the hippocampus undergoes plastic changes during fear conditioning, some of which may be necessary for memory formation of contextual fear. For example, intrahippocampal infusion of the NMDAR antagonist APV impairs contextual fear conditioning (Stiedl et al., 2000; Young and Wang, 2004), and contextual, but not auditory, fear conditioning is impaired in mice that lack the NR1 subunit of the NMDA receptor exclusively in area CA1 of the hippocampus (Rampon and Tsien, 2000). Further, fear conditioning leads to increases in the activation of αCaMKII, PKC, ERK/MAPK, and CRE-mediated gene expression in the hippocampus (Atkins et al., 1998; Impey et al., 1998b; Hall et al., 2000). These findings add support to the notion that NMDAR-dependent plastic changes in the hippocampus, in addition to the amygdala, are required for contextual fear conditioning. However, it should be emphasized that the exact contribution of this NMDAR-mediated signaling to contextual fear conditioning remains unclear. For example, most of these studies cannot distinguish between a role for NMDAR-mediated plasticity in formation of contextual representations as opposed to a role in fear memory acquisition and storage. Further, regulation of intracellular signaling cascades in the hippocampus by fear conditioning, while potentially indicative of some type of memory storage, does not necessarily indicate that these changes are related to the acquisition *fear* memories. They may be related to declarative or explicit memories of the training experience that are acquired at the same time as fearful memories (LeDoux, 2000). Indeed, a number of studies have shown that hippocampal cells undergo plastic changes during and after fear conditioning (Doyère et al., 1995; Moita et al., 2003), including auditory fear conditioning which is spared following hippocampal lesions (Kim and Fanselow, 1992). Clearly, more research is needed before a convincing picture of the role of the hippocampus in contextual fear conditioning emerges.

4.11.8.2 Fear Extinction

Extinction is a process whereby repeated presentations of the CS in the absence of the US leads to a weakening of the expression of conditioning responding. While extinction of conditioned fear has been well documented in the behavioral literature, until recently we learned comparatively little about its neurobiological substrates. Work in a

number of laboratories has recently implicated a number of structures, including the prefrontal cortex, amygdala, and hippocampus.

The medial prefrontal cortex (mPFC), and in particular the ventral mPFC, appears to play an important role in fear extinction. Early studies, for example, showed that selective lesions of the ventral mPFC retard the extinction of fear to an auditory CS while having no effect on initial fear acquisition (Morgan et al., 1993; Morgan and LeDoux, 1995). Further, neurons in the mPFC alter their response properties as the result of extinction (Garcia et al., 1999; Herry et al., 1999). Interestingly, studies by Quirk and colleagues suggest that the mPFC may not be necessary for fear extinction *per se,* but rather for the long-term recall of extinguished fear. For example, rats with mPFC lesions are able to extinguish within a session, but show impaired extinction between sessions (Quirk et al., 2000). Further, neurons in the mPFC fire strongly to a tone CS after behavioral extinction has occurred, and artificial stimulation of the mPFC that resembles responding in an extinguished rat is sufficient to inhibit behavioral expression of fear in nonextinguished rats (Milad and Quirk, 2002). Thus, it appears clear that the mPFC plays an essential role in long-term retention and/or expression of fear extinction. The question of whether the mPFC is a 'site of storage' of extinction or rather simply a region that is necessary for the long-term expression of extinguished memories has only begun to be explored. Recent studies, however, have shown that extinction training regulates the expression of the IEG cFos in regions of the mPFC (Santini et al., 2004). Further, intra-mPFC infusion of inhibitors to MEK or protein synthesis impairs long-term recall of fear extinction (Santini et al., 2004; Hugues et al., 2006), suggesting that essential aspects of the plasticity underlying extinction memory are localized in the mPFC.

The amygdala has also been shown to be an essential site of plasticity underlying fear extinction. Infusions of NMDAR antagonists or inhibitors of ERK/MAPK into the amygdala have been shown to impair fear extinction (Falls et al., 1992; Lu et al., 2001; Davis, 2002; Herry et al., 2006). Conversely, both systemic and intra-amygdala infusions of partial agonists of the NMDA receptor facilitate fear extinction (Walker et al., 2002). More recently, Ressler and colleagues showed that BDNF signaling in the amygdala was critical to the consolidation of fear extinction (Chhatwal et al., 2006). They showed, for example, that fear conditioning leads to an increase in BDNF expression in the LA and basal amygdala. Further, infusion of a viral vector encoding a dominant negative TrkB receptor into the amygdala impaired between-session, but not within-session, retention of fear extinction. These experiments suggest that some type of activity-dependent synaptic plasticity must take place in the amygdala during extinction learning, as it does during initial learning. After the memory of extinction is formed, the amygdala may then signal the mPFC to inhibit ongoing fear responses. Indeed, McDonald and colleagues have shown that the mPFC projects to GABAergic (GABA: gamma-aminobutyric acid) intercalated cells that are situated between the lateral and basal amygdala and the CE (McDonald et al., 1996), which may be important for regulating fear responses (Paré and Smith, 1993; Quirk and Gehlert, 2003; Quirk et al., 2003; Paré et al., 2004). In agreement with this hypothesis, a recent study has confirmed that stimulation of the mPFC neurons blunts the activity of CE neurons that are critical for the expression of fear responses (Quirk et al., 2003). Additional experiments will be necessary to define the exact contribution of connections between the mPFC and the amygdala in extinction processes, as well as the detailed biochemical mechanisms responsible for promoting fear extinction.

One of the more interesting facts about memories that have undergone extinction is that they are context specific. That is, an extinguished memory remains extinguished only in the context in which extinction has taken place, and responding returns or is subject to 'renewal' in a different context (Bouton and Bolles, 1979; Bouton and Ricker, 1994). This fact, along with the finding that fully extinguished memories are capable of 'reinstating' upon presentation of the US (Rescorla and Heth, 1975), has led to the long-held view that extinction does not result in the erasure of the original memory trace but is rather a new kind of learning that serves to inhibit expression of the old memory (Pavlov, 1927). Not surprisingly, recent studies have indicated that the hippocampus plays an important role in the contextual modulation of fear extinction. Maren and colleagues, for example, have shown that training-induced neurophysiological responses in the LA readily extinguish within a fear extinction session, but that this neural representation of extinction, like the behavior itself, is specific to the context in which extinction has taken place (Hobin et al., 2003). Further, functional inactivation of the hippocampus using the $GABA_A$ agonist muscimol can

impair the context-specific expression of fear extinction (Corcoran and Maren, 2001). While it remains unclear how the hippocampus might inhibit the expression of LA spike firing and fear behavior in a context-specific manner, it has been proposed that projections from the hippocampus to the mPFC may be critical (Hobin et al., 2003).

4.11.8.3 Retrieval and 'Reconsolidation' of Fear Memories

Fear extinction is not the only way to turn a fear memory off. Another, perhaps more clinically efficacious way, is to interfere with that fear memory's *reconsolidation*. The idea that memory undergoes a second phase of consolidation, or 'reconsolidation,' upon retrieval has been the subject of speculation for decades (Sara, 2000). Early studies showed that amnesic manipulations at or around the time of memory retrieval, rather than at the time of initial learning, resulted in loss of the memory on subsequent recall tests (Misanin et al., 1968; Lewis et al., 1972). These early findings suggested that the retrieval process could render a memory susceptible to disruption in a manner very similar to a newly formed memory.

Interest in the reconsolidation process has been rekindled in recent years, due in part to the progress that has been made in identifying the cellular and molecular mechanisms underlying long-term synaptic plasticity and the initial phases of memory consolidation (Milner et al., 1998). Accordingly, this has provided researchers with a set of tools and learning paradigms with which to study the reconsolidation process. Several years ago, for example, Nader and colleagues showed that infusion of the protein synthesis inhibitor anisomycin into the amygdala immediately after retrieval of auditory fear conditioning impaired memory recall on subsequent tests (Nader et al., 2000). This effect was clearly dependent on retrieval of the memory; that is, no memory deficit was observed if exposure to the CS was omitted. Further, the effect was observed not only when the initial recall test and drug infusion were given shortly after training (i.e., 1 day), but also if given 14 days later, suggesting that the effect could not be attributable to disruption of the late phases of protein synthesis necessary for the initial training episode. Thus, following active recall of a fear memory, that memory appears to undergo a second wave of consolidation that requires protein synthesis in the amygdala. More recent work has shown that this process does not appear to be attributable to rapid extinction of fear during the recall test, since fear memories that have failed to reconsolidate after intra-amygdala infusion of anisomycin fail to renew in a different context (Duvarci and Nader, 2004). Further, memories that fail to reconsolidate do not appear to be subject to reinstatement (Duvarci and Nader, 2004), a finding which suggests that manipulations of a fear memory at or around the time of retrieval may result in permanent impairment of the memory.

Reconsolidation does not appear to be unique to the amygdala; hippocampal-dependent contextual memories also appear to be sensitive to manipulation at the time of retrieval. In a recent study, Debiec et al. (2002) gave rats intrahippocampal infusions of anisomycin following recall of contextual fear conditioning and found that memory retrieval was impaired on subsequent tests. Interestingly, reconsolidation of contextual fear was impaired even when memory reactivation and intrahippocampal anisomycin treatment were given 45 days after the initial training session, a time when lesion studies have shown that contextual memories should no longer depend on the hippocampus (Kim and Fanselow, 1992). The initial experiments by Kim and Fanselow, however, used only a single recall test after training and hippocampal lesions; the ability of the animal to recall contextual fear on subsequent tests was not examined. Surprisingly, when Debiec et al. *reactivated* the contextual memory prior to making a lesion of the hippocampus, even as long as 45 days after training, subsequent recall was impaired (Debiec et al., 2002). Thus, hippocampal-dependent contextual memories appear to undergo both a cellular and a systems-level reconsolidation following memory retrieval. That is, recall of an older, hippocampal-independent contextual memory must return to the hippocampus during retrieval and undergo a protein synthesis–dependent process of reconsolidation to be maintained. As in most hippocampal studies, however, it remains unclear what information is being reconsolidated – the memory of the context or the contextual fear memory.

How might the reconsolidation process be accomplished at the cellular and molecular levels? Recent studies have shown that fear reconsolidation, like the initial phases of consolidation, requires both PKA and ERK/MAPK in the amygdala (Duvarci et al., 2005; Tronson et al., 2006). Further, transient overexpression of a dominant negative isoform of CREB in the forebrain at the time of memory retrieval impairs

reconsolidation of auditory and contextual fear conditioning (Kida et al., 2002). However, the reconsolidation process does not appear to be a mere recapitulation of the initial consolidation process; there have also been numerous reports of biochemical dissociations between consolidation and reconsolidation. These have included studies that have failed to find impairments in fear reconsolidation following inhibition of RNA synthesis (Parsons et al., 2006) or NO signaling (Schafe et al., 2005) in the amygdala. Further, reactivation of a contextual fear memory induces only a subset of genes in the hippocampus that are activated during the initial phases of memory consolidation (von Hertzen and Giese, 2005), and hippocampal-dependent reconsolidation of a contextual fear memory appears to be characterized by different classes of immediate early genes (Lee et al., 2004). Finally, a recent study has shown that blockade of β-adrenergic receptors in the LA impairs reconsolidation, but not consolidation, of fear conditioning (Debiec and Ledoux, 2004). Clearly, additional studies will be required for a full appreciation of how reconsolidation is accomplished at the cellular level.

4.11.8.4 Instrumental Fear Learning

In addition to its role in the rapid, reflexive learning that characterizes Pavlovian fear conditioning, the amygdala contributes to other fear-related aspects of behavior. Pavlovian fear conditioning, for example, is useful for learning to detect a dangerous object or situation, but the animal must also be able to use this information to guide ongoing behavior that is instrumental in avoiding that danger. In some experimental situations, the animal must learn to make a response (i.e., move away, press a bar, turn a wheel, etc.) that will allow it to avoid presentation of a shock or danger signal, a form of learning known as *active avoidance*. In other situations, the animal must learn *not* to respond, also known as *passive avoidance*. Both of these are examples of instrumental conditioning, and the amygdala plays a vital role in each.

Previously, we mentioned that only the LA and CE were critical for Pavlovian fear conditioning. However, we have recently begun to appreciate the significance of projections from the LA to the basal nucleus of the amygdala from studies that employ fear learning tasks that involve both classical and instrumental components (Killcross et al., 1997; Amorapanth et al., 2000). Amorapanth et al. (2000), for example, first trained rats to associate a tone with foot shock (the Pavlovian component). Next, rats learned to move from one side of a two-compartment box to the other to avoid presentation of the tone (the instrumental component), a so-called 'escape-from-fear' task. Findings showed that, while lesions of the LA impaired both types of learning, lesions of the CE impair only the Pavlovian component (i.e., the tone-shock association; **Figure 9(a)**). Conversely, lesions of the basal nucleus impaired only the instrumental component (learning to move to the second compartment; **Figure 9(b)**). Thus, different outputs of the LA appear to mediate Pavlovian and instrumental behaviors elicited by a fear-arousing stimulus (Amorapanth et al., 2000; **Figure 9(c)**). It is important to note, however, that these findings do not indicate that the basal nucleus is a site of motor control or a locus of memory storage for instrumental learning. Rather, the basal amygdala likely guides fear-related behavior and reinforcement learning via its projections to nearby striatal regions that are known to be necessary for instrumental learning and reward processes (Everitt et al., 1989, 1999; Robbins et al., 1989).

4.11.8.5 Memory Modulation by the Amygdala

Pavlovian fear conditioning is an implicit form of learning and memory. However, during most emotional experiences, including fear conditioning, explicit or declarative memories are also formed (LeDoux, 2000). These occur through the operation of the medial temporal lobe memory system involving the hippocampus and related cortical areas (Milner et al., 1998; Eichenbaum, 2000). The role of the hippocampus in the explicit memory of an emotional experience is much the same as its role in other kinds of experiences, with one important exception. During fearful or emotionally arousing experiences, the amygdala activates neuromodulatory systems in the brain and hormonal systems in the body via its projections to the hypothalamus, which can drive the hypothalamic-pituitary-adrenal (HPA) axis. Neurohormones released by these systems can, in turn, feed back to modulate the function of forebrain structures such as the hippocampus and serve to enhance the storage of the memory in these regions (McGaugh, 2000). The primary support for this model in animals comes from studies of *inhibitory avoidance learning*, a type of passive avoidance learning where the animal must learn not to enter a chamber in which it has previously received shock. In this paradigm, various pharmacological manipulations of the amygdala that affect neurotransmitter or

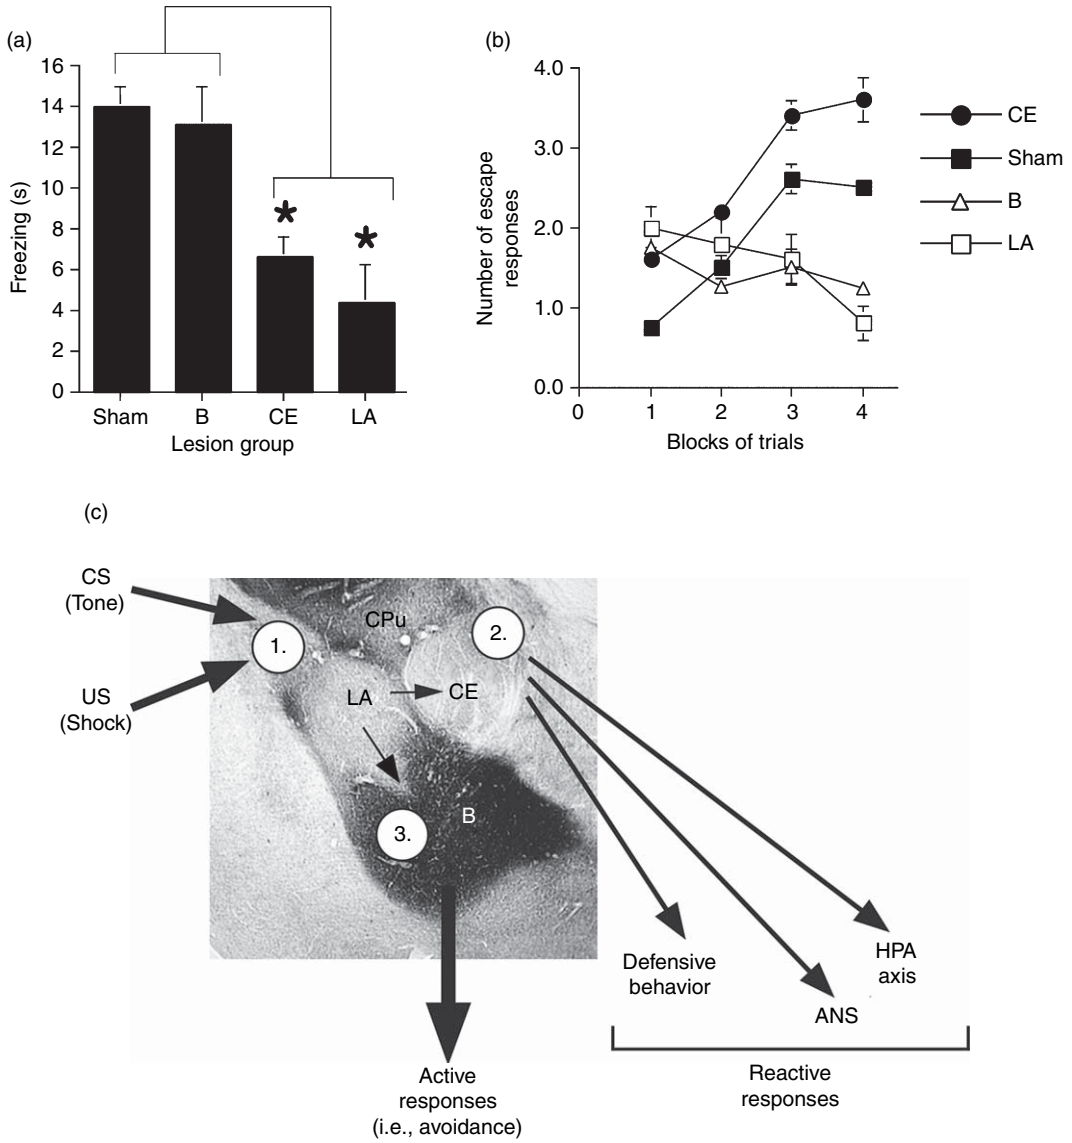

Figure 9 Active versus reactive fear. (a) Percent freezing in rats given auditory fear conditioning after receiving selective amygdala lesions. Auditory fear conditioning is impaired by lesions of the CE and LA, but spared by basal nucleus of the amygdala (B) lesions. (b) Number of escape responses across blocks of five trials during training in a one-way active avoidance task. Lesions of both LA and B impair this task, while lesions of CE do not. (c) The data are consistent with a model in which projections between LA and CE are sufficient for Pavlovian fear conditioning (reactive responses), while projections between LA and B are necessary for instrumental avoidance learning (active responses). HPA, hypothalamic-pituitary-adrenal; ANS, autonomic nervous system. neurohormonal systems modulate the strength of the memory. For example, immediate posttraining blockade of adrenergic or glucocorticoid receptors in the amygdala impairs memory retention of inhibitory avoidance, while facilitation of these systems in the amygdala enhances acquisition and memory storage (McGaugh et al., 1993; McGaugh, 2000). The exact subnuclei in the amygdala that are critical for memory modulation remain unknown, as are the areas of the brain where these amygdala projections influence memory storage. Candidate areas include the hippocampus and entorhinal and parietal cortices (Izquierdo et al., 1997). Indeed, it would be interesting to know whether the changes in unit

activity or the activation of intracellular signaling cascades in the hippocampus during and after fear conditioning, as discussed earlier, might be related to formation of such explicit memories, and how regulation of these signals depends on the integrity of the amygdala and its neuromodulators. Interestingly, a recent study has shown that stimulation of the basal nucleus of the amygdala can modulate the persistence of LTP in the hippocampus (Frey et al., 2001), which provides a potential mechanism whereby the amygdala can modulate hippocampal-dependent memories.

4.11.9 Fear Learning in Humans

Within the last 10 years, considerable progress has been made in understanding how the human fear learning system is organized and what features it shares with the fear learning system of lower vertebrates. In this final section, we will briefly summarize these findings. For a more comprehensive look at this topic, see Phelps and LeDoux (2005).

4.11.9.1 The Human Fear Learning System – Lesion and fMRI Studies

It has long been known that amygdala damage in humans confers deficits in fear conditioning (Bechara et al., 1995; LaBar et al., 1995). In these studies, fear conditioning is typically accomplished by pairing the presentation of visual stimuli with either mild electric shock to the skin or an aversive high-amplitude (i.e., 100 dB or more) tone. Conditioned fear is then measured by changes in skin conductance upon presentation of the CS. Damage to the amygdala in humans produces deficits in conditioned emotional responding to a CS even though the knowledge of the CS-US contingency remains intact (Bechara et al., 1995). That is, a patient with amygdala damage will not respond fearfully to the CS after it has been paired with an aversive US, but is capable of stating that the CS was previously presented and followed by the US. Interestingly, patients with selective hippocampal damage exhibit the converse effect; they will respond fearfully to the CS but cannot tell you why (Bechara et al., 1995).

Fear conditioning in humans also leads to increases in amygdala activity, as measured by functional magnetic resonance imaging (fMRI) (Buchel et al., 1998; LaBar et al., 1998). These changes largely mirror what has been seen in neurophysiological studies of amygdala activity in rodents, namely, increases in CS-elicited amygdala activity during and after fear conditioning, a corresponding attenuation of CS-elicited amygdala activity, and an increase in CS-elicited activity in the mPFC with extinction of the behavioral response (LaBar et al., 1998; Phelps et al., 2004). Further, as suggested by the animal work, the human fear learning system appears preferentially suited to use subcortical 'low-road' information during fear learning. In a study by Morris and colleagues, CS-elicited increases in amygdala activity were observed even if the CS was presented too fast to be perceived consciously, a so-called 'unseen CS' (Morris et al., 1999). When the activity of the amygdala during fear conditioning is cross-correlated with the activity in other regions of the brain, the strongest correlations are seen with subcortical (thalamic and collicular) rather than cortical areas, further emphasizing the importance of the direct thalamo-amygdala pathway in the human brain (Morris et al., 1999).

4.11.9.2 Instructed Fear – Using the High Road

In humans, direct experience with an aversive US does not appear necessary for fear learning to occur. In a series of experiments, Phelps and colleagues have demonstrated that simply telling a human subject that presentation of a CS *might* lead to an aversive outcome is sufficient to induce a learned fear state, a phenomenon known as 'instructed fear' (Phelps et al., 2001).

Like fears that are learned from direct experience, instructed fears require the amygdala (Funayama et al., 2001). Interestingly, however, it is the left amygdala that appears to be the most critical in this type of fear learning. In fMRI studies, the left amygdala is preferentially active in a paradigm utilizing instructed fear (Phelps et al., 2001), and amygdala lesions confined to the left hemisphere are most effective at impairing this type of fear learning (Phelps et al., 2001). In general, this stands in contrast to studies that have examined amygdala activation to fears that have been acquired through experience, especially those involving an 'unseen' CS. In those studies, amygdala activity is typically observed to be lateralized to the right amygdala (Morris et al., 1999). It has been hypothesized that this left lateralization in the instructed fear paradigm is the result of a linguistic/cognitive fear representation acquired through

language, which, like other verbally mediated tasks, is mediated in the majority of individuals in the left hemisphere (Funayama et al., 2001).

4.11.9.3 Declarative Memory Formation and the Amygdala

It has long been recognized that memories formed during emotionally arousing situations are more vividly remembered than those formed under neutral circumstances. Earlier in this chapter, we reviewed evidence from the animal literature which provides a potential neural mechanism for this phenomenon, namely, that the amygdala and its various neurotransmitter systems modulate the strength of explicit or declarative memory formation by influencing the longevity of cellular processes such as LTP in the hippocampus (Frey et al., 2001). Does the human amygdala play a similar role in declarative memory formation? Evidence suggests that it does. For example, administration of the β-adrenergic antagonist propranolol to human subjects impairs long-term recall of an emotionally arousing short story (Cahill et al., 1994), while administration of the $\alpha 2$-adrenergic antagonist yohimbine, which is known to be anxiogenic, enhances recall (O'Carroll et al., 1999). A similar picture emerges in patients with bilateral amygdala damage; they cannot recall the details of an emotionally charged story to the extent that intact controls can (Cahill et al., 1995). Further, amygdala activity appears to correlate with the extent to which an emotionally arousing story is remembered. In one study, subjects in a positron emission tomography scanner were shown either emotionally arousing or emotionally neutral stories and tested for recall at a later time. The findings revealed that right amygdala blood flow during the emotionally arousing, but not neutral, stories correlated highly with the extent to which details of that story could be recalled at later test (Cahill et al., 1996). More recently, Dolan and colleagues studied amygdala-hippocampal activations and recall of emotionally arousing and neutral words in patients with varying degrees of hippocampal and amygdala damage. The findings revealed that left amygdala damage was inversely correlated with memory for the emotional words and also activity in the left hippocampus. Memory for neutral words, in contrast, was only related to the degree of hippocampal damage (Richardson et al., 2004). These findings parallel those found in the animal literature and suggest that interactions between the amygdala and hippocampal formation influence the strength of declarative memory in the human brain.

4.11.10 Conclusions

In this chapter, we have provided a comprehensive view of the neural system underlying fear learning, including the key synaptic events and downstream cellular cascades that are responsible for the acquisition and consolidation of fear memories in the amygdala. These findings provide a foundation for the continued study of the neural basis of emotional learning and memory at the cellular level, and also for bridging the gap between studies of memory formation and synaptic plasticity in the mammalian brain. These studies also provide us with a set of tools to continue our analysis of more complex and clinically relevant aspects of fear learning, including contextual control of learned fear, fear extinction, and reconsolidation. Finally, recent studies translating and extending what we have learned from laboratory rats to the human brain suggest that similar mechanisms and neural pathways are conserved across species.

4.12 The Molecular Mechanisms of Reward

C. A. Winstanley, University of British Columbia, Vancouver, Canada

E. J. Nestler, The University of Texas Southwestern Medical Center, Dallas, TX, USA

4.12.1 Introduction

This article considers the molecular mechanisms which have been implicated in aspects of reward processing and reward-related learning. A brief description of the nature of reward and the animal learning theory associated with its assessment is provided. The neural circuitry involved in implicating these psychological processes is then described, with emphasis placed on the nucleus accumbens (NAc), amygdala, and frontal cortex. Dopaminergic regulation of these structures has been shown to play a pivotal role in mediating reward-related behavior, and the intracellular signaling cascades affected by dopamine release have provided us with novel insight into the molecular basis of reward processing. In particular, data are considered from research into both drug addiction and depression, with a focus on the transcription factors cyclic adenosine monophosphate response element binding protein (CREB) and ΔFosB as well as some of their downstream targets. Dissociable roles are identified for different molecules in the regulation of reward. Furthermore, in parallel to data from neurochemical investigations, the behavioral effects of manipulating molecular pathways depend on both the region targeted and the time course of action. Greater understanding of reward processing at the molecular level is being achieved through combining expertise developed within the fields of psychology and molecular biology. Such an approach can further our knowledge of the

detrimental changes in brain function which are inherent within addiction and affective disorders and which are associated with maladaptive assessment of reward and motivation.

4.12.2 Researching Reward Processes: What Do We Mean by Reward and How Do We Measure It?

Before we consider its molecular basis, we need to establish the nature of the psychological processes covered by the term 'reward.' This topic is dealt with in more detail elsewhere in this reference work (*See* Chapter 1.36); therefore, only a brief summary will be included here to enable discussion of subsequent experimental work. In its most simple terms, a reward is a positive stimulus, i.e., something which the individual values and enjoys. Rewards carry emotional significance, and individuals are motivated to expend effort to attain them. The study of how reward and reward-related stimuli inform behavior contributes a significant amount to our knowledge of learning and memory processes.

In terms of animal learning theory, an innately rewarding stimulus, such as food, is known as an unconditioned stimulus (US). This elicits an unconditioned, automatic response (UR), for example, salivation. If the US is repeatedly paired with a previously neutral stimulus, such as a light, an association will be learned between presentation of the light and food reward, such that illumination of the light alone will cause the animal to salivate. The light is now regarded as a conditioned stimulus (CS), and the response it elicits is termed a conditioned response (CR). This process is known as Pavlovian conditioning and forms the basis of associative learning. Although conceptually quite simple, the effects that a CS can exert over behavior are far-reaching and can influence goal-directed behavior. For example, a rat can learn to press a lever to earn a food pellet through instrumental conditioning processes (see **Figure 1**). If delivery of that food pellet is repeatedly paired with presentation of a light CS, the CS will acquire some of the appetitive value of the food and become rewarding in its own right such that the rat will press the lever to turn the light on. The CS is then called a conditioned reinforcer (CRf).

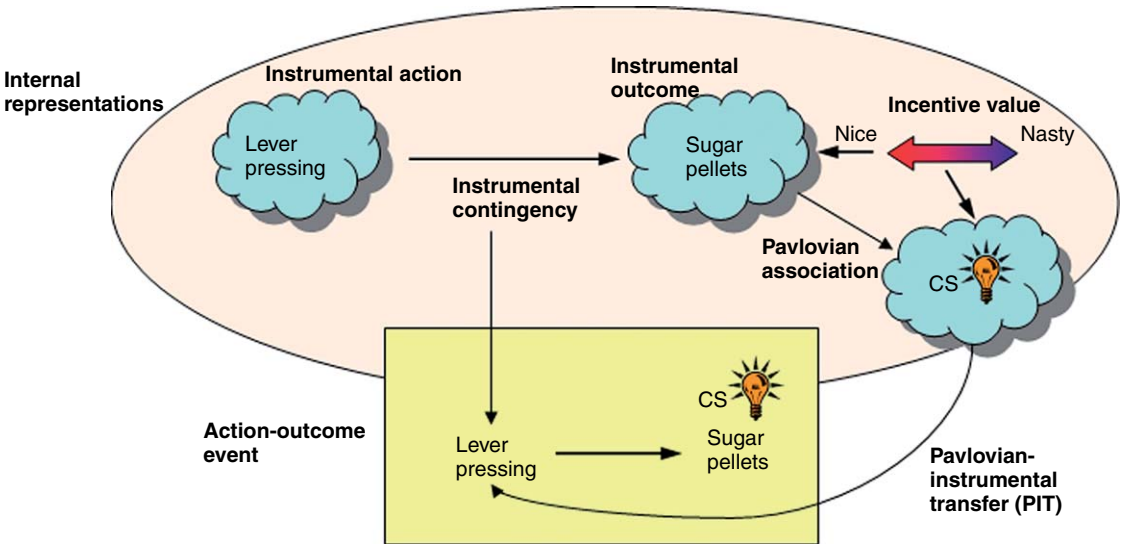

Figure 1 A schematic of some factors which affect instrumental learning. An action such as pressing a lever leads to the delivery of sugar pellets, accompanied by the onset of a stimulus light (the conditioned stimulus: CS). This action-outcome event (contained within the tan box) is detected and represented internally. Degrading the encoding of this contingency will have a direct effect on instrumental performance. The value of the outcome is determined by incentive learning (i.e., how nice the sugar pellets are). This can be affected by the motivational state of the animal. The attribution of incentive value affects the representation of the instrumental outcome, such that changing this value has an impact upon truly goal-directed instrumental behavior (see the section titled 'The prelimbic cortex'). The CS is also associated with the incentive value of the instrumental outcome through Pavlovian conditioning. Presentation of the CS can invigorate responding for the outcome through Pavlovian to instrumental transfer (PIT). Based on Cardinal RN, Parkinson JA, Hall J, and Everitt BJ (2002) Emotion and motivation: The role of the amygdala, ventral striatum, and prefrontal cortex. *Neurosci. Biobehav. Rev.* 26: 321–352; figure 2, p. 327; used with permission from Elsevier Science.

The noncontingent presentation of a CS can also influence ongoing instrumental responding in a process known as Pavlovian to instrumental transfer (PIT). For example, presentation of a tone associated with sucrose delivery will increase lever-pressing for sucrose (conditioned motivation). Conversely, if a light has been paired with a painful stimulus such as footshock, presentation of the light CS will decrease lever-pressing for reward (conditioned suppression).

These concepts inform more than just animal learning theory: experiments designed using these psychological constructs provide valuable insight into the processing of reward in psychopathology. The inability to find stimuli rewarding, as well as an excessive desire for certain rewards, are symptoms of several mental disorders, including depression, attention-deficit/hyperactivity disorder and drug addiction, among others. Research into the mechanisms of reward-related learning has therefore contributed to our understanding of these conditions. Just as a CS paired with food stimulates lever-pressing for reward in rats, stimuli paired with drug reward can lead to craving for drug and relapse to drug-seeking in both rats and human addicts (de Wit and Stewart, 1981; Childress et al., 1988). Failure to alter behavior when the incentive value of a reward changes also has obvious implications for substance abuse disorders, where addicts continue to use drugs despite increasingly negative consequences and reductions in the reward experienced. In rats, food reward can be devalued by pairing food delivery with an injection of lithium chloride, which induces nausea, or by feeding animals to satiation. Such devaluation procedures subsequently alter the way in which animals respond to food presentation or to a CS paired with that reward, making it possible to investigate the biological basis of this aspect of reward processing.

4.12.3 The Neural Circuitry of Reward

Considerable evidence has been amassed concerning the neural circuitry underpinning reward-related learning (see Cardinal, 2001, for review). The processing of reward occurs in a distributed network of structures comprising both cortical and subcortical areas, the majority of which are connected within the limbic or affective corticostriatal loop (**Figure 2**) (Alexander et al., 1986). Within this framework, structures involved in higher-order cognitive function such as the prefrontal cortex (PFC) interact with areas of the limbic system heavily implicated in emotional processing and memory, such as the amygdala and hippocampal formation. These structures are interconnected with the NAc, often described as the reward center of the brain. This circuit influences motor output and motivation via the ventral pallidum and mediodorsal thalamus, which also project back to the PFC. We will focus on three of the most studied areas: the NAc, the amygdala, and regions of the PFC. Given that the focus of this chapter is to discuss the molecular basis of reward, the majority of research of which has been undertaken in rodents, we will focus on data supporting a role for these regions in the reward system of the rat, although these areas and their homologues have been heavily implicated in reward processing in both monkeys and humans.

4.12.3.1 The Nucleus Accumbens

The NAc is probably the most widely studied region in terms of regulating reward-related learning. This region has been labeled the 'limbic-motor interface' due to its extensive connections with limbic structures, such as the amygdala, hippocampus, and PFC, in addition to its projections to motor output areas. The NAc is therefore thought to be a key node in the limbic corticostriatal loop, wherein diverse types of information from both cortical and subcortical structures are integrated and key signals generated to enable the implementation of behavioral change relevant to goal-seeking. The NAc can be divided into the core (NAc-C) and shell (NAc-Sh) subregions, which differ in both structure and function (Groenewegen et al., 1987; Voorn et al., 1989; Berendse et al., 1992). Whereas the NAc-C projects predominantly to the ventral pallidum, the shell also projects to subcortical structures, including the lateral hypothalamus and periaqueductal grey. Damage to the NAc does not prevent animals from making a response to earn food reward, or from adjusting their responding when the value of that reward changes, i.e., animals are still capable of goal-directed behavior (see the section titled 'The prefrontal cortex'). However, the ability of a CS to regulate behavior is profoundly affected by NAc lesions. Damage to the NAc-C disrupts PIT and the acquisition of autoshaping, a Pavlovian conditioning paradigm where presentation of a CS with food delivery leads animals to approach the CS (Parkinson et al., 1999; Hall et al., 2001). Damage to the NAc also impairs conditioned place preference, where animals learn to associate a specific context or place with reward delivery and therefore spend more time in this location. Neither

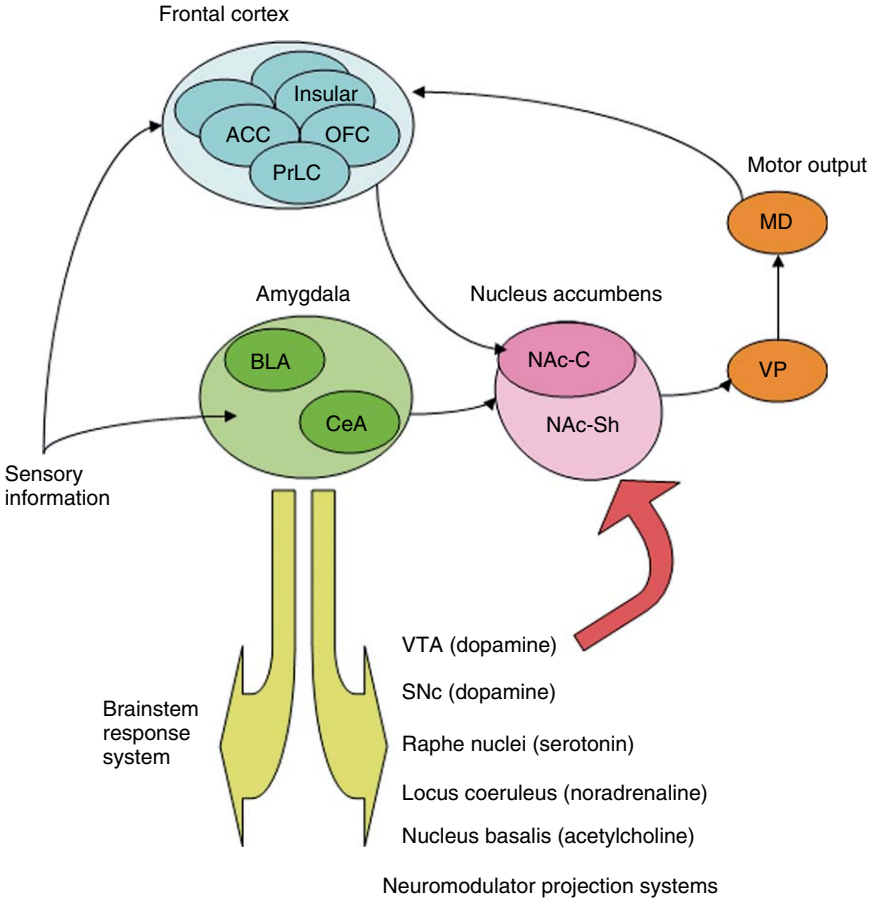

Figure 2 Simplified diagram of the limbic corticostriatal loop. (Abbreviations: ACC, anterior cingulate cortex, OFC, orbitofrontal cortex; PrLC, prelimbic cortex; BLA, basolateral amygdala; CeA, central amygdala; VTA, ventral tegmental area; SNc, substantia nigra pars compacta; NAc-C, nucleus accumbens core; NAc-Sh, nucleus accumbens shell; VP, ventral pallidum; MD, mediodorsal thalamus). The frontal cortex is functionally heterogeneous, and several frontal regions are involved in different aspects of instrumental responding. As discussed in the text, the PrLC, part of the medial prefrontal cortex, is involved in detecting the instrumental action-outcome contingency and is essential for the maintenance of goal-directed behavior. The functions of the ACC are complex and are not described in detail here, but involve resolving response conflict and error detection, whereas the insular cortex, containing the primary gustatory cortex, encodes the primary sensory qualities of specific foods. The OFC plays a role in integrating changes in the incentive value of a reward with representations of the expected outcome, a function which is thought to depend on its connections with the BLA. The BLA is one of the primary structures involved in encoding CS-US associations and is necessary for the presentation of a CS to trigger retrieval of the motivational value of its associated US. It can work in concert with the CeA to influence brainstem function, arousal, and neurotransmitter release. As the 'limbic-motor interface,' the NAc combines information from both frontal and amygdalar systems, as well as from other inputs, to generate motivational drive. The NAc-Sh signals the motivational properties of unconditioned (primary) reinforcers, whereas the NAc-C has a more pronounced role in mediating the motivational impact which Pavlovian conditioned stimuli have on behavior. Adapted from Cardinal RN, Parkinson JA, Hall J, and Everitt BJ (2002) Emotion and motivation: The role of the amygdala, ventral striatum, and prefrontal cortex. *Neurosci. Biobehav. Rev.* 26: 321–352; figure 3, p. 329; used with permission from Elsevier Science.

damage to the core or shell abolishes CRf *per se*, but manipulations of the dopaminergic innervation of the NAc can alter responding for CRf (see the section titled 'Dopamine and reward'). As well, damage to the NAc results in decreased tolerance to the delay of reward, such that animals will choose a small immediate reward over a larger but more delayed one, a concept which has direct relevance to models of impulsive behavior (Cardinal et al., 2001). In contrast, selective lesions of the NAc-Sh do not appear to have such a pronounced effect on the conditioned responses to rewards, i.e., reward-related learning, but this region plays an important role in the unconditioned response to primary reinforcers. In particular, the NAc-Sh appears to alter

the motivational impact of rewards, such that inhibition of NAc-Sh activity induces overeating, an effect attributable to its connections with the lateral hypothalamus (Stratford and Kelley, 1999). Inhibition of neuronal firing is also observed when animals engage in a sequence of reward-seeking and consumption (Taha and Fields, 2006), which results in disinhibition of activity in target brain regions such as the hypothalamus. Activity within the NAc may therefore act to gate appetitive behavior through its influence over reward-related brain circuitry.

4.12.3.2 The Amygdala

The first indication that the amygdala was one of the most important brain regions for the processing of affective stimuli was the discovery that damage localized to this area produced marked deficits in emotional display and apparent fearlessness in monkeys (Kluver and Bucy, 1939). Humans with damage to the amygdala show a variety of impairments in emotional perception and expression, and can unwittingly endanger themselves through failing to process danger or risk. The amygdala can be divided into multiple nuclei based on cytoarchitectonic distinctions (Pitkanen, 2000). Functional dissociations have also been observed between the different units. In particular, the central nucleus (CeA) and basolateral nucleus (BLA) of the amygdala have been implicated in divergent forms of affective processing (Everitt et al., 2000). Both the BLA and CeA receive sensory input, yet the BLA has more prominent connections with the frontal cortices and ventral striatum, while the CeA shares more numerous connections with areas within the hypothalamus and brainstem.

It is generally thought that the BLA plays an integral role in Pavlovian conditioning involving both appetitive and aversive stimuli (*See* Chapter 4.11) (Davis, 1998; LeDoux, 2000). One of the most commonly used paradigms to measure emotional learning is fear conditioning, in which animals form an association between a painful footshock and a particular stimulus such as a light or tone. Animals rapidly learn this association and freeze during subsequent presentations of the CS, indicative of a state of fear, yet this freezing is much less evident following BLA or CeA lesions. More sophisticated analysis of Pavlovian conditioning procedures suggests that the BLA is necessary in order for presentation of the CS to trigger retrieval of the value of the US with which it was paired. Although BLA-lesioned animals show evidence of learning simple CS-US associations, changing the value of a reward does not alter the way in which the animal responds to the associated CS. For example, BLA-lesioned rats show aversion to a devalued food, but still approach the food magazine when the CS paired with the devalued food is presented (Hatfield et al., 1996). Likewise, although BLA-lesioned monkeys show preference for different foods (i.e., can still make value judgments), they are unable to alter their choice preference when the value of a particular food has been changed through devaluation. This idea that the BLA is involved in processing the incentive value of rewards and reward-related stimuli associated with them has been very influential and is thought to depend on its connections with the orbitofrontal cortex (OFC) (Baxter et al., 2000; see the section titled 'The orbitofrontal cortex'). Given its proximity to the hippocampus and other limbic structures heavily implicated in memory processing and storage, the BLA is ideally positioned to mediate the effect of emotional arousal on memory.

4.12.3.3 The Prefrontal Cortex

The PFC is involved in numerous higher-order cognitive functions, such as decision-making, attention, problem solving, strategy development, and working memory (*See* Chapter 3.14). Such processes exert powerful control over goal-directed behavior. The PFC is both structurally and functionally heterogeneous, and a discussion of the role of each subregion is beyond the scope of this article. We will focus on two areas which appear to be particularly important in reward processing: the medial PFC (mPFC) as exemplified by the prelimbic and anterior cingulate regions, and the ventral PFC encompassing the orbitofrontal and agranular insular cortices.

4.12.3.3.1 The prelimbic cortex

This region of the rat mPFC is involved in the acquisition of goal-directed behavior. In order for action to be considered goal-directed, it must fulfill two criteria: (1) the animal must be aware of the *causal* link between the instrumental action and its outcome (i.e., a rat pressing a lever for food knows that pressing the lever results in delivery of food reward, and (2) the outcome for which the animal is responding must be considered a goal by the animal (i.e., the rat *wants* the food). Instrumental responding ceases to be goal-directed once it becomes habitual, that is, the animal is insensitive to changes in the incentive value of the reward or to the presence of an instrumental contingency. Behavior is instead controlled by simple stimulus-response (S-R)

associations in which stimuli or outcomes become directly associated with a motor response, so that the rat responds on the lever regardless of its motivational state. Damage to the prelimbic cortex (PrLC) not only retards acquisition of instrumental responding, but also disrupts the detection of instrumental contingencies (Balleine and Dickinson, 1998; Corbit and Balleine, 2003). These data indicate that rats with PrLC damage may acquire instrumental responses based on S-R associations and are no longer truly capable of goal-directed learning. The transition from goal-directed to habitual S-R responding can also happen naturally over time with repeated training and has some advantage in that it is thought to use fewer cognitive resources. However, habits are less flexible than goal-directed actions and can lead to maladaptive behavior, such as that commonly associated with addiction, where environmental stimuli trigger engagement in drug-taking even though drug intake itself is no longer rewarding.

In keeping with these data indicating that the mPFC is involved in maintaining cognitive flexibility, the PrLC is also thought to play an important role in extinction processes. Extinction refers to the decline in responding when that response no longer leads to the associated outcome. The role of the PrLC has been extensively studied in the extinction of conditioned fear (see Sotres-Bayon et al., 2004, for review). Repeated presentation of the CS in the absence of the associated shock reduces the ability of the CS to elicit fear-related responses such as freezing as the animal learns that the CS is no longer a reliable predictor of the US. This ability to update knowledge about what is, and what is not, an accurate predictor of a dangerous event is clearly important for adaptation and survival. Lesions to the mPFC encompassing the PrLC impair extinction of conditioned fear. The deficits in extinction observed in the absence of the PrLC may relate to the well-documented role of the frontal cortex in mediating behavioral inhibition and perseveration. Disconnection of the mPFC and the BLA also attenuates extinction of conditioned fear, suggesting that activity within the mPFC may act to inhibit the representations of the emotional value of the CS generated by the amygdala, highlighting the importance of prefrontal regulation of amygdala function in reward-related learning.

4.12.3.3.2 The orbitofrontal cortex

Perhaps more than any other region of the frontal cortex, the OFC has been heavily associated with the processing of rewarding or emotional stimuli and events. In humans, damage to the OFC produces a pattern of aberrant social behavior and maladaptive decision-making which is often described as impulsive. This behavior can be exemplified by performance of these patients on laboratory-based gambling tasks where subjects choose between different options to earn points. The optimal strategy is to choose options associated with small immediate gains but also low and infrequent losses, an approach which healthy volunteers learn. Persistent selection of options leading to large immediate gain but heavy losses in the long term is thought to reflect risky decision-making and is observed both in pathological gamblers (Cavedini et al., 2002) and substance abusers (Bechara et al., 2001) and in patients with damage to the OFC or BLA (Bechara et al., 1999). In the monkey, neurons within the OFC have been shown to fire preferentially to different food rewards and to decrease their firing rate specifically to a devalued reward (Critchley and Rolls, 1996). Similar to the BLA, the OFC therefore appears to be involved in creating representations of the incentive value of reward. The reciprocal connections between these two regions are well documented, and disconnection of the OFC and BLA prevents devaluation of reward from altering choice behavior in monkeys (Baxter et al., 2000). However, electrophysiology recordings in the rat suggest that the OFC may have a more sophisticated role to play in using this information. In a series of elegant studies, Schoenbaum and colleagues have developed the hypothesis that the OFC supports representations of outcome expectancy, that is, how rewarding the outcome of a certain action is anticipated as being (Schoenbaum et al., 2006). The BLA generates important information about the incentive value of reward-associated stimuli, which the OFC then uses to generate representations of the anticipated outcome predicted by those CS. Such outcome expectancy is then used to inform choice behavior.

Lesions to the OFC also affect aspects of impulsive and compulsive behavior in animals. As in humans, damage to the rodent or monkey OFC increases perseverative behavior and decreases cognitive flexibility. For example, in reversal learning paradigms, OFC-lesioned rats perseverate in responding to the previously rewarded stimulus (Schoenbaum et al., 2002; Chudasama and Robbins, 2003). In delay-to-reinforcement paradigms where rats choose between a small immediate versus a larger increasingly delayed reward, OFC-lesioned rats do not show such a strong aversion to the delay compared to their sham controls (Winstanley et al.,

2003). This deficit may arise from both perseverative tendencies as well as an inability to integrate the consequences of making a response with the incentive value of the reward, i.e., the delay does not sufficiently devalue the reward.

4.12.4 Dopamine and Reward

Converging evidence from numerous studies has implicated dopamine as the single most important neurotransmitter involved in the signaling of reward. Using intracranial self-stimulation techniques, where animals respond for electrical stimulation into a particular region of the brain, it has been shown repeatedly that animals will work for stimulation of their dopamine system (Wise and Rompre, 1989). Likewise, the addictive properties of drugs of abuse can be attributed in part to their ability to potentiate dopaminergic transmission. In particular, dopaminergic regulation of the NAc is critically involved in this process. The ventral tegmental area (VTA) sends dopaminergic projections to numerous regions within the brain including the NAc, PFC, and other parts of the limbic system. Both natural and drug rewards increase dopamine efflux in the NAc-Sh, whereas CS associated with such reward increase dopamine efflux in the NAc-C. Although animals are still capable of finding things rewarding or pleasurable in the absence of dopamine, they are no longer motivated to earn reward (Salamone et al., 2003), i.e., they are no longer capable of goal-directed behavior. Dopaminergic depletion of the NAc significantly decreases the amount of effort rats are willing to expend to earn reward, whereas manipulations which increase NAc dopamine function enhance goal-seeking.

Several groups have recorded from dopaminergic cells within the VTA in monkeys during Pavlovian conditioning paradigms. Using this methodology, it has been found that the firing of dopamine neurons may signal error prediction, i.e., they are particularly active when an unexpected reward is delivered, and firing is suppressed when an expected reward does not appear (Montague et al., 2004; Schultz, 2006). The potentiation of dopamine function caused by drugs of abuse may therefore generate a powerful signal that the reward was larger or better than expected regardless of the actual experience created by the drug (Hyman et al., 2006). Not only are psychostimulant drugs like amphetamine rewarding in their own right, they also enhance the effects of conditioned reinforcers, an effect which can be induced by direct application of amphetamine or dopamine agonists into the NAc, and which is blocked by dopaminergic lesions of the NAc and by ablation of the NAc-Sh (see Cardinal et al., 2002). Similarly, PIT can be enhanced by intra-NAc amphetamine and is abolished by dopamine receptor antagonists. This general potentiation of reward-related learning and reward-seeking likely plays an important role in the generation and maintenance of addiction.

Dopamine also regulates reward-related processing within the PFC. Data from both *in vivo* observations and computational modeling has led to the suggestion that phasic dopamine release acts as a gating mechanism, signaling when internal representations of reward and related stimuli need to be updated (Cohen et al., 2002). Damage to dopaminergic innervation of the PFC alters reward-related learning in a manner consistent with this theory. For example, lesions to dopaminergic inputs to the mPFC cause a deficit in fear extinction (Morrow et al., 1999), and ablation of dopaminergic terminals within the OFC leads to persistent choice of a larger but delayed reward, similar to excitotoxic lesions of these structures. Pharmacological manipulations also suggest that there is an optimum level of dopamine function within the PFC, and that too much as well as too little can have a negative impact on a range of cognitive behaviors (Arnsten, 1997). Long-term drug use leads to cognitive deficits that have been largely attributed to dysfunction of the frontal cortex (Rogers and Robbins, 2001), and hypofunction of the OFC has been observed in recently abstinent cocaine abusers (Volkow and Fowler, 2000). In rats, repeated exposure to addictive drugs has been shown to alter reward-related learning in tasks known to be dependent on the integrity of the OFC (Schoenbaum et al., 2004). Given the importance of the dopamine system in facilitating reward-related learning and the ability of addictive drugs to modulate this system, it seems likely that dysregulation of the dopaminergic input to frontal regions is responsible for these cognitive impairments.

4.12.5 Cellular and Molecular Targets of the Dopamine-Reward System: Insights from Drug Addiction

Given that the dopaminergic system has been heavily implicated in mediating the highly rewarding nature of addictive drugs, and that addictive behavior appears to arise from the hijacking of normal reward systems, a significant proportion of the data concerning the

molecular basis of reward have been obtained through studying the effects of drugs of abuse. The intracellular changes that occur following acute administration of an appetitive substance like cocaine can provide valuable information about the signaling cascades activated by such rewarding substances. However, the changes seen after repeated administration are of more relevance in determining the molecular basis of the alterations in reward-related learning underpinning the addicted state. Drug addiction is a chronic and often relapsing disorder, with human addicts remaining at risk of relapse even after years of abstinence. The fact that chronic drug intake produces such durable changes in brain function and behavior has led to the suggestion that long-lasting changes in gene transcription may play a prominent role (Nestler et al., 1993). This has led to a search for relatively stable markers of altered transcriptional regulation whose persistence matches the time course of aspects of addictive behavior. The contrasting effects of acute versus chronic administration of addictive drugs on intracellular signaling pathways can therefore provide information about different aspects of reward processing. The role played by these molecular mechanisms in the processing of natural rewards has also been studied in learning and memory paradigms, and also in animal models of depression.

The binding of dopamine, or any neurotransmitter or signaling molecule, by its membrane-bound receptors triggers the initiation of several intracellular signaling cascades which often culminate in the regulation of transcription factors (TFs), including those encoded by immediate early genes (**Figure 3**). In terms of our understanding of reward processing and addiction, a considerable amount of data is now available concerning the particular TF families activated by dopaminergic agents. In this section, we will focus on some specific examples of this aspect of gene regulation and consider the role of these different TFs in the development of addiction as well as in the response to natural rewards. In terms of reward-related learning, we will largely restrict our discussion to key areas within the affective corticostriatal loop highlighted in the previous section. However, it should be noted that many of these intracellular signaling pathways have been implicated in the emotional memory processes

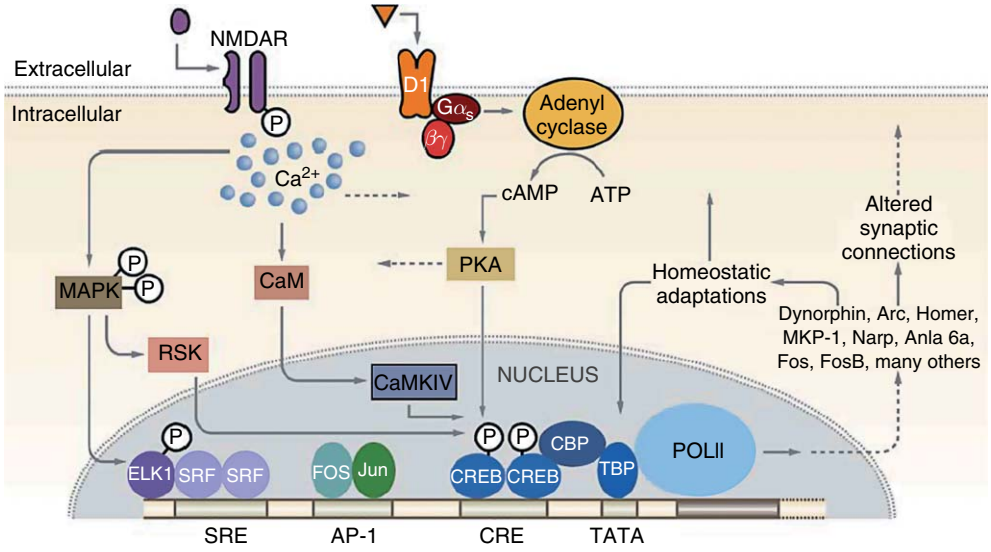

Figure 3 Regulation of gene expression within the striatum by dopamine and glutamate. Stimulation of dopaminergic D_1 receptors and glutamate receptors activates intracellular second messenger signaling cascades which result in changes in gene expression within the cell nucleus. Shown here are examples of DNA binding sites within the cFos promoter, including a serum response element (SRE), an activator protein-1 element (AP-1), and a cyclic adenosine monophosphate (cAMP) response element (CRE). Numerous other genes are also activated, including Homer, Arc, FosB, etc. Abbreviations: CBP, CREB binding protein; CREB, cAMP response element binding protein; MAPK, mitogen-activated protein kinase; NMDAR, *N*-methyl-D-aspartate glutamate receptor; PKA, protein kinase A; TBP, TATA binding protein; RSK, ribosomal S6 kinase; CaMKIV, Ca^{2+}/calmodulin-dependent kinase IV; ELK1, Ets-like transcription factor; SRF, serum response factor; POLII, RNA polymerase II; TATA describes a short sequence of base pairs that is rich in adenine (A) and thymidine (T) residues. Reprinted from Hyman SE, Malenka RC, and Nestler EJ (2006) Neural mechanisms of addiction: The role of reward-related learning and memory. *Annu. Rev. Neurosci.* 29: 565–598; used with permission from the Annual Reviews Permission Department.

involved in fear conditioning through their actions in the hippocampus (HPC).

Several techniques have been combined to determine whether these changes in TF regulation alter addiction-related behavior. Mice lacking these TFs have been developed, as have transgenic mice which either overexpress certain TFs or express mutant or dominant negative proteins which inhibit their effects. Reporter lines have also been developed, where the promoters regulated by a particular TF (e.g., cAMP response elements (CREs)) drive expression of a reporter gene expressing an easily visualized marker, such as β-galactosidase or green fluorescent protein (GFP). Such mice enable the consequences of different environmental manipulations on that TF to be determined. As well, viral vectors designed to express these proteins can be infused into specific regions using standard stereotaxic surgical techniques, which localizes the effects of changes in gene transcription to particular areas of interest. A small number of studies have infused antisense oligonucleotides into a certain brain area, although concerns remain about the toxicity and specificity of this approach. In addition to monitoring changes in cellular excitability and synaptic plasticity caused by these manipulations, development of these tools has made it possible to investigate the role these TFs play in reward-related learning. The majority of these studies have used conditioned place preference to assess the hedonic impact of substances of abuse given the relatively high throughput of this method. Instrumental responding for drug reward can also be assessed using self-administration paradigms, where animals learn to press a lever to obtain a drug infusion delivered into an indwelling intravenous catheter.

As mentioned before, one of the factors central to understanding addiction is the changes in behavior and brain function which occur following repeated rather than acute administration. In terms of behavioral output, one of the most widely studied phenomena is that of locomotor sensitization, whereby repeated administration of virtually any abused drug leads to a potentiation of the hyperlocomotor response seen after an acute drug injection in rodents. This increased sensitivity to the motor stimulating properties of addictive drugs is long-lasting, indicating that it could be mediated by some of the long-term changes in gene transcription and brain function which characterize the persistent nature of addiction. However, human addicts do not show sensitization to the arousing effects of drugs like cocaine following repeated use, with most users reporting tolerance of the drugs' stimulant effects. Nevertheless, it is hoped that understanding the changes in neuronal activity that accompany the development of locomotor sensitization may provide valuable insight into the changes in brain function caused by long-term drug use. The behavioral phenotype is very robust and easy to study, thereby facilitating the investigation of its underlying neurobiology. Furthermore, there is evidence to suggest that sensitization to psychostimulants enhances their ability to potentiate the impact of CS on behavior (Taylor and Horger, 1999). Some of the mechanisms underlying behavioral sensitization could also be involved in mediating the powerful ability of addictive drugs to influence goal-directed behavior and stimulate drug-seeking.

Given that addictive drugs heavily stimulate the dopamine system to cause long-term behavioral changes, it is likely that the regulatory mechanisms controlling neuronal plasticity within reward circuitry are targets of drugs of abuse. Repeated activation of neurotransmitter receptors leads to a change in the physiological state of neurons, rendering them more or less sensitive to subsequent stimulation. This could be mediated via changes in the effective strength of synaptic connections (referred to as synaptic plasticity), or via changes in the overall excitability of the affected neurons (referred to as whole-cell plasticity). The former in particular have been implicated in learning and memory processes. In keeping with this hypothesis, chronic administration of several, but not all, addictive drugs increases dendritic spine formation within the NAc (Robinson and Kolb, 2004). This increase in synaptic plasticity is proposed to underlie the locomotor sensitization discussed earlier. Considering the importance of the NAc in mediating the rewarding properties of addictive drugs, the majority of molecular studies have focused on manipulating gene transcription in this region.

4.12.5.1 The CREB and Fos Families of TFs

Ligand-binding at the dopamine D_1 receptor activates the cAMP second messenger signaling cascade, leading to the phosphorylation of protein kinase A (PKA) which can in turn phosphorylate downstream protein targets. Among the prominent targets of this signaling cascade is CREB. This transcription factor is constitutively expressed at fairly high levels throughout the brain, but needs to be phosphorylated for full transcriptional activity. In addition to PKA, CaM kinases such as Ca^{2+}/calmodulin kinase type IV (CaMKIV) and growth factor-associated kinases are all capable of

performing this phosphorylation event, indicating that CREB activation is a point of functional convergence for several signaling pathways. Dimers of CREB bind to CRE sites located within the promoter regions of certain genes and alter the rate at which they are transcribed. More information about this pathway can be found in other chapters in this reference work (*See* Chapters 4.21, 4.27).

Acute administration of psychostimulant drugs stimulates phosphorylation of CREB through D_1 receptor-dependent mechanisms at several nodes within the reward circuitry, including the VTA, amygdala, PFC, and NAc. Increased expression of cFos, a product of an immediate early gene, is observed in similar locations, and its induction may be partly dependent on CREB activation, at least for amphetamine (Konradi et al., 1994). This occurs through CRE sites present in the promoter region of the cFos gene. cFos expression is also induced by several other intracellular signaling cascades, in particular, serum response factor (SRF) acting on serum response elements (SREs) within the cFos promoter. cFos is a member of the Fos family of transcription factors, which includes FosB, Fra1, and Fra2. These proteins heterodimerize with members of the Jun protein family to form the activator protein 1 (AP-1) transcription factor complex, which then binds to AP-1 sites within gene promoter regions. Increases in the activation of both cFos and CREB are rapid and transient, returning to basal levels within hours of the acute stimulus. In fact, repeated administration of drug causes the induction of cFos to desensitize, so that subsequent drug exposure no longer induces the robust elevation seen following first administration (Nestler et al., 2001). A similar pattern is observed in the expression of FosB. In contrast, the activation of CREB appears to become greater and more persistent with repeated drug exposures, an effect most firmly established within the NAc (Shaw-Lutchman et al., 2003). This pattern of expression suggests a more pronounced role for CREB-mediated gene transcription in aspects of addiction.

However, in contrast to all the TFs mentioned so far, isoforms of a truncated splice variant of FosB, known as ΔFosB, is only induced at high levels within the same reward-related areas following chronic, *but not acute*, administration of addictive drugs (**Figure 4**) (Nestler et al., 2001). The 35–37 kDa isoforms of ΔFosB dimerize predominantly with JunD to form an active AP-1 complex. These isoforms of ΔFosB also have an unusually long half-life due to their resistance to degradation by the proteosome, a property conferred at least in part by its truncated C-terminus and by a casein kinase 2–mediated phosphorylation (McClung et al., 2004). Once induced, levels of ΔFosB have been detected up to 2 months after cessation of drug treatment. Such accumulation has been observed following treatment with virtually any addictive substance, including cocaine, *d*-amphetamine, morphine, nicotine, alcohol, and phencyclidine (PCP). This relatively unique pattern of induction and stability has lead to the suggestion that ΔFosB may be a particularly important mediator of long-term changes in gene regulation associated with addiction.

Activation of PKA within the NAc reduces the rewarding effects of cocaine in self-administration and relapse assays, whereas inhibition of PKA has the opposite effect (Self et al., 1998). Likewise, overexpression of CREB in the NAc, through viral mediated gene transfer, decreases place conditioning

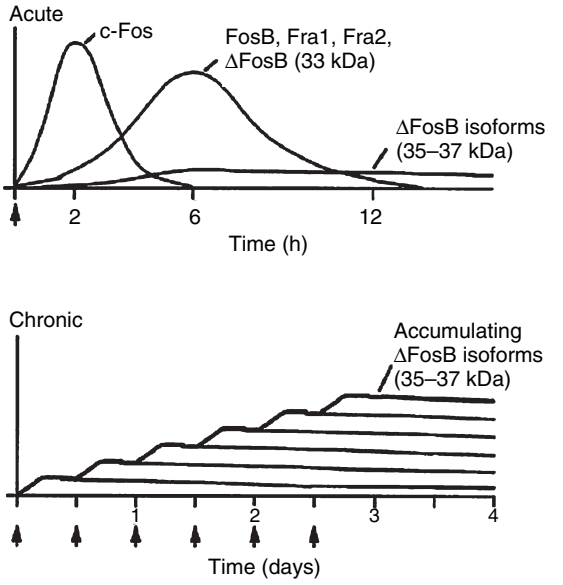

Figure 4 Diagrammatic representation of the induction of the Fos family of transcription factors (TFs) by acute and chronic drugs of abuse. The top panel charts the response to acute stimulation. cFos is rapidly induced, followed by FosB, Fra-1, and Fra-2. Levels of these TFs return to baseline between 6 and 12 hours poststimulation. Only a small increase is observed in levels of stabilized isoforms of ΔFosB. As shown in the bottom panel, this induction persists in the brain for a much longer time course and accumulates with chronic drug administration. Taken from Nestler EJ, Barrott M, and Self DW (2001) ΔFosB: A molecular switch for addiction. *Proc. Natl. Acad. Sci. USA* 98: 11042–11046; used with permission from National Academy of Sciences, USA.

to cocaine and to morphine, whereas overexpression of a dominant negative mutant form of CREB (mCREB), which cannot be phosphorylated due to a point mutation (Ser133 to Ala), potentiates the rewarding effects of both drugs (Carlezon et al., 1998; Barrot et al., 2002). Similar results are seen in transgenic mice that inducibly overexpress CREB or mCREB in the NAc and dorsal striatum. These data suggest that inhibition of CREB in the NAc enhances the hedonic value of cocaine and morphine; thereby animals 'like' the drug more, or alternatively could be facilitating the formation of the Pavlovian CS-US association between context and drug exposure. The viral infusions targeted the NAc-Sh, which is associated with encoding the rewarding properties of primary reinforcers rather than Pavlovian conditioning processes linking those rewards to environmental stimuli (see earlier). Therefore, it is likely that the behavioral changes observed arise from enhancing the rewarding effects of the drug. This interpretation is consistent with preliminary findings that mCREB decreases brain stimulation reward thresholds, while CREB has the opposite effect (Carlezon et al., 2005). Nevertheless, analysis of tissue from animals killed shortly after completion of the place conditioning test demonstrated increases in the phosphorylated form of CREB in the NAc core but not shell. Blocking this induction disrupted both the retrieval and consolidation of the CS-US association, indicating that CREB in the NAc-C is critically involved in this aspect of reward-related learning (Miller and Marshall, 2005). Thus, activation of CREB may play distinct roles in these two subregions of the NAc. CREB has been heavily implicated in multiple memory processes, particularly those underpinning long-term memory, which may reflect the known role for CREB in mediating certain changes in synaptic plasticity.

Transgenic mice have been developed which selectively overexpress ΔFosB within the NAc and dorsal striatum (Kelz et al., 1999). Furthermore, this overexpression is inducible (it occurs in adult animals) and is cell-type specific in that it is only observed in medium spiny neurons containing dynorphin/substance P (as opposed to those which contain enkephalin). The behavioral phenotype of these mice resembles animals treated chronically with drugs in several ways. The mice are more responsive to cocaine-induced hyperactivity, both acutely and after repeated administration, suggesting that ΔFosB expression may be involved in the development of locomotor sensitization. They also show enhanced place conditioning for cocaine and morphine, indicative of increased sensitivity to the rewarding properties of drugs or (as discussed earlier for CREB) of potential enhancement of the ability to form CS-US associations (Kelz et al., 1999; Zachariou et al., 2006b). Mice overexpressing ΔFosB self-administer lower doses of cocaine than wild-type controls and are more motivated to work for cocaine reward, as indicated by their elevated breakpoints in progressive ratio schedules (Colby et al., 2003). In contrast, mice overexpressing ΔcJun, a truncated form of cJun which acts as a dominant negative antagonist of all AP-1 mediated transcription, show reduced place conditioning to cocaine and morphine (Peakman et al., 2003). Together, these data may reflect more generalized increases in incentive motivation for reward.

One important molecular target of the dopamine system is dopamine and adenosine 3′5′-monophosphate-regulated phosphoprotein (32 kDa), or DARPP-32 as it is commonly known (Fienberg et al., 1998). DARPP-32 has been shown to be a potent modulator of both CREB and ΔFosB as well as many other facets of dopaminergic transmission. As with CREB, D_1-receptor-mediated activation of PKA induces the phosphorylation of DARPP-32 at threonine 34 (Thr34), which then acts as a potent inhibitor of protein phosphatase-1 (PP-1). In contrast, dopaminergic activation through D_2 receptors inhibits PKA signaling, through G-protein-coupled inhibition of adenylyl cyclase, leading to a decrease in phosphorylation of DARPP-32. Through its inhibition of PP-1, DARPP-32 regulates the phosphorylation of numerous proteins. With respect to TFs, mice lacking DARPP-32 show reduced phosphorylation of CREB in response to stimulant drugs of abuse, as well as reduced induction of cFos, in striatal regions (Fienberg et al., 1998). The mice also show reduced induction of ΔFosB after chronic stimulant administration. Consistent with these deficits in biochemical responses to drugs of abuse, DARPP-32 mutant mice show reduced responses to acute drug administration, including reduced locomotor activation and place conditioning (Zachariou et al., 2002). However, paradoxically, the mice show enhanced locomotor sensitization to chronic cocaine. The molecular basis of this latter abnormality is hard to explain on the basis of available data and requires more investigation (Hiroi et al., 1999). Mice in which Thr34 of DARPP-32 is mutated to Ala exhibit virtually the same biochemical and behavioral phenotype as DARPP-32 knockout mice, which demonstrates the importance of DARPP-32's phosphorylation by PKA in regulating its function (Zachariou et al., 2006a).

4.12.5.2 Clock

TFs traditionally associated with other roles of the dopamine system have also been recently implicated in reward-processing and the response to addictive drugs. For example, the dopaminergic system exerts an important influence over the entrainment of circadian rhythms during fetal development and in response to food and other stimuli, and disruption of the sleep cycle is observed in patients treated with dopaminergic drugs, such as *d*-amphetamine and L-DOPA. Abnormal circadian rhythms are also commonly found in substance abuse disorders. The most studied focus of circadian rhythms in brain is the suprachiasmatic nucleus (SCN) of the hypothalamus. This nucleus is particularly important for entraining the body's circadian rhythms to environmental lighting. The molecular basis of the circadian clock is now well established. The transcription factor Clock dimerizes with Bmal1 to form a transcription factor complex essential for accurate circadian rhythmicity (Vitaterna et al., 1994). The complex activates expression of Period and other proteins, which feed back and suppress their own expression in addition to regulating many other cellular targets. Increasing evidence indicates that this molecular clock operates in all tissues, which raises the interesting notion that many circadian rhythms are driven outside the SCN. For example, recent findings have shown that Clock is highly expressed within dopaminergic neurons of the VTA (McClung et al., 2005). Mice lacking functional Clock protein are hyperactive under baseline conditions, an effect which is most pronounced during the transition from the light to dark phases of their diurnal light cycle. Despite this hyperactivity, these mice show still greater activity following administration of cocaine as compared to littermate controls, and also show increased place conditioning to cocaine as well as decreased brain stimulation reward thresholds. These findings suggest that Clock, at the level of the VTA, may serve to dampen dopaminergic function and suppress reward, and that this may contribute to circadian rhythms in reward and motivation that have been well documented over the years.

4.12.6 The Role of CREB and ΔFosB in Response to Natural Rewards and Stress

Understanding the response to natural rewards has implications for research into depression due to the obvious relationship between value judgments and anhedonia. Pharmacologically, most currently used antidepressant treatments inhibit the reuptake of the monoamines serotonin and noradrenaline, or inhibit monoamine oxidase (a major catabolic enzyme for monoamine neurotransmitters). Although the dopamine system is critically associated with reward judgments, it is less well studied in the context of depressive etiology. However, changes in some of the same intracellular signaling mechanisms identified in drug addiction research are also affected in animal models of depression and within areas associated with reward-related learning such as the NAc, PFC, and BLA, as well as in areas more strongly associated with memory storage and retrieval such as the HPC (Nestler and Carlezon, 2006). Animal models of depression have generally focused on the response to stress, such as the forced swim test (FST), where antidepressants have been shown to increase the latency to immobility and decrease the total time rodents spend immobile when confined to a water-filled container. Similarly, antidepressants increase the time an animal struggles when suspended by its tail. A lack of struggling in these models is regarded as indicative of a state of behavioral despair. Likewise, animals exposed repeatedly to inescapable stressors, such as shocks, show an increased latency to escape when subsequently given the opportunity.

CREB activity in the NAc appears to play an important role in gating an individual's response to both rewarding and aversive stimuli (Barrot et al., 2002). Increased CRE-mediated transcription in the NAc has been observed following several stressors, including inescapable foot shocks, restraint stress, and the more natural stress of introducing an animal into a novel social group. Increased CREB expression reduces both the nociceptive reaction to painful stimuli and conditioned place aversion to naloxone withdrawal in morphine-dependent rats, whereas mCREB potentiates the response to these aversive stimuli. A similar pattern is observed in anxiety tests, where intra-NAc infusion of herpes simplex virus (HSV)-CREB appears to be anxiolytic and HSV-mCREB anxiogenic. In addition to modulating place conditioning for drug rewards, CREB in the NAc also alters preference for sucrose as assessed by a simple two-bottle choice test. Overexpression of CREB decreases sucrose preference, whereas mCREB increases sucrose preference. Conversely, levels of CRE-mediated transcription in the NAc decrease following protracted social isolation, a manipulation which increases anxiety and impairs initiation of sexual behavior. This

phenotype can be rescued by overexpressing CREB within the NAc using viral-mediated gene transfer. Likewise, overexpressing mCREB in this region mimics these effects of isolation in nonisolated rats, an effect that can be reversed with the anxiolytic diazepam (Barrot et al., 2005).

In summary, CREB appears to reduce the impact of emotionally significant stimuli, whereas inhibition of CRE-mediated transcription enhances emotional responsivity. Although mCREB is not a naturally occurring protein, the endogenous inhibitor of CREB function, inducible cAMP early repressor (ICER), is capable of mediating the same functions as mCREB *in vivo* and is induced by both stress and amphetamine (Green et al., 2006). In keeping with this hypothesis that CREB in the NAc numbs the emotional response to stimuli, overexpression of CREB in the NAc induces depressive-like behavior in the FST and learned helplessness test, whereas inhibition of CREB function in this region, through overexpression of either mCREB and ICER, induces antidepressant-like behavior in these tests (Pliakas et al., 2001; Green et al., 2006).

The proposal that CREB gates the response to emotional stimuli within the NAc is consistent with recent elecrophysiological findings, where CREB was shown to increase the electrical excitability of NAc neurons and mCREB to cause the opposite effect (Dong et al., 2006). Moreover, direct inhibition of NAc neurons, via viral-mediated overexpression of a K^+ channel, which would mimic the mCREB effect, increased an animal's behavioral response to cocaine. These findings are interesting in light of work, cited earlier, where inhibition of NAc neurons has been linked with increases in goal-directed behavior.

The effect of CREB in the NAc contrasts with its established role in the HPC where, as noted earlier, CREB is thought to mediate long-term memory formation. Virally mediated overexpression of CREB in the HPC also produces antidepressant-like behavior in rats, an effect potentially mediated in part by CREB-induced elevations of brain-derived neurotrophic factor (BDNF; see section 'Brain-derived neurotrophic factor'). Changing CRE-mediated gene transcription within different brain areas, therefore, has very different effects (Carlezon et al., 2005). Such functional dissociations are not uncommon when considering the effects of neurotransmitters such as dopamine or serotonin. Therefore, it is not surprising that the same intracellular signaling mechanisms activated by these neurotransmitters likewise produce region-specific changes in behavior.

In comparison to CREB, less is known regarding the role of ΔFosB in regulating the response to natural rewards or stressors. ΔFosB upregulation is seen after chronic wheel-running behavior, an activity which rodents are thought to find pleasurable but potentially compulsive or 'addictive,' and mice overexpressing ΔFosB in striatal regions exhibit greater compulsive wheel-running than their wild-type littermates (Werme et al., 2002). Moreover, overexpression of ΔFosB in striatal regions, either by viral vectors or in inducible transgenic mice, increases motivation for food in progressive ratio and instrumental learning tests (Olausson et al., 2006). These findings support the hypothesis, mentioned earlier, that ΔFosB in this neural pathway promotes reward.

4.12.7 Target Genes of CREB and ΔFosB

This section will primarily focus on examples of the downstream targets of CREB and ΔFosB associated with reward processing, addiction, and depression-like behavior at the level of the brain's reward pathways. A broad survey of CREB and ΔFosB targets in the NAc has been published recently (McClung and Nestler, 2003). However, changes in targets upstream of the TFs considered here have also been associated with the response to rewarding stimuli, including the enzymes responsible for the synthesis and degradation of cAMP, namely adenylyl cyclase and cyclic nucleotide phosphodiesterases, respectively. Kinases such as PKA and extracellular signaling kinases (ERKs) have been implicated in the effects of addictive drugs as well as in numerous facets of learning and memory. These aspects of the intracellular response to reward are considered in other chapters (*See* Chapters 4.21, 4.22, 4.25).

4.12.7.1 Dynorphin in the VTA-NAc Pathway

One of the primary mechanisms by which CREB is thought to affect reward-related learning and addiction is through induction of dynorphin within the NAc (**Figure 5**). Dopaminergic neurons in the VTA innervate GABAergic neurons in the NAc, which express dynorphin and in which activation of CREB has been observed after chronic treatment with addictive drugs. Dynorphin acts on κ opioid receptors expressed on the terminals of these

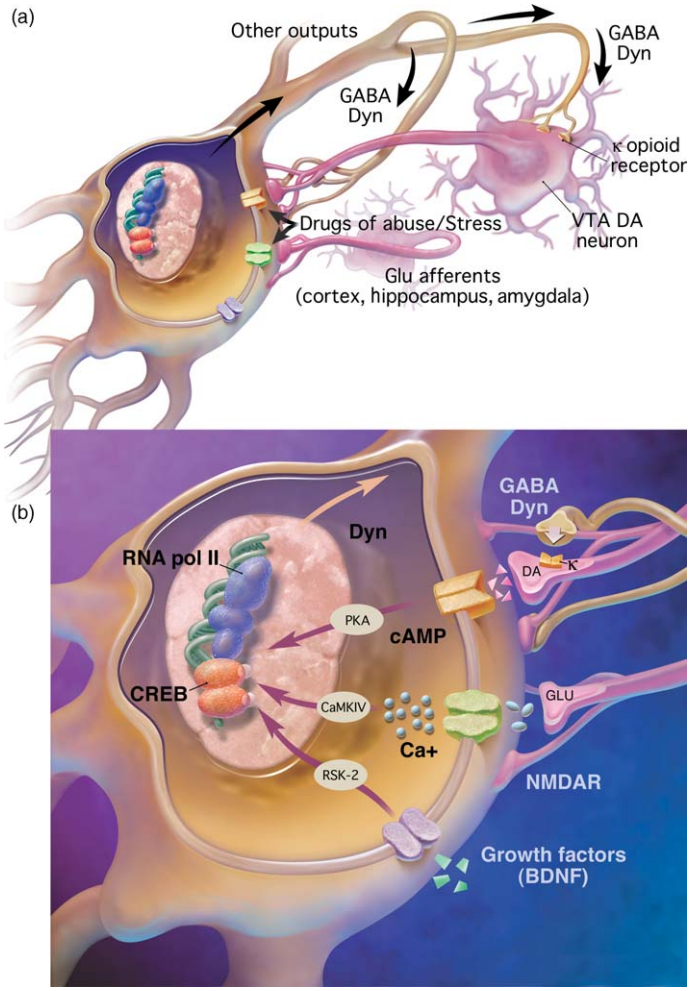

Figure 5 Regulation of NAc function by CREB and dynorphin (Dyn). The figure shows a dopaminergic neuron from the VTA innervating a medium spiny neuron within the NAc which expresses dynorphin. Glutamatergic input from other areas such as the PFC and amygdala, as well as BDNF (released from glutamatergic or dopaminergic projections) are also shown. Dynorphin acts as a negative feedback signal: when released, it binds to κ opioid receptors on dopaminergic neurons and inhibits their function. Drugs of abuse and stress increase CREB activity and induce dynorphin expression, upregulating this feedback loop. Activation of CREB could be caused by some of the mechanisms shown in the figure, all of which lead to its phosphorylation at Ser 133. Abbreviations: GABA, gamma-aminobutyric acid; NMDAR, *N*-methyl-D-aspartate receptor; PKA, protein kinase A; CaMKIV, Ca^{2+}/calmodulin-dependent protein kinase type IV; RSK-2, ribosomal S6 kinase-type 2; RNA pol II, RNA polymerase II complex. Taken from Nestler EJ, Barrot M, DiLeone RJ, Eisch AJ, Gold SJ, and Monteggia LM (2002) Neurobiology of depression. *Neuron* 34: 13–25; used with permission from Cell Press.

dopaminergic projections and inhibits their function, thereby forming a negative feedback loop to minimize the effects of dopaminergic stimulation. This dampening of the dopamine signal could contribute to the depressant-like effects of overexpressing CREB within the NAc and the reduction in place conditioning to addictive drugs (Carlezon et al., 2005). Increased ΔFosB is also primarily observed in dynorphin-containing cells within the NAc, but acts to decrease expression of dynorphin (Zachariou et al., 2006b) and to thereby potentiate dopaminergic signaling. Such reciprocal regulation of dynorphin by CREB and ΔFosB could explain some of the reciprocal behavioral changes observed following upregulation of these TFs. It could also account for the changes in reward processing that occur during different timepoints of withdrawal from addictive drugs. Drug-induced activation of CREB is relatively short-lived, yet increasing drug use potentiates CREB expression. The anhedonia and negative emotional symptoms which predominate during acute withdrawal could therefore arise partly from the ability of

CREB to downregulate dopaminergic signaling. In contrast, the sensitization to the rewarding effects of addictive drugs and the incubation of craving which predominate at later timepoints could be mediated in part by the prolonged expression of ΔFosB.

4.12.7.2 Cyclin-Dependent Kinase 5

Cyclin-dependent kinase 5 (Cdk5) was identified as a downstream target of ΔFosB within the NAc through microarray analysis (Bibb et al., 2001). Activation of Cdk5 alters dopaminergic signaling through phosphorylation of DARPP-32 at a different site from PKA, namely threonine 75 (Thr75) (see Benavides and Bibb, 2004). This converts DARPP-32 from an inhibitor of PP-1 to an inhibitor of PKA. The fact that DARPP-32 can function as either a protein phosphatase inhibitor or a protein kinase inhibitor, depending on the site at which it is phosphorylated, may be unique, and this high level of phosphorylation-site-specific regulation further highlights the importance of this molecule in intracellular signaling cascades. Furthermore, PKA activation can decrease phospho-Thr75 DARPP-32 through activation of protein phosphatase 2A (PP-2A). Acute administration of cocaine can increase phosphorylation of DARPP-32 at Thr34 and reduce it at Thr75 via activation of PKA and inhibition of the PP-2A pathway, respectively. However, chronic cocaine administration has the opposite effect, increasing phosphorylation of Thr75, and reducing the ability of D_1 receptor stimulation to activate PKA. Cdk5 is upregulated by chronic cocaine administration, and this effect appears to be mediated by ΔFosB: overexpression of ΔFosB induces Cdk5 expression, while expression of the dominant negative ΔcJun prevents the ability of cocaine to induce the enzyme (Bibb et al., 2001; Peakman et al., 2003).

The behavioral contribution of Cdk5 induction is complex. Intra-NAc infusion of the Cdk5 inhibitor roscovitine has been shown to potentiate the hyperlocomotor response to cocaine seen following chronic drug administration (Bibb et al., 2001). These behavioral data suggest that cocaine-induced upregulation of Cdk5 activity may be an attempt to compensate for overstimulation of the dopaminergic system. However, intra-NAc infusions of roscovitine also block the increase in dendritic spine proliferation seen in this region with chronic cocaine administration, which is correlated with the development of locomotor sensitization (Norrholm et al., 2003). As discussed earlier, these neuroplastic changes are one potential mechanism by which repeated drug administration perpetuates changes in learning and memory processes integral to the sensitized and addicted state. Chronic cocaine exposure, via ΔFosB, may therefore trigger an adaptive homeostatic response involving increased Cdk5 activity that ultimately commits the affected neurons to a maladaptive process of cytoarchitectural changes.

4.12.7.3 Nuclear Factor Kappa B

Nuclear factor kappa B (NFκB) is a transcription factor induced in many tissues by inflammation and immune responsiveness (see Chen and Greene, 2004). It is composed of two subunits, most commonly p50 and p65. Under basal conditions, it remains sequestered in the cytoplasm by inhibitory kappa B (IKB) protein. Upon phosphorylation by I kappa kinase (IKK), IKB releases an inactive dimer of p50 and p65, which can then be phosphorylated and transported to the nucleus where it can initiate gene transcription (*See* Chapter 4.28). This TF is more commonly associated with the field of immunology than neuroscience. However, in parallel to Cdk5, both ΔFosB overexpression and chronic cocaine treatment upregulate NFκB-related proteins such as p65, the precursor of p50 (p103), and IKB within the NAc (Ang et al., 2001). NFκB has been implicated in regulating cell survival and neuroplasticity and has been associated with long-term potentiation (LTP) and long-term depression (LTD), responses implicated in learning and memory processes. In terms of reward processing, intra-amygdala infusions of κB decoy DNA impaired fear-potentiated startle responses, suggesting that this molecule may play a role in the intracellular signaling pathway underpinning emotional CS-US learning (Yeh et al., 2002). Preliminary data also indicate that potentiating NFκB signaling within the NAc through overexpression of a constitutively active form of IKK increases place conditioning to cocaine and also increases local dendritic spine formation.

4.12.7.4 Brain-Derived Neurotrophic Factor

Neurotrophic factors facilitate neural growth and differentiation during development and also have a critical role to play in mediating neuronal survival and plasticity in adulthood. BDNF has been identified as an important downstream target of CREB and is implicated in numerous processes related to learning and memory, particularly within the HPC.

BDNF also modulates emotional learning within the amygdala, where increases in BDNF mRNA have been reported following fear conditioning. In addition, overexpression of a mutated dominant negative form of the tyrosine kinase B (TrkB) receptor within the amygdala blocks the acquisition of fear conditioning (Rattiner et al., 2004), indicating that the ability of BDNF to mediate changes in synaptic plasticity could be of particular import in the encoding of emotionally significant events in this region.

4.12.7.4.1 The neurotrophic hypothesis of depression

The neurotrophic hypothesis of depression suggests that a deficiency in neurotrophic support may contribute to the observed hippocampal pathology associated with depression (e.g., reduced hippocampal volume in depressed patients, decreases in dendritic arborization, decreased adult hippocampal neurogenesis), and that antidepressants relieve the symptoms of depression through increasing neurotrophic action. BDNF has been widely studied within the context of this hypothesis. Chronic administration of numerous antidepressant drugs increases expression of BDNF within the HPC despite their diverse pharmacological actions (Nibuya et al., 1995). Both acute and chronic stress decreases BDNF expression in hippocampal regions, effects which may contribute to the etiology of depression and which can be blocked by antidepressant treatment. Direct infusion of BDNF into the hippocampus also produces antidepressant-like effects on the FST and learned helplessness paradigms (Shirayama et al., 2002), while mice lacking BDNF do not show antidepressant behavioral responses (Monteggia et al., 2004, 2007), further indicating that BDNF may be important in mediating depressive symptoms.

Observations that both intra-cerebral infusions of BDNF (Pencea et al., 2001) and chronic administration of antidepressants (Malberg et al., 2000) increase adult neurogenesis has led to the suggestion that this may be one mechanism underlying the therapeutic action of antidepressants. However, a direct, causal relationship between neurogenesis, BDNF, and antidepressant action has proved difficult to demonstrate conclusively. Although X-ray irradiation of the brain blocks cell proliferation and also prevented the chronic effects of antidepressants in a novelty-suppressed feeding assay (Santarelli et al., 2003), irradiation also disrupts numerous intracellular signaling cascades, which may confound interpretation of these findings (Silasi et al., 2004).

Although it is clear that antidepressants can increase CREB and that CREB activity can increase BDNF expression, it is currently unclear as to whether CREB-mediated activation of BDNF is the critical pathway for the antidepressant actions of BDNF. Thus, the increase in BDNF caused by antidepressant administration is blocked in CREB-deficient mice (Conti et al., 2002), yet these mice still respond to antidepressant drugs in tests such as the FST. Although CREB phosphorylation is thought to have pro-survival properties in newly formed hippocampal neurons, the atypical antidepressant tianeptine increases hippocampal neurogenesis but does not activate the cAMP signaling cascade (Czeh et al., 2001). The role of CREB in the antidepressant effects of BDNF clearly merits further study (Malberg and Blendy, 2005).

4.12.7.4.2 BDNF within the VTA-NAc: Reward processing and addiction

In addition to its roles in neuroplastic responses, BDNF is critically involved in the regulation of dopaminergic neurotransmission. Through binding at TrkB receptors on dopaminergic terminals within the NAc, BDNF is capable of potentiating dopamine release in this region. In addition, BDNF acts directly on TrkB receptors expressed by NAc neurons. Hence, it is not surprising that this molecule has been implicated in addiction and reward-related learning. Direct administration of BDNF into the NAc or VTA increases cocaine-induced hyperactivity, whereas BDNF heterozygous knockout mice show reduced locomotor activity and reduced place conditioning to cocaine (Hall et al., 2003). Intra-NAc BDNF also increases responding for CRf (Horger et al., 1999), suggesting that induction of BDNF may contribute to the increases in incentive motivation for drugs that are associated with addiction. In support of this hypothesis, increases in BDNF have been observed in the NAc, BLA, and VTA following withdrawal from cocaine, and these increases appear to track the incubation (potentiation over time) of craving for cocaine as measured by drug-seeking behavior following presentation of a drug-paired CS (Grimm et al., 2003). A direct infusion of BDNF into the VTA can also potentiate such drug-seeking behavior (Lu et al., 2004).

However, despite these increases in incentive motivation for drugs and the potentiation of local dopaminergic transmission, increases in BDNF within the NAc and VTA appear to induce a pro-depressant phenotype. Intra-VTA infusions of BDNF decreased

the latency to immobility in the FST, whereas overexpression of a mutant TrkB receptor within the NAc (which inhibits BDNF signaling) produces an antidepressant-like effect in the same task (Eisch et al., 2003). Recent data using the social defeat model of stress in mice provide further insight into the role of BDNF in affective processing. In this paradigm, an animal is defeated by a larger, dominant, and aggressive mouse and is then housed in close confinement with the aggressor (although the animals can no longer fight). Animals defeated chronically in this way develop a behavioral syndrome characterized by numerous indices of anhedonia which may reflect aspects of human depression, such as decreased preference for natural rewards such as sucrose, sex, and social interaction, as well as a general decrease in locomotor activity. Some of these changes are particularly long-lasting and are reversed by chronic antidepressant treatment (Berton et al., 2006). Knocking out BDNF within the VTA selectively, by use of a viral vector expressing the Cre recombinase, prevents the development of this depressive-like syndrome following social defeat. These data suggest that BDNF within the VTA-NAc pathway plays an important role in reward-related learning, and that overstimulation of this signaling pathway by repeated drug intake or chronic stress could lead to potentiated and maladaptive learning, both to rewarding and aversive stimuli. As with CREB, the effects of BDNF in the HPC versus the VTA-NAc appear to be diametrically opposed. Indeed, the observation that stress decreases BDNF in the HPC, yet increases it in the VTA-NAc, indicates that these areas mediate very different aspects of an animal's behavioral repertoire in response to stress.

4.12.7.5 Glutamate Receptors

In addition to the changes observed in dopaminergic signaling, repeated administration of addictive drugs increases the expression of both alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and *N*-methyl-D-aspartate (NMDA) glutamate receptor (GluR) subunits within the VTA. The GluR1 subunit of the AMPA receptor has received particular attention (Carlezon et al., 2002). Increases in the number of GluR1 subunits present in an AMPA receptor increase its overall conductance as well as its permeability to calcium (Ca^{2+}) ions. Ca^{2+} is involved in numerous intracellular signaling pathways, and changes in levels of intracellular Ca^{2+} can alter the regulation of gene expression. Given that sensitizing regimes of drug administration increase the electrophysiological responsiveness of dopaminergic cells within the VTA to AMPA receptor agonists (Thomas and Malenka, 2003), and that the increase in GluR1 subunits is most prominent in animals showing behavioral signs of sensitization (Churchill et al., 1999), it has been suggested that upregulation of the GluR1 subunit may be one molecular mechanism underlying the potentiated response to chronic drug treatment. In support of this hypothesis, increasing GluR1 expression within the VTA increases both conditioned place preference and hyperlocomotion caused by morphine (Carlezon et al., 1997). Recent evidence indicates that drug-induced upregulation of GluR1 in the VTA may be mediated via drug induction of CREB in this brain region (Olson et al., 2005).

In contrast, increases in GluR1 subunit expression within the NAc-Sh can facilitate the extinction of cocaine-seeking (Sutton et al., 2003), suggesting that increased glutamatergic action within this region can reverse some of the detrimental adaptations caused by chronic drug intake. Chronic cocaine treatment has been shown to reduce the electrophysiological sensitivity of NAc neurons to AMPA agonists (Thomas and Malenka, 2003). This effect may be accounted for by increased levels of GluR2 subunits within the NAc, which decrease the conductance of AMPA receptors and reduce their permeability to Ca^{2+}. Overexpression of ΔFosB increases GluR2 levels within the NAc, while ΔcJun prevents the ability of cocaine to induce the protein (Kelz et al., 1999; Peakman et al., 2003). Moreover, viral-mediated overexpression of GluR2 within the NAc mimics the effects of increased ΔFosB, in that both manipulations enhance place conditioning to cocaine (Kelz et al., 1999). Drug-induced adaptations in several postsynaptic density proteins, which modulate GluR function, have also been observed in the NAc (Yao et al., 2004). It would, therefore, appear that drug-induced changes in the expression of different GluR subunits within different reward-related regions may have opposing actions on cellular excitability, yet may both contribute to the addicted phenotype.

4.12.8 Molecular Changes within the PFC

The majority of work to date has focused on changes in transcriptional regulation within the subcortical regions of reward-related circuitry, with an understandable emphasis on the NAc and VTA. However,

changes in gene expression within the PFC have also been observed in models of addiction and depression, although less is known about their functional consequences (Kalivas, 2004). For example, a recent study examined patterns of cFos expression within the PrLC, NAc, and BLA following reexposure to a cocaine-associated context, as assessed by place conditioning. The authors observed a selective increase in GABAergic cells expressing cFos within the PrLC (Miller and Marshall, 2004). Similarly, a decrease in protein kinase C (PKC) has been observed in this region during retrieval of a discrete CS paired with cocaine during self-administration training (Thomas and Everitt, 2001). These data suggest that output from this region is reduced in response to cue exposure, a finding which may be of relevance to cue-elicited drug craving.

Alterations in G-protein-coupled receptor signaling pathways within the mPFC have recently been identified which may underlie potentiated responding to drug versus natural rewards and relapse to drug-seeking (Kalivas et al., 2005). The activator of G-protein signaling 3 (AGS3) is increased in the mPFC following withdrawal from cocaine self-administration, and reinstatement of cocaine seeking can be blocked by decreasing levels of AGS3. AGS3 sequesters the alpha subunit of inhibitory G proteins ($Gi\alpha$) and reduces signaling through $Gi\alpha$-coupled receptors such as D_2 dopamine receptors. It is thought that this reduction in D_2 receptor signaling leads to increased inhibition of PFC output to the NAc which can only be overcome by relatively strong inputs, such as drug reward. This hypothesis needs further investigation, but potentially provides a molecular mechanism to explain the increased control over goal-directed behavior exerted by drugs of abuse.

Increases in ΔFosB have also been reported in regions of the frontal cortex following chronic exposure to both addictive drugs and stressful manipulations (Perrotti et al., 2004). Recent evidence suggests that increased expression of ΔFosB within this region increases preference for sucrose, potentially indicative of an increased sensitivity to rewarding stimuli. Increased ΔFosB in this region also appears to sensitize animals to the locomotor stimulant actions of cocaine, yet produces tolerance to the disruptive effects of the psychostimulant on operant behavioral measures of motivation and impulsivity. These changes closely parallel those observed after chronic cocaine treatment. Further work aimed at understanding the changes in cognition caused by long-term drug use, and their underlying molecular basis, is clearly warranted.

4.12.9 Beyond Corticolimbic Circuitry: A Role for Hypothalamic Feeding Peptides in Reward-Related Learning?

The hypothalamus is one of the most important regions of the brain in terms of regulating more physiological aspects of reward such as the homeostatic control of hunger and thirst. Animals will preferentially self-stimulate the lateral hypothalamus (LH), a finding partially explained by the fact that dopaminergic fibers from the VTA to the NAc pass through this structure. Intriguingly, the threshold for LH self-stimulation in the perifornical region increases with weight loss, suggesting a relationship between the physiological homeostatic drive for natural rewards and the sensitivity of the brain to rewarding stimuli in general (see Shizgal et al., 2001). Although this region has not been associated with the more cognitive process of mediating goal-directed behavior, modulation of hypothalamic activity forms a critical part of the output pathway of the corticolimbic circuitry discussed earlier. The maintenance of energy balance depends on the allocation of behavior between feeding and competing activities; therefore, the signals of hunger or satiety generated by the hypothalamus have significant impact on the motivation for food reward and, therefore, potentially on numerous models of goal-seeking discussed previously. Whether modulation of this signal is also involved in assessment of the rewarding properties of addictive drugs is currently under investigation. The hypothalamic–pituitary adrenal axis is also one of the most prominent mechanisms by which the brain reacts to stress. Neurons in the paraventricular nucleus of the hypothalamus secrete corticotropin-releasing factor, which stimulates the release of adrenocorticotropin from the anterior pituitary. This in turn leads to production of glucocorticoids (cortisol in humans and corticosterone in rodents) within the adrenal cortex, which can have profound effects on behavior and brain function in numerous regions, as well as affecting general metabolism. Given that stress contributes to the development of affective psychiatric disorders such as depression and can trigger relapse to drug-seeking, a growing number of studies are addressing the role of signaling peptides within this region in reward-related learning and emotional processing. Some examples are considered in the following, though this is by no means an exhaustive list.

Melanin-concentrating hormone (MCH) is an orexigenic (pro-appetite) protein expressed within

the lateral hypothalamus. The MCH_1 receptor is highly expressed within the NAc, and intra-NAc infusions of MCH increase food intake, whereas antagonists of the MCH_1 receptor have the opposite effect. MCH_1 receptor antagonists acting within the NAc also exert antidepressant effects within the FST, an effect which is also observed in MCH knockout mice (Georgescu et al., 2005) and with systemic administration of MCH antagonists (Borowsky et al., 2002). These data suggest that molecules primarily thought to control the regulation of food intake can also have an effect on mood through their influence on NAc function.

Orexin (hypocretin) may have a similar role to play. Expressed within the lateral hypothalamus, orexin increases food intake by promoting a state of wakefulness and arousal, and deficits in orexin are known to cause the sleep disorder narcolepsy (Mignot, 2001). This debilitating condition, characterized by daytime sleepiness, cataplexy, and other sleep abnormalities, is frequently associated with depression, and some of the sleep-related symptoms are treated with antidepressants (Daniels et al., 2001). Narcolepsy and depression are both associated with alterations in circadian rhythms, and a dampening in the naturally occurring diurnal variation in orexin levels has been observed in depressed patients (e.g., Salomon et al., 2003). One mechanism by which hypothalamic peptides may influence reward processing may be via their modulation of the dopaminergic system. For example, orexin neurons project prominently to the dopaminergic cells of the VTA, where orexin binds to orexin 1 (OX_1) receptors to stimulate the neurons. Administration of an OX_1 receptor antagonist blocks the development of locomotor sensitization to cocaine (Borgland et al., 2006), whereas orexin precipitates relapse to drug-seeking in animals withdrawn from cocaine self-administration through induction of a stress-like state (Boutrel et al., 2005). Orexin knockout mice also show reduced physical dependence on morphine as indicated by a reduction in the physical signs of naloxone-precipitated withdrawal symptoms (Georgescu et al., 2003).

Functional interactions between the dopaminergic system and another hypothalamic peptide family, the melanocortins, have been reported and have likewise been implicated in mediating drug reward. Mice lacking the melanocortin-4 (MC_4) receptor, which is highly expressed within the NAc, fail to develop locomotor sensitization, and direct intra-NAc infusions of an MC_4 antagonist peptide, SHU-9119, reduces cocaine self-administration and place conditioning. As with BDNF, this peptide also prevents cocaine from potentiating the response to CRf (Hsu et al., 2005).

Neuropeptide Y (NPY) is perhaps best known for its ability to antagonize the behavioral consequences of stress within the central nervous system (CNS) (see Heilig, 2004). Administration of NPY is anxiolytic in numerous animal models, which is thought to result in part from its actions at Y_1 receptors within the amygdala. Acute stress decreases NPY expression, whereas chronic stress exposure, which leads to behavioral habituation, reverses this effect so that NPY is upregulated. The hypothesis that increased NPY expression could mediate coping responses is supported by the observation that NPY transgenic rats are less sensitive to stressful manipulations (Thorsell et al., 2000). In keeping with the view that stress promotes depression, at least in vulnerable individuals, antidepressant treatments also increase NPY within the frontal cortex, providing another mechanism by which antidepressant drugs may confer their therapeutic benefit. Dysregulation of NPY regulation has also been implicated in drug addiction, particularly in relation to alcoholism, where it is thought to mediate the anxiolytic properties of alcohol, thereby increasing motivation to consume the drug (see Valdez and Koob, 2004).

Whether induction of these hypothalamic feeding peptides is regulated by the same TFs as other proteins implicated in reward and addiction has yet to be determined. However, it is known that NPY is a downstream target of CREB, and whether the behavioral effects of NPY expression likewise vary depending on its locus of action remains a possibility.

4.12.10 Overview

Within this article, we have briefly considered the psychological processes involved in signaling rewarding events, and the roles played by different regions within the corticostriatal loop associated with reward-related learning. Through analysis of the intracellular signaling cascades affected by the dopaminergic system, specific molecules involved in mediating aspects of reward processing have been highlighted, and data pertaining to their influence over reward-related behavior have been discussed. In parallel to much of what is known regarding the neurochemical basis of reward signaling, it is clear that different molecules can have very different effects on behavior depending on their

locus of action. Likewise, the time course of molecular changes, whether transient or long-term, can have a profound influence on their behavioral consequences. The molecular tools have now been developed to directly manipulate intracellular signaling pathways and gene transcription at the level of different transcription factors and their downstream targets within highly circumscribed brain nuclei. As these advances in molecular biological techniques become more accessible, a wider array of behavioral and genetic studies will become possible. Although significant progress has been made in determining the role of such molecular events in reward-related learning, further integration between the fields of psychology and molecular biology will enable greater understanding of the biological basis of goal-directed behavior.

4.13 Conditioned Taste Aversion and Taste Learning: Molecular Mechanisms

K. Rosenblum, Department of Neurobiology and Ethology, Mount Carmel, University of Haifa, Haifa, Israel

4.13.1 Introduction

The sense of taste, together with that of odor, belongs to the family of chemical senses, and it is an important defensive sense, evolved to guide food intake and to aid in avoiding poisons. Moreover, the very existence of an organism is dependent on its ability to maintain intrinsic homeostasis in a continuously changing world. The guarding gate, both for the intake of energy and other metabolites necessary for the organism's survival and for the avoidance of poisonous substrates, is the sense of taste. In order to maintain homeostasis, the organism must recognize its bodily needs, identify the relevant substances that contain the means to satisfy these needs, and ensure that the process of ingestion maintains the balance between the needs and the intake. In addition and in parallel, the organism must avoid substances that will make it sick.

In order to consume the necessary and beneficial substances and to avoid the damaging ones that may cause malaise, the organism mainly uses taste and tags the substances as pleasant, indifferent, or unpleasant. However, the reaction of the organism to a specific substance is determined by a combination of automatic responses that developed during evolution and learning mechanisms that are plastic and can modify the perceived food value according to individual experience. An ethological view may account for the predisposition for different tastes according to the theory that the animals are well adapted to conditions that may occur with high probability and/or have critical survival value.

Learning the value of new tastes may be in line with or in contrast to this evolution-dependent genetic programming. There are just five different taste categories: Sweet, salt, bitter, sour, and the less well known umami (manifested in monosodium glutamate). However, combinations of different concentrations within these five categories and the additional information related to texture and temperature enable the characterization and identification of thousands of different tastes. Animals, including humans, can react to the various tastes by using two main strategies: Genetic programming (like sweet, dislike bitter), and complex learning mechanisms that involve the participation of several forebrain structures.

Taste learning has been found and studied in vertebrates and invertebrates and seems to be universal throughout the animal kingdom. However, most of the research into the biological mechanisms underlying taste learning has involved mice and rats, and the present chapter deals mainly with these studies. A simple sense stimulus such as taste can be very well defined in terms of a number of molecules (e.g., known molarities in a known volume). However,

even simple unimodal taste input includes not only the chemical properties of a substance, but also other physical dimensions, such as temperature and texture, and association with other cues and modalities.

This chapter does not address taste recognition on the receptor level, nor taste reactivity as it is defined genetically. The aim of this chapter is first to describe taste behavior in the context of laboratory attempts to identify molecular and cellular mechanisms of learning and memory, to present the various learning paradigms used in the laboratory, and the relevant neuroanatomy. Later, I will review and discuss in detail the molecular and cellular mechanisms of taste learning in the gustatory cortex, which reside in the insular cortex. I focus this chapter on recent publications, because the earlier development of the subject is covered in a seminal book by Jan Bures, Federico Bermudez-Rattoni, and Takashi Yamamoto (Bures et al., 1998). Finally, I present the current working model of taste memory formation, consolidation, and retention and suggest future research directions.

4.13.2 Measuring Taste Learning, Memory, and Consolidation: The Behavioral Paradigms

Learning is conventionally classified from the behavioral point of view into nonassociative (habituation and sensitization), associative (relationships between amounts and events), and incidental learning (learning in the absence of an explicit external reinforcer). In addition, memory can be classified according to the temporal phases of short- and long-term memories. The use of several different behavioral paradigms enables the different classification and temporal phases to be analyzed. Taste learning and conditioned taste aversion are considered to be implicit learning paradigms and they can result in short-term memory (hours) or lifelong memory (Bures et al., 1998; Houpt and Berlin, 1999). In animals, as in humans, a subject can prefer one taste over another without recognizing either (Adolphs et al., 2005).

The most familiar taste-learning paradigm is an association between taste and malaise: The process of conditioned taste aversion (CTA). In CTA learning, an animal learns to avoid a novel food associated with delayed poisoning (Garcia et al., 1955; Bures et al., 1988). CTA can be explained as an associative learning paradigm: The novel taste is the conditioned stimulus (CS), the malaise-inducing agent is the unconditioned stimulus (UCS), and the learned avoidance of the taste is the conditioned response (CR). However, it was clear from the first time that CTA was reported scientifically (Garcia et al., 1955) that CTA has very special and unique features.

The most prominent characteristic of CTA learning is the long delay between the novel food that serves as the CS and the toxic substance that serves as the UCS. This time frame of association is measured in hours (1–12 h) (Bures et al., 1998), which is in strong contrast to other forms of association, which tolerate time frames of a few seconds. The long delay between the CS and the UCS can be explained on the sensory level or in terms of the slow release of a substance from the stomach. Moreover, short time frames or backward conditioning do not yield good association and learning (Schafe et al., 1995). Thus, the long delay between the CS and the UCS in CTA should be explained in terms of the neuronal system subserving the CTA learning. Theoretically, the internal representation of the novel taste is kept in an on-hold position for many hours, ready for the UCS to produce the association. It is not clear how the internal representation of taste is stored, but it is hypothesized that it underlies ongoing activity that is dependent in part on the gustatory cortex (Katz et al., 2002; Bahar et al., 2003; Berman et al., 2003). CTA has other special features such as one-trial learning that produces strong and stable long-term memory; it can produce aversion to odor by odor potentiation taste aversion (Schneider and Pinnow, 1994), and, in contrast to the strong association between taste and malaise, there is no or very weak association between other sensory stimuli (e.g., sound, light) and malaise or discomfort. Similarly, there is hardly any association between taste and noninternal stresses, such as pain.

CTA can be affected if the CS is experienced either before the CTA, i.e., latent inhibition of CTA (LI-CTA), or after it, i.e., CTA extinction, as can other learning paradigms, but with specific characteristics for taste learning. In LI-CTA, if a taste stimulus was learned with no negative consequence there will be decreased aversion for the same taste following CTA (Rosenblum et al., 1993). This modulation in behavior can be attributed either to reduced strength of the association at the time of the CTA or to competition during the retrieval phase (Lubow, 1989). LI-CTA can be used successfully in a method

to study incidental taste learning, i.e., learning with no external reinforcer or association. One exposure to the novel taste has a significant effect on reducing the aversion elicited by CTA. However, a critical parameter is the amount of the novel taste consumed at the preexposure (Belelovsky et al., 2005), e.g., consuming 5 ml or less of a novel taste will produce no significant latent inhibition (LI) in rats (Belelovsky et al., 2005).

Experiencing a given taste after its association with malaise will reduce the aversion responses, i.e., the experience will cause an extinction of the learned CTA. The extinction of the association is dependent on the strength of the association, the number of extinction trials, and the amount of novel taste consumed during the session (Dudai, 2006). Extinction can be viewed as imparting an evolutionary advantage when the food supply is restricted and there is a constant need to test the negative or positive effects of a given food.

Two other behavioral phenomena that are important with respect to taste learning are attenuation of neophobia and taste interference. Neophobia to food, as to other stimuli, is manifested in the careful consumption of a novel food/taste. If a few exposures to the novel taste lead to no gastric consequences, consumption of the given food will increase and thus will reduce the primary neophobic response. In a similar way to extinction, attenuation of neophobia will mark a given taste as safe and will increase its consumption in response to other needs of the animal.

An interaction between different familiar and unfamiliar tastes can lead to overshadowing or blocking. However, in interference one taste can interfere with the learning of another taste (Merhav et al., 2006). Specifically, it was shown that when two novel tastes are given before an associated malaise, only the second taste will acquire the association (Best and Meachum, 1986), Moreover, by using the latent inhibition paradigm, it was shown that consumption of a novel taste after another taste will eliminate completely the effect of the first taste (Merhav et al., 2006). This interference was inversely correlated with the time between the two tastes, and could be established only if the second taste was novel but not if it was familiar.

The above behavioral paradigms were established mainly with rats and mice. In all methods, mild water restriction is needed to stimulate the animals to consume the taste in a specific time. However, harsh water deprivation can modulate the behavior, and the behavioral method itself determines the biological mechanisms underlying taste learning (Berkowitz et al., 1988; Bernstein et al., 1996a,b; El-Gabalawy et al., 1997; Koh et al., 2003; Wilkins and Bernstein, 2006). The following are the main methods used in these experiments.

1. Single pipette: Animals are presented with single pipette with a given taste. The amount of intake can be compared with the amount of water consumed on the previous day, following one of the behavioral manipulations described.
2. Multiple pipettes: A main problem with the single bottle setup is conflict between the animal's urges to drink, because it is water-deprived, and not to drink, because it underwent CTA. The most common behavioral test is to allow the animals to choose, during the retention phase, from a series of pipettes containing water or the taste that is under investigation. Usually, an aversion index is calculated (water/water + studied taste). The more aversive the animal is to the conditioned taste, the higher the aversion index will be.
3. Taste reactivity test: The amount of drinking measured in session with one or multiple pipettes does not necessarily mirror the attractiveness of a given taste. This can be measured directly according to several characteristic responses to palatable or unpalatable tastes, in a taste reactivity test (Grill and Norgren, 1978), or via the licking behavior (Halpern and Tapper, 1971).
4. Learning without ingestion: In some behavioral studies, it is possible or necessary, sometimes because of limitations of the experimental setup, e.g., when studying electrophysiology in the anesthetized animal, to test taste learning without ingestion or consumption of the novel food. In such cases, the test is performed by intraoral infusion of the food/taste onto the tongue to elicit the response of the taste buds. CTA and other taste learning can be acquired through this passive experience. However, it seems that learning with or without ingestion could involve different learning mechanisms (Bernstein et al., 1996a).

4.13.3 Neuroanatomy of Taste and Conditioned Taste Aversion Learning

The sensation of taste involves, similarly in principle to the other senses, chemical recognition but, in addition, the physical features are always associated with hedonic aspects of the sensory input. Indeed, functional analysis of the taste neuroanatomic

pathway reveals a strong association with the reward and feeding centers in the brain, including the ventral tegmental area (VTA), the nucleus accumbens (NAcb), the ventral palladium (VP), and the lateral hypothalamus (LH). The central gustatory pathway has been studied extensively in humans, monkeys, and rodents. **Figure 1** shows a schematic depiction of the rat's main taste pathway. Following activation of the taste buds, three cranial nerves (VII, IX, X) convey the taste input to the rostral part of the nucleus of the solitary tract (NTS), the first relay nucleus. In addition, the NTS receives input both from the area postrema (AP), which is sensitive to blood-transported toxins, and from the vestibular system, which is sensitive to nausea caused by motion. Lesioning this part of the NTS induces severe impairment of taste preference, but CTA can be still learned (Shimura et al., 1997). Taste information is that transduced from the NTS to the parabrachial nucleus (PBN) in the pons. The main taste-responsive neurons in the NTS project to medial subnuclei of the PBN, and the PBN projects both to the parvocellular part of the ventralis postmedial thalamic nucleus (VPMpc) and to other forebrain structures, including the amygdala, the lateral hypothalamus, the substati innominata, and the bed nucleus of the stria terminalis.

Yamamoto et al. (1995) studied the effects of lesions to various forebrain structures including the PBN, the hippocampus, the VPMpc, the gustatory

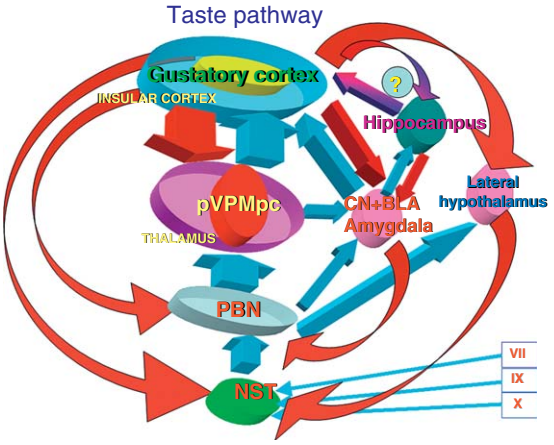

Figure 1 The neuroanatomy of the taste system. The processing of gustatory information begins with transduction of chemical stimuli which reach the oral cavity. Taste can be divided among five primary sensations: salty, sour, sweet, bitter, and umami. Typically, taste cells are broadly tuned and respond to several taste stimuli. The sensitivity to taste quality is not uniformly distributed throughout the oral cavity, and the same chemotopic arrangement is preserved to some degree at the gustatory relay. CN, central nucleus; BLA, basolateral amygdala.

Taste cells are innervated by cranial nerves VII, IX, X, which project to the primary gustatory nucleus in the brainstem (nucleus of solitary tract, NST). The NST sends information to three different systems:

1. The reflex system. This comprises medullary and reticular formation neurons which innervate the cranial motor nuclei (trigeminal, facial, hypoglossal).
2. The lemniscal system. The gustatory portion of the NST projects to the secondary nucleus situated in the dorsal pons (parabrachial nucleus, PBN). The PBN sends axons to the parvocellular part of the ventralis postmedial thalamic nucleus of the thalamus (VPMpc), which, in turn, relays gustatory information to the anterior part of the insular cortex (gustatory cortex, GC). The transition from the somatosensory lingual representation to the gustatory representation corresponds to the transition from the granular to the agranular insular cortex. The GC is thus situated dorsally to the intersection of middle cerebral artery and the rhinal sulcus and can be identified easily using these two markers. Although rodents have only a primary taste cortex, humans also have a second one.
3. The visceral-limbic system. The central gustatory pathway involves a collateral network of connections to the hypothalamus and limbic areas in the forebrain. The PBN is connected to the amygdala, the hypothalamus, and the bed-nucleus of the stria terminalis. All the limbic gustatory targets are interconnected with each other as well as with the PBN and the gustatory cortex. The GC and the thalamocortical system are required for acquisition and retention of taste information. The amygdala is required for learning the negative and possibly positive values of a taste. The prefrontal cortex is involved in CTA extinction. It is not clear what is the specific role of the hippocampus in taste learning, though it is hypothesized that it takes part in novel taste learning.

and enthorinal cortices, the amygdala, and the lateral and ventromedial hypothalamic nuclei, and reported that lesions to the PBN impaired both acquisition and retention of CTA. Other studies suggested that basic integration between taste and visceral inputs indeed took place at the level of the PBN.

The PBN projects to the VPMpc (Hamilton and Norgren, 1984), and from the relay station in the thalamus the taste information is transuded to the gustatory cortex (GC), which resides within the anterior portion of the insular cortex. Small lesions to the VPMpc did not affect CTA learning nor retrieval (Reilly and Pritchard, 1996), but a combination of lesions to the VPMpc and the GC eliminated CTA learning (Yamamoto, 1995).

Humans and monkeys have an additional, secondary area of taste, and it has been suggested that subdivisions within the insular cortex might serve as a secondary taste area in the rat brain. Similarly to the way the subcortical areas convert taste information, as described, the insular cortex also processes both taste information (in its anterior part) and visceral information (caudodorsally to the GC).

The first indication of the role of the GC in processing taste information was provided by Braun et al. (1972). Later, many experimental techniques, based on lesions, electrophysiology, imaging, correlative biochemistry, pharmacology, and, recently, direct imaging studies, were proven to be useful in analyzing the role of the GC in taste learning. It is clear that the GC plays a pivotal role in CTA acquisition and retention. Reversible inactivation of the amygdala and the insular cortex by microinjection of tetrodotoxin (TTX) to these two brain structures at different intervals before taste learning suggested that the insular cortex is pivotal for taste learning, whereas the amygdala is crucial for CTA formation (Gallo et al., 1992). The insular cortex and its gustatory portion can be anatomically divided into granular (normal neocortex), dysgranular, and agranular cortices (i.e., the gradual disappearance of the fourth layer). In rodents, most of the neurons that are responsive to taste stimuli reside within the dysgranular insular cortex. However, the input from the VPMpc terminates in both the granular and the dysgranular insular cortices. A topographical spatial organization of the GC in relation to the various taste stimuli was suggested recently by means of direct imaging of the GC *in vivo* (Accolla et al., 2007).

The experience of taste has other dimensions than the chemical input itself, including temperature and structure. These dimensions were hypothesized to be processed by the adjacent cortex, but also by the granular insular cortex itself (Simon et al., 2006).

The hippocampus, a forebrain structure known to be involved in many forms of learning, has been investigated also in relation to its role in taste learning. The role of the hippocampus in CTA is controversial; however, its involvement in neophobic responses to taste has been reported in several experiments. A temporal correlative response was found in the hippocampus and the GC. However, different molecular pathways were activated in the hippocampus and in the insular cortex (Yefet et al., 2006).

4.13.4 Long-Term Potentiation in the Insular Cortex

Long-term potentiation (LTP) is an attractive model for learning and memory: Activity-dependent, sustained increases in synaptic efficacy have been suggested to be the cellular manifestation of the learning process (Bliss and Collingridge, 1993; *See* Chapter 4.16). LTP was first described in the hippocampus but has been investigated in other brain structures, including the cortex; recently it was studied in the pathway from the basolateral amygdala to the insular cortex (Escobar et al., 1998) and in correlation with taste learning. High-frequency stimulation to the basolateral amygdala induced *N*-methyl-D-aspartate (NMDA)-dependent but metabotropic glutamate receptor (mGluR)-independent LTP in the insular cortex (Escobar et al., 1998, 2002). A pharmacological administration of the neurotrophin brain-derived neurotrophic factor (BDNF) locally to the insular cortex induced LTP that inclined slowly in a similar way to BDNF-induced LTP in the hippocampus (Escobar et al., 2003). Analysis of the molecular mechanisms of basolateral amygdala-insular cortex (IC) LTP identified correlative induction of extracellular signal-regulated protein kinase (ERK) activation and muscarine-dependent induction of several immediate early genes, including Zif268, Fos, Arc, and Homer (Jones et al., 1999). In a similar way to novel taste learning and to LTP in other brain structures, ERK was both correlative and necessary for LTP expression in the IC (Jones et al., 1999). It is clear from other studies that LTP and taste learning share molecular mechanisms in the IC. However, very little is known about the hypothesized possibility that LTP-like mechanisms in the IC subserve taste learning. A study that examined the possible interaction

between the two found that LTP in the insular cortex enhanced CTA retention (Escobar and Bermudez Rattoni, 2000). However, much more investigation is needed to achieve better identification of the relevant circuit within the IC, and to prove that LTP-like processes underlie taste learning in the GC.

4.13.5 Processing of Taste in the Gustatory Cortex

Neuronal responses in the GC are driven by somatosensory and chemosensory inputs received from the oral cavity (Yamamoto et al., 1989; Ogawa et al., 1992a,b). Neurons in the GC are responsive to both the quality of a given taste, i.e., chemical identification, and its hedonic value, i.e., attractive, palatable, or repulsive (Yamamoto et al., 1989), and it is difficult to dissociate the two from one another. This may represent a unique feature of the taste sensory information, whereby a given stimulus is always tagged as pleasant, indifferent, or repulsive, i.e., this value represents one of the dimensions of gustatory processing, including the chemical and physical dimensions. Relatively very few cells (<10%) are responsive to a specific taste (Yasoshima and Yamamoto, 1998; Bahar et al., 2003), and most of the others are broadly tuned. Recently, however, direct imaging of the insular cortex was used to reveal some spatial distribution of the various taste stimuli within the GC (Accolla et al., 2007). An interesting correlation between neuronal activity in the GC and novel taste input is that the increased response to a novel taste was not detected until 1 day following learning (Bahar et al., 2003). Currently, there are no good models of taste coding in the taste system. The two main models of taste coding in the neuronal system are labeled line and cross-fiber patterns. Both models are static and noninteractive and are insufficient to describe taste learning (Katz et al., 2002). Another hypothesis is that the anatomical divisions of the insular cortex, i.e., granular, dysgranular, and agranular, serve as primary, secondary, and tertiary sensory cortices, respectively.

A recent review on the subject suggested that the gustatory pathways, including the GC, use distributed, ensemble codes of the various dimension of taste stimuli, i.e., chemical, thermal, and tactile, to produce an internal representation of a given taste (Simon et al., 2006). Other reviews summarized a vast amount of seminal research on taste, olfactory, food texture, and control of food intake (Rolls, 2004, 2006), but that research is not within the scope of the current chapter and mainly addressed monkeys.

4.13.6 Molecular Mechanisms of Taste Learning in the Taste Cortex

The previous sections introduced the behavioral, neuroanatomical, and cellular levels of analysis. The sections below discuss aspects of molecular mechanisms that subserve taste learning in the taste cortex, within the frameworks of the behavior and the neuroanatomy, in more detail. The working hypothesis underlying the research in the field is that during learning, physical or chemical information about the world is depicted in part by the organism's sensory system, i.e., in the present case, the taste system. This information is transformed into neuronal activity that uses neurotransmitters to create an internal representation of the received sensory information in the central nervous system (CNS). This neuronal creation or modification of an internal representation, i.e., sensory learning, comprises several different temporal phases: Acquisition, which immediately follows experiencing the sensory input, the imprinting of the internal representation in the CNS, a consolidation phase that is divided into two major processes: molecular consolidation, which is dependent on functional protein synthesis in the relevant brain area and is limited to several hours following learning; and system consolidation, which involves the transfer of information between brain areas and which has a temporal domain ranging from many days to months. The consolidation phase is defined in negative terms; it is the time window during which the memory trace is still fragile and can be disrupted by various interventions: behavioral (e.g., Merahv et al., 2006), pharmacological (Rosenblum et al., 1993), or others (Bures et al., 1998). In addition, it is highly likely that the consolidation phase contains subdivisions. For a given internal representation, the last phase is retrieval. However, any retrieval may have the dimension of relearning, as discussed in detail elsewhere (*See* Chapters 1.05, 2.16).

Taste learning and CTA are highly suitable learning paradigms for studying the molecular mechanisms of learning and memory. Their relevant features include one-trial learning; strong incidental learning; clear and short learning time; minimal behavioral manipulation, since the animals can learn in their home cage with very little interference from

other modalities; clear definition of the sensory input, which can be quantified in molecular terms; and clearly defined cortical area(s) subserving the learning. Within the framework of the present chapter, we will specifically discuss molecular mechanisms taking place in the GC which underlie the various phases of taste learning. It is important to note that two basic means of acquiring information are studies of the correlations between taste behavior and molecular modifications/processes and causality experiments, which show that a given biochemical pathway is necessary for a given phase in taste learning. In addition, it is highly likely that one signal transduction cascade can operate in one brain area and not another. For example, protein kinase B (PKB)/Akt phosphorylation is correlated with taste learning in the hippocampus but not in the GC (Yefet et al., 2006); also, ERK is activated in the GC but not in the hippocampus after the same length of time after learning (Yefet et al., 2006). These examples suggest that from the neuroanatomical point of view, positive correlation between molecular changes and learning is informative, whereas negative correlation can teach us very little. A summary of recent molecular observation related to taste learning and mainly to the taste cortex is presented in the following sections.

4.13.7 The Neurotransmitters in the Gustatory Cortex Involved in Taste Learning

Information on the physical and chemical properties of a given taste and also on its prominence reaches the GC via different neurotransmitters. Several different neurotransmitter systems are released in the GC, and the relevant receptors for these neurotransmitters are expressed in the GC. These include acetylcholine (ACh), dopamine, noradrenaline, gamma-aminobutyric acid (GABA), glutamate, and various neuropeptides. However, only the muscarinic and NMDA receptors have been studied extensively for their role in taste memory acquisition, consolidation, and retention. I will, therefore, focus mainly on these two neurotransmitter systems and their possible role in taste memory formation. The physical and chemical taste information is transferred from the oral cavity to the cortex via fast neurotransmission mediated by the neurotransmitter glutamate. This is consistent with other known modalities (*See* Chapter 4.30). Glutamate is the main excitatory neurotransmitter in the mammalian CNS, and it acts via both ionotropic and metabotropic effects. However, the prominence of a given taste is hypothesized to be mediated via activation of the neuromodulatory system (e.g., Kaphzan et al., 2006). It is thus conceivable that the interaction between the two systems produces a long-term taste memory trace and that it coincides on specific neurons and probably molecules that can serve as coincidence detectors of the sensory input and its meaning (Kaphzan et al., 2006). Glutamate can affect four types of receptors – alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), NMDA, kainate, and mGluRs – that can produce complex fast (ion influx) and slow (second messenger) changes in the neuron. These receptors are structurally and functionally multifaceted molecules (*See* Chapter 4.30). Microdialysis studies of the amygdala and the IC demonstrated enhanced glutamate release in both the amygdala and the IC, following induction of malaise (Miranda et al., 2002).

Application of the AMPA/kainate antagonist, NBQX, specifically to the insular cortex impaired both acquisition and retrieval of taste memory, which suggests that, in agreement with the general understanding, the AMPA receptor plays a major role in mediating the physical properties of the taste (Berman et al., 2000) and that normal activity of the AMPA receptor is needed to mediate taste properties in either learning or recognition. In contrast to the effects on the AMPA receptor antagonist, microinjection of the NMDA antagonist aminophosphonovaleric (APV) into the GC induced severe impairment of CTA and taste memory acquisition, but not of retrieval (Rosenblum et al., 1997; Berman et al., 2000). Thus, taste learning and CTA are dependent on the NMDA receptor in the insular cortex similarly to many other learning paradigms. Moreover, LTP in the insular cortex is NMDA-dependent, which suggests that similar molecular mechanisms subserve learning and LTP (Jones et al., 1999).

Application of the NMDA antagonist specifically to the insular cortex blocked taste memory formation and reduced the correlative activation of ERK (Rosenblum et al., 1997; Berman et al., 2000). It did not, however, reduce the basal level of ERK phosphorylation (Berman et al., 2000) as it did in hippocampal slices (Kaphzan et al., 2006). In addition, the NMDA antagonist, APV, did not affect the correlative increase in tyrosine phosphorylation of the NMDA receptor, suggesting that this increased phosphorylation is

dependent on neuromodulatory neurotransmitters, most probably ACh (Rosenblum et al., 1997). Interestingly, APV microinjection to the insular cortex impaired long-term memory but did not affect short-term memory (Ferreira et al., 2002). These results are in contrast to the dogma that the NMDA receptor is crucial for memory formation but not for its consolidation, and may hint at the existence of unique molecular mechanisms that subserve the CS in the CTA case and that remain active for many hours.

Posttranslation modification and, especially, phosphorylation of the glutamate receptors, was hypothesized to play a major role in learning and LTP induction (*See* Chapter 4.30). The dogma suggests that changes in the steady state of the phosphorylation site of a specific receptor, e.g., the AMPA receptor, caused by modulation of the activity of kinases or phosphatases, alter the function of the receptor so as to increase or decrease synapse efficacy and thus to imprint a new cellular structure in the brain, which is manifested in the formation of an internal representation. However, on the assumption that the kinase/phosphatase modulation of activity is reversible, the memory of such a change is limited to the time span of the receptor that underwent phosphorylation. Different proteins are known to have different half-lives but, in any case, this cannot account for structural stability lasting more than a few days. In addition, the very rapid turnover of the receptors between different subcellular compartments shortens the time during which the receptor is expressed in the brain. Phosphorylation occurs on serine, threonine and, to a much smaller extent, tyrosine residues. However, tyrosine phosphorylation events have been found to be crucial in many cellular functions (Huang and Reichardt, 2003).

In the forebrain of mature animals, the NMDA receptor is composed of the NR1 subunits and a combination of NR2A and B subunits (*See* Chapter 4.20). The main tyrosine phosphorylated protein in the synapse is the 2B subunit of the NMDA receptor (Moon et al., 1994). However, it is clear that the 2A subunit is phosphorylated on tyrosine also, and in response to physiological inputs (Thornton et al., 2003). Tyrosine phosphorylation of both subunits induces modulation in the receptor function (Kalia et al., 2004), and it can be measured for a specific residue of a given protein, e.g., 1472 of the NR2B subunit, or as total tyrosine phosphorylation of a given protein after immunoprecipitation, or of a population of proteins. This measurement can be taken using antiphosphotyrosine antibodies for a population of proteins. Measuring tyrosine phosphorylation using general antiphosphotyrosine revealed that, compared with other tissues, the brain is highly phosphorylated on tyrosine residues in the absence of stimulation. In addition, following CTA or novel taste learning, tyrosine phosphorylation of a set of proteins was increased, but a familiar taste did not induce this correlative effect (Rosenblum et al., 1995). Following taste learning, the main molecular weights to be modulated in the insular cortex were 100, 115, and 180 kDa. At the same time, other proteins were unaffected by learning (Rosenblum et al., 1995). With regard to the findings of many other studies that identified correlations between posttranslation modifications and learning, the following questions can be raised in attempting to understand mechanistically the role of tyrosine phosphorylation in the GC during the formation of the internal representation of a taste:

- What is the identity of the tyrosine-phosphorylated proteins?
- What is the identity of the specific residue that is phosphorylated in a given protein?
- Is this phosphorylation event a mere correlation or a necessary step in memory formation?
- Can similar modifications be found in other learning paradigms or learning models?
- What is the time window and what is the physiological function of such phosphorylation?
- What are the upstream events that induce this phosphorylation in correlation with learning, and which neurotransmitters induce the modifications?
- What, and in which cortical layer, are the cells that are involved in these modifications? What is the localization, i.e., subcellular compartment, of such modification within the cells?

There are answers to some of these questions, whereas others are still subjects of ongoing research. It is clear that the NR2B is tyrosine phosphorylated in correlation with taste learning in the taste cortex (Rosenblum et al., 1997); a similar increase in NR2B tyrosine phosphorylation was detected in the hippocampus following LTP (Rosenblum et al., 1996; Rostas et al., 1996). As for the specific residue, the main tyrosine to be phosphorylated in the sequence of the NR2B is residue 1472. Indeed, a clear increase in pY1472 was correlated with taste learning in the GC. A recent study of genetic replacement of pY1472 in the mouse forebrain identified malfunction in amygdala-dependent learning, and suggested

that the localization of the NR was defective in these transgenic mice (Nakazawa et al., 2006). In any case, mapping of the phosphorylation sites specifically on the NR and generally in synaptic proteins, which might explain synaptic plasticity, is currently the subject of proteomic investigation (Schrattenholz and Soskic, 2006).

In order to test the hypothesis that induced tyrosine phosphorylation is necessary for taste learning, the general tyrosine kinase inhibitor, genistein, was injected locally into the GC during taste learning; it inhibited the induced tyrosine phosphorylation of the NR2B and attenuated taste learning, which suggests that tyrosine phosphorylation during learning is crucial for memory formation.

What might be the identity of the neurotransmitter that induces tyrosine phosphorylation of the NR2B? Surprisingly, local blocking of the NMDA receptor itself by microinjection of APV into the GC blocked taste learning but did not affect the induced level of its tyrosine phosphorylation correlated with learning (Rosenblum et al., 1997). Thus, it seems that the process is not Ca^{2+} dependent and is involved in cross-talking with other receptors. Indeed, pharmacological activation of the muscarinic ACh receptor (AChR) in the GC induced tyrosine phosphorylation of the NR2B (Rosenlum et al., 1996). This cross talk between the two receptors may partly account for the important role played by muscarinic AChRs in novel taste learning. An interesting point is that the time window of increased tyrosine phosphorylation correlated with taste learning. The induction was still clear several hours following learning, in clear contrast to the behavior of other phosphorylation events that can be monitored only within minutes following learning. It is therefore suggested that the synaptic tyrosine phosphorylation represents an intermediate phase of molecular mechanisms and that it is not involved in the acquisition phase but rather in the consolidation phase. Another possibility is that this prolonged increase in tyrosine phosphorylation following learning is unique to taste learning and plays a role in the ability of the taste to be on hold, ready for association with malaise.

The involvement of muscarinic AChRs in taste and CTA learning was studied mainly through the administration of antagonists during the various phases of taste learning, followed by microdialysis measurements of ACh in the GC. Indeed, local application of atropine or scopolamine to the GC disrupted both taste learning and CTA (Naor and Dudai, 1996; Gutierrez et al., 2003; Berman et al., 2000). It was suggested that microinjection of scopolamine but not APV to the insular cortex attenuates the acquisition of familiarity of a novel taste (Gutierrez et al., 2003), though APV clearly affected latent inhibition of CTA (Rosenblum et al., 1997). Another study suggested that APV treatment impaired only long-term but not short-term taste memory (Ferreria et al., 2002). In a similar way to the prolonged duration of NR2B tyrosine phosphorylation, this result implies that the NR is more involved in the consolidation than in the acquisition processes. Microdialysis experiments have shown that ACh is released in the GC following consumption of novel but not of familiar tastes (Shimura et al., 1995; Miranda et al., 2000) in a similar way to other modalities. It is yet to be determined whether the prolonged endogenous release of ACh is the physiological reason for tyrosine phosphorylation of the NR; what is the exact function of such interaction? Other biochemical interactions between these two receptors may occur and await further analysis.

The glutamatergic and cholinergic systems were studied in detailed in the GC following novel taste aversion. Fascinatingly, the correlated expression of different immediate early genes in the GC that followed LTP induction was dependent both on NMDA and muscarinic AChR activation. However, the involvement of other neurotransmitters is well documented. Local microinjection of antagonists for the $GABA_AR$, dopamine (D1, 5), mGluR, and β-adrenergic neurotransmitters into the GC impaired both novel taste learning and CTA acquisition. However, only application of the AMPA/kainate antagonist and the $GABA_AR$ impaired CTA retrieval (Berman et al., 2000). A recent report suggests that metabotropic GABA receptors are differentially involved in CTA learning. The $GABA_{B(1a)}$ receptor was found necessary for CTA learning, whereas the $GABA_{B(1b)}$ receptor was involved in extinction of CTA (Jacobson et al., 2006), but the brain locus involved in these manipulations could not be identified. Various pharmacological tools have been used to assay the correlative induction of ERK with taste learning. It was found that antagonists for AMPA/kainate, dopamine (D1, 5), mGluR, and agonist of the $GABA_AR$ reduced the basal level of ERK activation, whereas $GABA_AR$ antagonist induced the levels of ERK activation in the GC (Berman et al., 2000). However, antagonists of the muscarinic AChR, NMDAR, AMPA/kainate, dopamine (D1, 5), and mGluR inhibited the induced expression of ERK with learning (Berman et al., 2000). It is clear from these experiments

that cortical excitation is positively correlated with ERK activation and that antagonizing the muscarinic and the NMDA receptors is correlative with both taste and CTA learning, and with the correlative induction of ERK.

4.13.8 The Role of the MAPK/ERK Pathway in the Gustatory Cortex

ERK1 and ERK2 belong to the mitogen-activated protein kinase (MAPK) family of signal cascades. ERK is activated in and is necessary for the development of several forms of memory, such as fear conditioning, CTA memory, spatial memory, step-down inhibitory avoidance, and object recognition memory (*See* Chapter 4.25). Inhibition of MAP/ERK (MEK), the upstream kinase of ERK, affected both early and late phases of LTP in the hippocampus (Rosenblum et al., 2002). The role of ERK activation in the GC was first studied by means of radioactive kinase assays and, indeed, increased ERK activity was found in the GC, in correlation with novel taste learning. Later, most of the experiments in the field used phospho-specific antibodies that recognized the phosphorylated state of ERK as well as the activated state of these proteins in this unique case (*See* Chapter 4.25).

ERK activation was correlated with novel taste learning, whereas the actual amount of ERK protein was unchanged (Berman et al., 1998; Belelovsky et al., 2005). The time scale of the induced activation was a few minutes following consumption of a novel taste, and it could not be detected after more than 1 h. Microinjection of the MEK inhibitor into the GC prior to learning attenuated CTA memory; examination of other members of the MAPK family revealed that Jun N-terminal kinase 1/2 (JuNK1/2) was activated 1 h following novel taste learning, whereas p38 was not modified at any of the examined time points (Berman et al., 1998). A similar study in mice identified different temporal activation of ERK following novel taste learning (Swank and Sweatt, 2000). Further examination of the phosphorylation of the ERK substrate ELK-1 found a similar time scale for the relation between ERK activation and ELK-1 phosphorylation following novel taste learning as well as similarity in the neurotransmitters that induce ELK-1 phosphorylation in the GC in response to taste learning (Berman et al., 2003). Interestingly, the expression of LTP in the GC was found to be ERK dependent, and ERK was activated in correlation with LTP induction in the GC (Jones et al., 1999).

Similarly to other brain areas, ERK activation is correlated with learning, and possibly mainly with the consolidation phase of learning. Moreover, as discussed, the upstream mechanisms for ERK activation have been studied extensively in the GC and elsewhere. However, we know very little about the downstream targets of ERK or about the mechanisms in neurons that affect learning and synaptic plasticity. Much more proteomic research is needed to identify ERK substrates and to understand the effects of ERK on various neuronal processes, including trafficking, membrane properties, and nuclear targeting. One major role attributed to the ERK pathway is regulation of gene expression and, recently, translation regulation (Govindarajan et al., 2006).

4.13.9 The Role of Translation Regulation in Taste Memory Consolidation

Memory consolidation is defined biochemically by its dependence on functional protein synthesis within the relevant brain structures (Davis and Squire, 1984). Indeed, local application of the protein synthesis inhibitor anisomycin to the GC attenuated CTA and taste learning, as measured in the latent inhibition paradigm (Rosenblum et al., 1993). However, another study found that the same treatment had no effect on short-term memory, which suggests that short-term taste memory is independent of protein synthesis (Houpt and Berlin, 1999). Local application of anisomycin had a dose-dependent effect on CTA learning: Whereas 50- and 75-μg doses had no effect, 100- and 150-μg doses abolished CTA. This study (Rosenblum et al., 1993) is one of very few that measured the effect of anisomycin on protein synthesis *in vivo*. Local application of anisomycin inhibited more then 90% of protein synthesis in the GC for hours, but not in the hippocampus. Application of the same amount of anisomycin to the lateral ventricles did not affect either taste learning or CTA, and had a weaker and much faster effect on protein synthesis in the GC (Rosenblum et al., 1993; Meiri and Rosenblum, 1998). Usually, in order to achieve an effect on memory and LTP consolidation, one should apply the protein synthesis inhibitor(s) just before or immediately after learning, though some studies have suggested the existence of two or more sensitive periods for application of protein synthesis inhibitors. A recent study determined the temporal phase of sensitivity for

protein synthesis inhibitors, and found that up to 100 min following novel taste learning, local application of anisomycin attenuated taste learning, which suggests that the short period after learning, i.e., the beginning of consolidation, is not the only sensitive period, but so, also, is a more advanced phase of consolidation.

As discussed, sensitivity for protein synthesis is a negative definition of memory consolidation. One may assume that following learning there is increased expression of proteins in the relevant brain areas (*See* Chapters 4.22, 4.33), but it was only recently that scientists began to explore directly the possibility that the translation machinery is regulated during memory consolidation (Govindarajan et al., 2006). Translation comprises initiation, elongation, and termination phases. The initiation phase is the most highly regulated step and it is modulated via phosphorylation of initiation factors and ribosomal proteins (Proud, 2000). Analysis of taste learning in mice that lacked the translation repressor eukaryotic initiation factor 4E-binding protein (4E-BP2) revealed no difference in taste recognition but enhanced CTA learning (Banko et al., 2007). Similarly, mice with reduced phosphorylation of eukaryotic initiation factor 2 (eIF2α) exhibited enhanced taste learning, with no effect on taste recognition (Costa-Matiolli et al., 2006). In addition, it is clear that in these mice other forms of learning and plasticity are enhanced during the consolidation phase. Both the 4E-BP2 and eIF2α mice represent genetic modifications that enhanced translation initiation and thus induced better taste learning and memory. In contrast, knockout mice for both S6K1 and S6K2, which are characterized by reduced initiation rates, exhibited impaired taste learning.

Analysis of the initiation phase suggests a simple image: More initiation, better taste learning. However, the picture is more complex when the elongation phase of translation is analyzed.

The elongation phase requires activity of eukaryotic elongation factors (eEFs). Eukaryotic elongation factor 2 (eEF2) mediates ribosomal translocation (Ryazanov and Davydova, 1989) and is phosphorylated on Thr56 by a specific Ca^{+2}/calmodulin-dependent kinase. Phosphorylation of the kinase inhibits its activity and leads to general inhibition of protein synthesis (Nairn and Palfrey, 1987). Analysis of eEF2 phosphorylation in the GC, following novel taste learning, revealed that, in contrast to the simple hypothesis, the phosphorylation of eEF2 was increased and not decreased, which indicates an attenuation in translation elongation (Belelovsky et al., 2005). At the same time and among the same samples, the phosphorylation levels of S6K1 and ERK were increased, which suggests that the initiation levels were indeed increased (Belelovsky et al., 2005). On the assumption that the increased initiation and decreased elongation were taking place in the same neurons in the GC, one may suggest that this situation might lead to increased expression of mRNAs that are poorly initiated (see **Figure 2** for the proposed model). The suggested mechanisms could serve as a switch-like mechanism to express a specific set of mRNAs for a restricted time in a cellular microdomain such as the synapse.

It is clear that in the near future much more research will be aimed at understanding how regulation of the various phases of translation subserves consolidation processes. Other important proteins such as mammalian target of rapamycin (mTOR) and ERK are thought to be molecules that integrate the information delivered by the various neurotransmitters, in time and space, and translate it into a cellular decision that enables the consolidation of memories. In the near future, these very same molecules could serve as targets for possible cognitive enhancers in the consolidation phase.

4.13.10 Modulation of Specific Protein/mRNA Expression During Taste Learning and Consolidation

In many studies, a positive correlation was identified between enhanced expression of protein and/or mRNA, on the one hand, and learning in the relevant brain area(s), on the other hand (e.g., Guzowski, 2002). This correlation was assumed to be the positive aspect of the dependence of memory and synaptic plasticity on protein and mRNA inhibitors. As shown in **Figure 3** and discussed in detail earlier, many phosphorylation events are correlated with both novel taste learning and CTA learning. However, two conceptual observations can be derived from these findings. First, the posttranslation modulation that is correlated with novel taste learning is attributed to the meaning/prominence/novelty dimension and not to the physical/chemical dimension of the taste information (**Figure 3**); a familiar taste does not induce these correlations. One may suggest that the synaptic and neuronal activities underlying the formation of the taste memory *per se* are so small compared with the ongoing activity in the cortex that the biochemical methods used in these studies are not sensitive enough

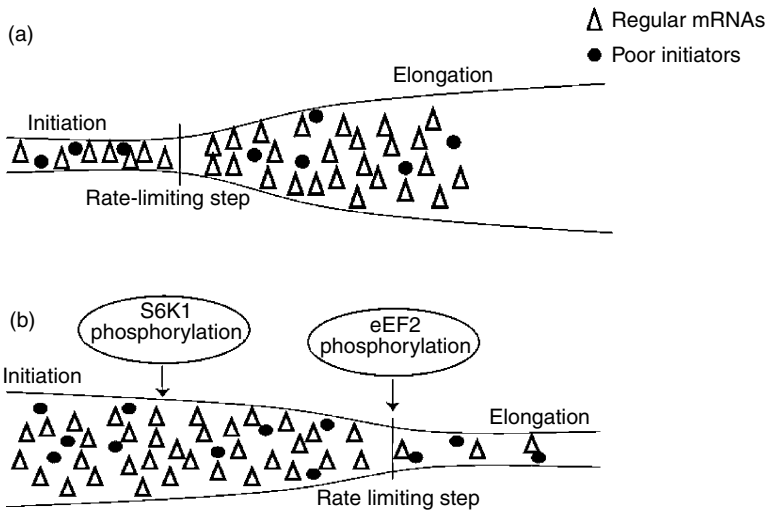

Figure 2 A proposal for the role of translation regulation underlying memory consolidation. (a) In a normal situation the rate-limiting step of protein synthesis is the initiation phase. The amount of protein synthesis is dependent on mRNA availability and the initiation rate as determined by ribosomal proteins and initiation factors. For a given amount of mRNA, regular mRNAs (triangles) are translated more than poor initiators (circles). A component of the intracellular signaling can alter the initiation rate, e.g., as in MAPK activation. (b) Taste memory consolidation is correlated with an increased initiation rate, which can be measured as increased ERK2 activation and decreased eIF2α phosphorylation and S6K1 phosphorylation. Within the same time frame, and possibly within the same cellular compartment, there is also a decrease in translation elongation, which can be detected in the increase in eEF2 phosphorylation. The end result of increasing initiation and decreasing elongation may be a shift in the rate-limiting step to the elongation phase. Together with the decrease in total protein synthesis, the synthesis of poorly initiated proteins such as α-Ca^{2+}/calmodulin-dependent protein kinase II (α-CaMKII) is probably increased. The mechanism described here can perform a switch-like function for various biological processes that shift protein expression patterns within a restricted time scale. In the cortex the mechanisms described can serve as molecular mechanisms that consolidate changes in synaptic strength over time. Adapted from Belelovsky K, Elkobi A, Kaphzan H, Nairn AC, and Rosenblum K (2005) A molecular switch for translational control in taste memory consolidation. *Eur. J. Neurosci.* 22: 2560–2568 with permission.

to detect the biochemical alterations subserving the physical properties of the taste. However, it is clear that some of the observed correlations (Rosenblum et al., 1997; Belelovsky et al., 2005) can be detected in the synaptosomal fraction. Another possibility lies in the strong link between taste and its perceived quality that is less inherent in other modalities. Taste is always perceived as good, bad, or indifferent, and thus the qualitative value of the physical input is a major building block in the memory of any taste.

The second observation is the difficulty of distinguishing between the biochemical correlations with the CTA or with the UCS itself, the malaise. In many experiments, the correlation between CTA and biochemical alterations can be detected following the UCS itself. In addition, the feeling of sickness is a strong input that can modulate several different parts of the brain.

What about mRNA or protein expression in the insular cortex that is correlated with taste learning or CTA?

The most common immediate early gene to be studied in correlation with learning is c-fos. Indeed, acute suppression, but not chronic genetic deficiency, of c-fos attenuated CTA learning (Yasoshima et al., 2006). Correlative studies for c-fos expression were carried out in Ilen Bernstein's laboratory (Wilkins and Bernstein, 2006; Koh et al., 2003; Koh and Bernstein, 2005) and elsewhere (Houpt et al., 1996; Ferriera et al., 2006). Exposure to a novel but not to a familiar taste induced c-fos expression in the central amygdala and the GC. The injection of the malaise-inducing agent LiCl induces c-fos in several brain structures, including the central amygdala and the IC. It is important to note that the posterior part of the IC processes visceral information and, therefore, it is possible that c-fos expression is not located in the same brain loci. The peak in c-fos expression can be detected about 1 h following novel taste learning and the malaise induced by the LiCl injection, and is degraded thereafter similarly to the processes in other brain areas subserving other learning paradigms (Wilkins and Bernstein, 2006).

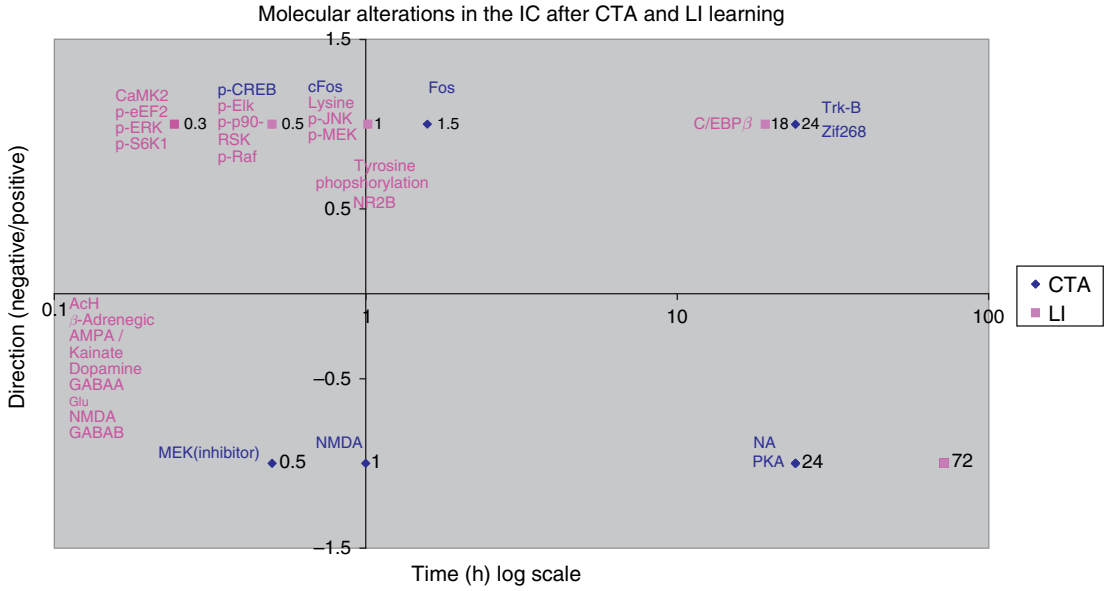

Figure 3 Summary of recent molecular analysis of taste learning in the rodent brain. The figure summarizes recent publications that examine the molecular mechanisms of taste learning; it shows whether the changes are correlative or are necessary for memory formation, and the direction of the changes. In addition, the figure indicates the method that was used and the temporal window of the changes. As can be seen, the research by Swank and Sweatt (2001) that used solid food with high metabolic value revealed a different time scale from that revealed by the other studies, which used liquid. In addition, the data in the figure can be divided into those related to CTA or novel taste learning; gene expression modulation, e.g., c-fos, or posttranslation regulation, e.g., MAPK activation; and manipulation affecting acquiring, retention, or both.

Another protein to be induced in correlation with taste learning in the GC is CCAAT enhancer binding protein β (C/EBPβ). However, the striking difference lies in the temporal phase of its induced expression. C/EBPβ is induced in both the hippocampus and the GC 18 h after taste learning (Yefet et al., 2006). Such late expression can be found following other learning paradigms (Taubenfeld et al., 2001). The correlative temporal increase in C/EBPβ 18 h following novel taste learning suggests that in a simple implicit learning task such as taste learning, both the hippocampus and the cortex are engaged in memory consolidation many hours after the acquisition phase. Moreover, another study demonstrated that this correlative induction of C/EBPβ can be deleted if another novel taste is consumed after the studied taste. A second novel taste induces memory interference that can be measured in behavior. However, at the same time, the second taste interferes with the correlative expression of C/EBPβ. Both the biochemical and behavioral interference suggest that a very long process of consolidation of taste information takes place, at least in part, in the GC (Merhav et al., 2006).

Careful analysis of the literature reveals very few correlations between mRNA-induced expression and taste learning. There are a few reports that identified induced expression of various mRNAs following CTA or LiCl injection (Lamprecht and Dudai, 1995, 1996). These investigations did not observe any modulation in mRNA expression in the insular cortex, following novel taste learning *per se*. Interestingly, LTP induced strong elevation in the expression of various mRNAs in the GC. These induced expressions were dependent on NMDA and muscarinic AChR (Jones et al., 1999). It is yet to be determined whether the major process that induces protein in the GC, in correlation with taste learning, is indeed translation and not transcription. Another possibility is that the temporal window for mRNA induction is prolonged and different from those in other learning paradigms, which would be consistent with the ability of the CS (novel taste) to maintain an on-hold position and to be associated with malaise hours later.

4.13.11 Temporal Phases in Taste Learning

The main feature of CTA learning is the long delay between the taste-related CS and the aversive internal symptoms (UCS). As a matter of fact, when first

published in the scientific community, this long delay put the behavioral results into question (e.g., Garcia et al., 1955). The delayed CS–UCS association cannot be explained as a phenomenon related to transfer of the taste input but as one related to the processing machinery itself within the CNS. In a way that is not clear, a better association is created with a time interval in the range of many minutes than with shorter time intervals (Sachfe et al., 1995). Thus, the system is well suited for prolonged delay between the CS and the UCS. It may be assumed that taste sampling creates a taste memory that remains ready for association, for many minutes. This taste memory trace is both short-lived for an association (usually a few hours) and also long-lived (weeks or more), as can be measured in the latent inhibition paradigm. The creation of taste memory is dependent on the functional taste cortex. One way to study the stability of the taste memory trace, which is dependent on GC activity, is to examine the interactions between taste inputs. Indeed, it was shown recently that taste memory is fragile and can be disrupted for hours by learning another novel taste input (Merhav et al., 2006). This intrinsic limitation of the taste system may be related to its capacity for prolonged association. Interestingly, the interference interaction is only for a second taste over the first one. The inverse interaction of the first novel taste on the second one induces a facilitation effect for the second taste. This facilitation effect has a time window of a few hours; it is shorter than the interference effect and it may be attributed to molecular interactions within the same neuron, i.e., a similar phenomenon to that in the tagging hypothesis model in LTP or to interactions among neuromodulators released within vast GC areas over a long period.

In any case, the unique ability of the taste system to form an association in such a delayed manner presents the researcher with the possibility of studying associative learning in a time frame that allows biochemical/molecular experiments, and not only electrophysiological manipulations and measurements.

4.13.12 Summary and New Directions

It was clear from the first scientific report of CTA that some of its features do not suit the mainstream learning models (Garcia et al., 1955). The two main differences, which may in fact be linked to one another, are the long delay between the CS (taste) and the malaise, and the built-in meaning of a given taste input. Thus, the chemical internal representation of a given taste always has a value: good, bad, or indifferent. It is indeed possible that any taste input is remembered by its association with its value. Definitely, the biochemical correlates of taste learning in the taste cortex – those that have been identified so far – are always correlated with the novelty of the taste input, which is a major factor in the saliency of any input. This means that, according to the current synaptic-Hebbian view of memory formation, the biochemical correlates cannot be attributed to encoding of the physical properties of the taste input. It is possible that these biochemical and cellular modifications are too small to be detected with the currently available technology.

One may argue that any long-term memory trace is associated with a value; however, it is clear that incidental taste learning (i.e., with no known external associations) is genetically strongly associated with the implication of the input for the animal, and it is clear that food consumption is a major factor in animal survival. Whereas the various senses can report to the brain regarding the potential of a given food for the animal (e.g., sound, color, smell, texture, and shape), the taste conveys the essence of the food for the animal. It is interesting that in Hebrew the word 'taste' is synonymous with meaning or reasoning, while 'vision' (I see) is analogous to understanding in English.

In any case, the perceived value of a given taste can be changed rapidly. The association with malaise is strong (CTA), but past experience (the behavioral paradigm of LI-CTA) and future experience (the behavioral paradigm of CTA extinction) can modify the taste value, and all three learning modes are dependent, at least in part, on the GC.

Taste learning offers unique opportunities to study the biological mechanisms underlying learning and memory. In the last decade, a number of laboratories have contributed to vast progress in this field. The development of new research tools (e.g., multielectrode arrays, genetic and molecular tools, and imaging techniques) enables us to ask new questions and to propose new hypotheses. Here are some of the major questions that will be addressed in the near future.

1. A major question in the neurobiology of learning and memory is whether the diverse experiences that create the internal representations are

modifications of a major internal representation or represent competition between different internal representations. It seems that the current knowledge of the taste system favors competition between different internal representations. However, further research is needed to obtain better evidence for one or the other of the options.

2. CTA learning is a hybrid between conscious learning, i.e., learning the taste information, and unconscious learning, i.e., visceral information. A major question concerns where this association takes place within the brain and neuronal circuit. The data so far indicate that the mainly subcortical structures, most probably the PBN, subserve the association. New tools and further analysis may enable us to answer this question.

3. Taste information is encoded, at least in part, by the GC, which resides within the insular cortex. However, very little is known about the circuit within the GC, and there are no good models that encompass the correlation between the electrophysiological and molecular information, on the one hand, and taste learning, on the other hand. A major line of research involves dissecting out the functional organization of the insular cortex on the circuit level, in order to better understand the encoding, consolidation, and retrieval processes, and it includes a number of questions. What types of cells produce the plasticity? Are they inhibitory interneurons, or excitatory cells? In which layer within the cortex do the correlative biochemical alterations take place? Does a given neuron contribute to the encoding of different tastes? Where within a given neuron do the modifications take place? The current experimental tools, which provide good spatial and temporal resolution, should provide answers to these basic questions in the near future.

4. Taste information can be kept on hold for many hours, waiting for an association, in contrast to other associations that have time windows measured in seconds. It is not clear if this unique ability represents distinct biological hardware, or if it is a prolongation of similar biological processes that underlie conventional association processes. A major question is how this associative potential is retained for many hours. If the mechanisms are similar to those in other learning paradigms, this unique ability of CS, which derives from processing mechanisms within the CNS, could be exploited to study association mechanisms by means of research tools with resolution times of minutes to hours, which could not be used in other learning paradigms, i.e., most molecular/biochemical tools.

5. The time frame of molecular modifications in the GC that are correlated with taste learning (see **Figure 2**) opens with posttranslation modifications within minutes after learning (e.g., ERK, eEF2; see **Figure 2** for more details), proceeds with other posttranslation modifications to synaptic proteins on a time scale of hours (e.g., tyrosine phosphorylation of the NR2B), and continues with protein expression on a time scale of hours to days following learning (e.g., the inductions of postsynaptic density 95 and C/EBPβ, which occur 3 and 18 h following learning, respectively). A major task will be to organize a temporal and spatial chart of these correlations in order to understand the stream of molecular and cellular events underlying taste memory formation.

In addition, the known identities of molecular events, and their time windows, are in accord with other brain structures that subserve other learning paradigms, for example, the expression of C/EBPβ in the relevant brain structure 18 h after learning. However, some of the events are different. For example, there are several indications that functional NMDA receptor in the GC is necessary for the consolidation phase, in contrast to other learning and LTP protocols, whereas the NMDA receptor is necessary mainly for the acquisition/induction phase. One possibility is that this is a unique feature of taste learning and that it is related to the ability of the taste memory trace to be associated after such a long delay. However, further analysis is needed to understand the role of NMDA receptor activity, localization, and posttranslation modification within the GC during taste memory formation.

6. In the last few years, the role of translation regulation in taste learning consolidation has been studied extensively. The results demonstrate intrinsic regulation of both the initiation and the elongation phases during taste memory formation. Moreover, it is clear that those genetic and pharmacological modifications that enhance the initiation phase also enhance performance. Much more research is needed to achieve understanding of translation regulation in memory consolidation to answer such questions as: What are the upstream neurotransmitters and signal transduction cascades? What are the targets and what are the mRNA populations and their localizations? However, the taste system can serve as a platform from which to study new targets for drugs, to be used as cognitive enhancers.

4.14 Memory Reconsolidation

C. M. Alberini and S. M. Taubenfeld, Mount Sinai School of Medicine, New York, NY, USA

4.14.1 Definitions and History of Memory Reconsolidation

Memory is an organism's ability to store, retain, and subsequently recall information.

The formation of memory takes place through complex and very dynamic processes. Following learning, the newly acquired information is in a fragile state and stabilizes over time to be finally stored as a long-lasting representation of the learned experience. This process of progressive stabilization of the memory is known as memory consolidation, and the internal representation of the memory is referred to as the memory trace or engram.

The concept of memory consolidation evolved from many studies over the last century in both humans and animal models. Toward the end of the nineteenth century, clinical observations showed that head injury or other traumatic insults to the brain lead to forgetting of more recent memories, while gradually sparing older ones. This gradient of retrograde amnesia (RA) was later reproduced using human verbal learning by the pioneering studies of Muller and Pilzecker around 1900. These authors reported that memory for a newly learned list of words is disrupted by the learning of a second list of words if it is presented shortly after the original one, a phenomenon known as retroactive interference. The authors concluded that neural processes activated by recently acquired information require time in order to become permanently 'fixated' or consolidated (Muller and Pilzecker, 1900).

The consolidation hypothesis has greatly influenced the neurobiological studies of memory throughout the last century. Starting from 1940, many laboratories investigated RA and experimentally reproduced the human data using animal models, particularly mice and rats. These animal studies confirmed that, if within a limited time window after acquiring the information the subject encounters some type of interfering stimuli, memory does not stabilize and the experience is forgotten. Stimuli able to disrupt memory consolidation can be different in nature and include, among others, brain trauma, new learning, seizure, electroconvulsive shock (ECS), brain cooling, and pharmacological treatments that inhibit basic molecular functions such as transcription and translation (Dudai, 2004). During the same years, in parallel with the multitude of studies on RA, an interesting complementary cellular view of how neuronal mechanisms store long-lasting changes was proposed. Inspired by Freud's earlier theories, in 1949 Hebb proposed that memories strengthen and stabilize through reverberating neural circuits and suggested a possible neuronal mechanism for the temporal gradient of RA: the disruption of reverberating circuits prevents the synaptic changes necessary for memory consolidation, and this effect gradually decreases as the changes progress over time. This concept of reverberating circuits, together with the conclusions from the findings on RA, led to the hypothesis that memory consolidation builds on biological modifications occurring over time, which become integrated and preserved as a lasting engram or impression (trace) in the brain.

One important issue that emerged from these original consolidation studies and still remains to be understood is the duration of the consolidation process. This has not yet been clarified, possibly because interferences of different nature likely affect different phases of the consolidation process itself. Various types of interfering stimuli have revealed at least

two levels, or phases, of consolidation. An early, rapid phase occurs over minutes or hours and is sensitive to molecular intervention, such as inhibition of RNA or protein synthesis or disruption of the expression of specific genes. In addition, at a later time, a second, slower phase of consolidation that can last for weeks, months, or even years in humans is believed to reorganize the circuits that bear the memory trace. This late consolidation phase can be disrupted by events that produce lesions or inactivation of neuronal circuits (e.g., hippocampal inactivation) (Squire et al., 2001). Despite that, this important issue remains unsettled: Until very recently, memory consolidation has been considered to be a one-time process that from its initial fragile state progressively strengthens memory over time (McGaugh, 2000). This chapter, unless otherwise specified, refers to the use of the term 'consolidation' that indicates the early phase of memory fragility, which depends upon new synthesis of RNA or proteins or the expression of specific molecules.

Discoveries reported in the 1960s and 1970s showed that, in contrast to the idea of a unitary process of memory consolidation, a memory that has become sufficiently stable and insensitive to various interfering stimuli, including the administration of ECS or RNA and protein synthesis inhibitors, could return to a fragile state for a limited time if the memory was retrieved or in some way 'reactivated.' During this fragile state, memory could be disrupted by the same interfering stimuli that were known to affect the initial consolidation. Consequently, a different hypothesis of memory stabilization was proposed: it is not the age of the memory that makes a memory more consolidated and resilient to disruption but, rather, its 'active' state (Lewis, 1979). Thus, a memory in its 'active' state (e.g., after training or retrieval) is fragile, whereas an 'inactive' memory is stable. It was also found that a memory could be reactivated by several means, the most common of which is the recall or retrieval of the learned experience (e.g., a conditioned stimulus (CS) exposure for Pavlovian conditioning memories). Memory reactivations, however, could also occur effectively by reexperiencing the motivational aspect of the learned event (e.g., drive states such as hunger) or by reliving the entire learning experience (e.g., another training trial). Thus, it was concluded that, after becoming again active and therefore fragile, memory needs to undergo again a stabilization process that, as revealed by RA, shares similarities to posttraining consolidation. For this reason, this process was later named reconsolidation.

After this series of experiments, in the 1970s, controversies set in, in part because of some failure to reproduce the findings of RA after memory reactivation and in part because, in several cases, spontaneous recovery from amnesia was reported. Therefore, alternative views that could explain postreactivation RA were put forward, and the lack of memory retention was considered a retrieval deficit rather than a failure of consolidation or reconsolidation (Riccio et al., 2006), raising a question that, as discussed below, still remains to be answered.

Subsequently, the issue of postreactivation memoryfragility quieted down for several decades, with the exception of a few sporadic studies, but then strongly reemerged in 2000, when an important study extended the notion that an established fear-conditioningmemory is disrupted if, after its retrieval, protein synthesis is inhibited in the amygdala (Nader et al., 2000a). The authors, in agreement with previous hypotheses, proposed that an established memory, once reactivated, becomes transiently labile and undergoes another consolidation phase in order to be maintained. This process was therefore named *reconsolidation* (Nader et al., 2000a,b; Sara, 2000a). In the last 6 years, a large number of manuscripts have been published on this subject, reflecting the exponential increase of the acquired knowledge about memory reconsolidation. All these studies have proven that numerous types of memories elicited with different protocols in different species ranging from snails to humans undergo reconsolidation (**Table 1**). In the following subchapters, the major recent findings about the mechanisms, features, circuits, and functions of memory reconsolidation are summarized.

4.14.2 Mechanisms and Circuits of Memory Reconsolidation

An important question that has been the focus of attention during the last 6 years and partially still remains to be fully understood is whether and to what extent the posttraining consolidation phase and reconsolidation are mechanistically similar at the molecular and cellular levels.

A premise that needs to be made here is that the identification of which molecular mechanisms underlie both memory consolidation and reconsolidation is one of the biggest technical challenges in neurobiology. Understanding the complexity of the

Table 1 Species, learning and memory tasks, brain regions, and molecules involved in memory reconsolidation

Species	*Tasks*	*Brain regions*	*Molecules*
Caenorhabditis elegans	Contextual fear conditioning	Hippocampus	C/EBPβ
Helix lucorum	Inhibitory avoidance	Amygdala	Zif268
Lymnaea stagnalis	Classical conditioning	Insular cortex	CREB
Chasmagnathus granulata	Implicit conditioning (mobile conjugate	Nucleus accumbens	NFκB
Honeybee	reinforcement)	Ventromedial prefrontal	PKA
Medaka fish	Radial arm-maze	cortex	MEK

molecular changes accompanying behavioral responses and their functional role requires both the identification and functional testing of multiple molecules and mechanisms ongoing in different brain regions over time, an arduous task with the technology currently available. Currently, the most comprehensive approaches available can only identify correlative changes to behavioral responses occurring within specific brain regions or cell populations and are based on differential screenings using DNA microarrays or proteomics. These techniques offer the advantage of simultaneously evaluating the expression levels of thousands of genes or proteins, respectively, in a given experimental condition (e.g., time, space, treatment). The comparison among different experimental conditions (e.g., trained vs. controls) leads to the identification of specific genes or proteins. Although these techniques are incredibly powerful, presently they still possess several limitations: they are very laborious and expensive and are still not sufficiently sensitive for detecting small changes in heterogeneous tissues such as brain regions. Moreover, they can target only one time point at a time, and therefore each experiment only reveals a single snapshot of the ongoing molecular changes. Despite these limitations, several studies in the last few years have investigated comprehensive changes during posttraining consolidation using DNA microarrays or proteomics. However, perhaps due to its more recent reemergence, very little progress has been made investigating the reconsolidation process. The approaches thus far employed to uncover the nature of the molecular mechanisms underlying memory reconsolidation have been based on testing the potential roles of individual molecules which had been previously found to play a critical function during the consolidation phase. This approach, which has limited the potential for identifying new molecules and mechanisms, has been mainly used for another purpose: addressing the question of whether the reconsolidation process is a recapitulation of consolidation (Dudai and Eisenberg, 2004; Alberini, 2005; Nader et al., 2005). This question has been the focus of many debates. For example, it has been argued that it is expected that reconsolidation is not an exact copy of the posttraining consolidation, as new learning is distinct from a reactivation process, which often occurs through only a partial reexperience (i.e., reactivation by recall, in which, for example, for Pavlovian conditioning only a CS presentation occurs). However, for the precise reason that reactivation is generally different than training, other authors have felt that it is important to determine how similar or different their underlying mechanisms of stabilization actually are. With this in mind, several studies have examined whether the disruption of protein or RNA synthesis or of the expression of specific molecules that were known to block consolidation affected the reconsolidation of the same memories. Disruption of specific molecules was achieved by stereotactic injection of molecular inhibitors such as specific antagonists or antisense

sequences, or by region-restricted gene expression interference in transgenic animals. The conclusions from these studies revealed that a number of mechanisms are commonly used by both consolidation and reconsolidation, while other mechanisms are regulated and required for the consolidation of a particular memory but not during its reconsolidation. In summary, reconsolidation appears to be only a partial recapitulation of the initial posttraining consolidation process (von Hertzen and Giese, 2005). One study also reported that molecular mechanisms required in the hippocampus during either consolidation or reconsolidation are distinct or show distinct temporal dynamics. The genes examined thus far belong to different functional classes including kinases such as mitogen-activated protein kinase (MAPK), serum and glucocorticoid-induced kinase 3 (SGK3), and cAMP-dependent protein kinase A (PKA); transcription factors such as cAMP-response element binding protein (CREB), CCAAT enhancer binding protein β (C/EBPβ), zif 268, and nuclear factor kappa B (NFκB); neurotrophic factors such as brain-derived growth factor (BDNF); and membrane receptors, such as glutamate, noradrenergic, cannabinoid, and glucocorticoid receptors (**Table 1**).

In addition to specific mechanisms, it was also investigated whether similar or distinct brain areas (circuits) are recruited during consolidation or reconsolidation. These questions have been addressed by disrupting neuronal activity (inactivation) or specific molecules within restricted brain areas or even distinct cell populations within brain regions. The results indicate that not all the same brain regions engaged during memory consolidation are also involved during the reconsolidation of the same memory. Hence, in a variety of memories, similar to what has been observed for the molecular mechanisms, only a partial overlapping of circuitry between the two processes was revealed.

In summary, the two processes of consolidation and reconsolidation appear to only partially share molecular mechanisms and brain areas. Hence, the term 'reconsolidation' refers to the concept of memory restabilization and does not indicate the reiteration of underlying mechanisms.

Our understanding of how memory reconsolidation, but also consolidation, occurs mechanistically at the molecular and cellular levels is still very primitive. While, as mentioned above, several molecules required for memory reconsolidation have been pinpointed, the sequence of the molecular events that are activated during the onset and development of the process is unknown. Some recent studies have found intriguing correlations between the expression level of glutamate receptors and memory reconsolidation, suggesting that, like memory consolidation, a critical role might be carried out by the regulation of alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors (Rose and Rankin, 2006). Further studies will be important for unraveling the sequence of molecular events necessary to restabilize a memory after it has been reactivated.

4.14.3 Temporal Constraints

Two types of temporal constraints have been found to characterize memory reconsolidation: (1) the persistence and duration of the amnesia and (2) the age of the memory.

4.14.3.1 Persistence and Duration of Amnesia Induced by Postreactivation Interference

Some researchers have found that, whereas the amnesia caused by protein synthesis inhibition after training is long lasting, the amnesia resulting from inhibition of protein synthesis after memory reactivation spontaneously recovers over time (Anokhin et al., 2002; Lattal and Abel, 2004; Salinksa et al., 2004) or recovers after exposure to a reminder event (Fischer et al., 2004). Thus, several authors believe that the amnesia caused by postreactivation interference results from a retrieval deficit. On the other hand, these results have not always been reproduced, and in several cases memory disruption after reactivation lasted for a long time (weeks or months in animals), and memory retention never returned even following a strong reminder. Several reasons may explain these opposing results. First, the question of the persistence of the amnesia induced by protein synthesis inhibitors after reconsolidation may be related to the degree and duration of protein synthesis inhibition. Unfortunately, very few studies have determined the rate of protein synthesis inhibition with the conditions and protocols used in reconsolidation experiments. The same issue had been under debate for the consolidation process a few decades ago, and a possible explanation offered for the temporary effect was that protein synthesis was only partially inhibited or inhibited for an insufficient length of time. Indeed, it has been reported

that stronger memories require longer (stronger) inhibition of protein synthesis to be permanently disrupted (Flood et al., 1973, 1975; Barraco and Stettner, 1976; Davis et al., 1978). In addition, in agreement with these results, it has been recently demonstrated that a partial inhibition of protein synthesis during the consolidation or reconsolidation phase precisely results in temporary impairment that recovers at later times (Milekic et al., 2006; Miller and Sweatt, 2006). A second possibility that can explain why amnesia results more frequently after postretrieval rather than posttraining interference is that disrupting a memory that had been already stabilized is more difficult than disrupting a newly acquired memory. Logically, a memory trace that has been previously established would be more resistant to disruption than a newly developing trace. Therefore, the same amnesic treatments may result in a total amnesia for new memories, but only a partial amnesia for a reactivated memory. In the latter case, a reminder may increase the strength of the memory trace and result in a memory recovery, which would be misinterpreted in favor of a potential retrieval failure rather than a loss of stored information. Third, by definition, it is always impossible to exclude that an amnesia results from a retrieval deficit, because even though no recovery might be observed under any circumstances, currently there is no direct method to prove that the memory trace has been completely erased.

4.14.3.2 Age of the Memory

The hypothesis of memory reconsolidation predicts that when a memory is active (following training or reactivation) it is in a labile state, and when inactive it is stable. This implies that *every time* a memory is reactivated it becomes transiently labile. A number of recent studies have tested whether this hypothesis is correct or whether the memory changes over time. The results have clearly shown that, in most cases, the passage of time influences the stability of a memory and that the older a memory becomes the less susceptible it is to disruption following its reactivation. These results have been found using several fear conditioning types of tasks in many different species including rat, mouse, chick, and Medaka fish. In general, an increasing resilience to disruption following memory reactivation has been reported over several weeks. For example, in rat inhibitory avoidance 2- and 7-day-old memories became fragile and are disrupted by protein synthesis inhibitors administered after recall, while older, 14- and 28-day-old memories are resistant to the same treatment (Milekic and Alberini, 2002) (**Figure 1**). Similarly, in Medaka fish, the administration of a Na^+ channel blocker upon reactivation disrupts a 4-day-old memory but has no effect on a 15-day-old memory and an intermediate effect on a 9-day-old memory (Eisenberg and Dudai, 2004). Likewise, numerous other studies in different species have confirmed the existence of a temporal gradient of progressive resilience to memory disruption after reactivation (Litvin and Anokhin, 2000; Suzuki et al., 2004; Boccia et al., 2006; Frankland et al., 2006). An important extension of these findings revealed that, in addition to the age of the memory, the strength of the memory and the reactivation intensity interact to influence the degree of vulnerability of a reactivated memory (Suzuki et al., 2004). In fact, whereas protein synthesis inhibitors can disrupt a 24-h- to 3-week-old contextual fear memory after reactivation in mice, an 8-week-old memory remains insensitive to disruption by a similar reactivation session. However, if the reactivation session is prolonged, even the older memory can be disrupted. Finally, weak (one shock) versus strong (three shocks) training protocols correlate with more or less susceptibility to disruption after reactivation, respectively. Interestingly, using associative learning in *Lymnaea*, it was found that reconsolidation at both 6 and 24 h, which requires protein synthesis, undergoes progressive molecular changes, because only reconsolidation at 6 h after training, but not at 24 h, requires protein kinase A activity. This phase-dependent differential molecular requirement for reconsolidation supports the idea that even

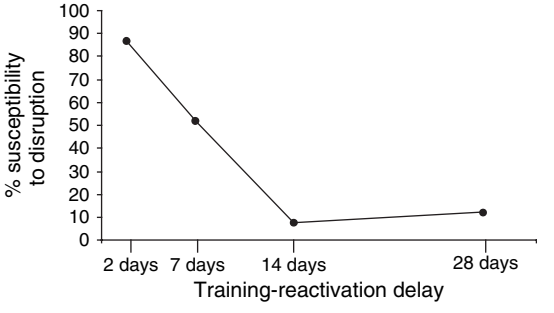

Figure 1 Temporally graded decrease of susceptibility to disruption of a reactivated memory. Susceptibility to disruption by anisomycin of reactivated inhibitory avoidance memories of different ages. Taken from Milekic MH and Alberini CM (2002) Temporally graded requirement for protein synthesis following memory reactivation. *Neuron* 36: 521–525, with permission from Elsevier.

seemingly consolidated memories undergo further selective molecular maturation processes (Kemenes et al., 2006).

In conclusion, an important temporal constraint characterizes memory reconsolidation: as the time interval since training lengthens, there is increasing resistance to postreactivation disruption. This indicates that the reconsolidation process is a manifestation of a lingering consolidation (Dudai and Eisenberg, 2004; Alberini, 2005).

Some authors disagree with this interpretation. Some studies show that 2-day- and 2-week-old memories of cued fear conditioning as well as a 45-day-old contextual fear conditioning memory in rats are disrupted by postretrieval bilateral injections of anisomycin into the amygdala or hippocampus, respectively (Nader et al., 2000a; Debiec et al., 2002). In contrast, other groups have reported opposite results using contextual fear conditioning in mice (Suzuki et al., 2004; Frankland et al., 2006). Furthermore, memories that are based on multiple training trials appear to show a long-lasting temporal window of postreactivation fragility: a 21-day-old appetitive instrumental response (sucrose self-administration) is disrupted by systemic injection of the beta-adrenergic antagonist propranolol, and a 27-day-old cocaine-induced conditioned place preference is disrupted by postreactivation amygdala injections of zif 268 antisense (Diergaarde et al., 2006; Lee et al., 2006). These opposing data can be explained by the findings discussed above showing that the nature of the learning, the intensity of training, and reactivation protocols produce gradients of protein synthesis requirements after reactivation that show different temporal evolutions. Hence, under certain experimental conditions (e.g., the reactivation intensity and time points chosen), the memory may still lie within the labile period. Following the same logic, it will be consistent with a lingering consolidation and the results of RA affecting remote memories that the stabilization process may take a long time, and therefore, some memories may remain sensitive to postretrieval interference for an extended period of time.

Importantly, the existence of a gradient does not exclude the possibility that reactivation of fully consolidated memories is accompanied by a phase of *de novo* protein synthesis. However, new molecular changes induced by the reactivation of a fully consolidated memory may occur without manifested fragility of the consolidated information. This view is in agreement with a hypothesis that had been proposed to explain memory stabilization over time, which suggested that memory stability correlates with the distributed nature of the memory trace (Nadel and Moscovitch, 1997) and is also in line with the hypothesis mentioned above of reverberating circuits proposed by Hebb (1949).

The mechanisms underlying the progressively decreasing gradient of memory fragility are not yet clear. However, future investigations should be able to address this question.

4.14.4 Functions of Memory Reconsolidation

The reason why memories become labile after reactivation is still unknown. Two main, non–mutually exclusive hypotheses have been proposed. First, as suggested above by the hypothesis of a lingering consolidation, a function of reconsolidation might be to strengthen memory retention (Sara, 2000b). A second possible role of reconsolidation may be to allow the integration of new information into the background of the past. In other words, reconsolidation might be required "to associate new learning with already established and reactivated memories" (Lewis, 1979; Sara, 2000a; Dudai, 2004). Although no direct proof has yet been provided, the results of several studies support the idea that memory reactivation leads to increased memory strength and prevents forgetting. For example, electrical stimulation of the mesencephalic reticular formation (MRF) improves the retention of memories, including fear conditioning and linear maze, when the stimulus is applied after memory reactivation (DeVietti et al., 1973; Sara, 2000b), indicating that memory retention can be enhanced during a postreactivation phase. In addition, recent studies in *Lymnea stagnalis* showed that the reexperience of a conditioned stimulus in the same context where the subject previously underwent a training that elicits an intermediate-term memory converts a residual memory trace into long-term memory (Parvez et al., 2006). Finally, several modulatory compounds, including angiotensin II and agonists of protein kinase A, have been found to increase memory retention if present during the reconsolidation phase (Frenkel et al., 2005; Tronson et al., 2006), suggesting once again that after reactivation, memory can be strengthened.

The second proposed function, that the reconsolidation process mediates the formation of associations between new and reactivated information, is now

beginning to be understood. Toward this end, one study utilized a second-order conditioning paradigm (Tronel et al., 2005) in which two associations are established in series. First, a conditioned stimulus (CS1) is paired with an unconditioned stimulus (US), such as when a given context (context A) is paired with a footshock. Then the established properties of CS1 are paired with a new stimulus, CS2, producing a CS1-CS2 association. For example, the subject that has learned the context A-US pairing is then exposed to a different context (context B) in which one cue of context A is presented. This experience reevokes the result of the CS1-US association, which now becomes linked with context B. Therefore, the subject learns to fear context B even though this context has never been associated with a shock.

Using inhibitory avoidance, it was found that systemic inhibition of protein synthesis after the exposure to context B (which also contains a cue from context A) disrupts both the new association (CS2-CS1) and the recalled memory (CS1-US). Region-restricted inhibition of the transcription factor C/EBPβ allows the functional dissociation of the consolidation and reconsolidation of inhibitory avoidance. Inhibition of C/EBPβ in the hippocampus disrupts inhibitory avoidance consolidation but not reconsolidation, and conversely, inhibition of C/EBPβ in the amygdala disrupts reconsolidation but not consolidation. If memory reconsolidation mediates the incorporation of new information into a reactivated memory, then it is predicted that after the exposure to context B the inhibition of C/EBPβ in the amygdala should disrupt both memories. Instead, it was found that such a C/EBPβ inhibition only and selectively disrupted the old memory for context A but spared the new memory for context B. Thus, the reconsolidation of the original memory takes place independently from the formation of the new association. Conversely, the memory for context B was selectively disrupted by hippocampal C/EBPβ inhibition, suggesting that the formation of the new association is mediated by molecular mechanisms similar to those underlying the initial consolidation of a new memory. In conclusion, although the old memory needs to be retrieved in order to associate new information, its reconsolidation process is not engaged in establishing the link between the new information and the reactivated memory.

Another study investigated memory 'updating' by approaching this question from a different angle. Repeated learning presentations of the same event using attenuation of neophobia (AN) in rats were used to test (1) how the acquisition of a new learning trial becomes linked to the consolidated memory established by the previous trials and (2) the fragility of both the updated and previously established memories (Rodriguez-Ortiz et al., 2005).

In AN, the animal gradually increases the intake of a tastant after repeated presentations of the tastant itself. Each additional learning could be considered as a memory updating event. Using multiple training trials, each separated by 24 h, it was found that, while after the first and second trials an infusion of anisomycin into the insular cortex completely disrupted memory retention, after the third trial a partial disruption was observed. Moreover, after six trials, a similar treatment had no significant effect. Thus, it was concluded that, while additional learning is acquired, part of the older, consolidated memory in the insular cortex becomes independent of protein synthesis. Furthermore, rats that after seven trials of AN were trained to conditioned taste aversion (CTA) for the same taste in the presence of anisomycin developed amnesia for CTA the following day. In light of these results, it was concluded that "protein synthesis is required to update previously consolidated memory trace regardless of the valence of the tastant." This study, in agreement with the first one, indicates that the formation of a new association linked to a previously established memory requires protein synthesis. Because it was not determined whether the protein synthesis required for the reconsolidation or persistence of the old memory is recruited to mediate the incorporation of new information, it is possible that AN updating, like inhibitory avoidance (IA) second-order conditioning, utilizes consolidation-like mechanisms and not the reconsolidation process of the original memory. In agreement with this hypothesis, the AN study shows that the old and new memories are dissociable processes because, while the old memory can become resistant (consolidated), the updating is sensitive to disruption. In conclusion, it is important to experimentally dissect what is being disrupted – the process that mediates an association between a new experience and a retrieved information, or the restabilization process of a reactivated, previously established memory.

4.14.5 Clinical Applications

The reemergence of research focusing on memory reconsolidation has stimulated interest in the medical community, particularly among mental health professionals treating disorders that are based on

pathogenic memories. Two examples of these directives are posttraumatic stress disorder (PTSD) and drug addiction, both of which can be viewed as the result of dysfunctional memory processes.

PTSD can develop after an exposure to an emotionally or physically traumatic event, and the illness is characterized by repeated, intrusive memories of the experienced trauma. Patients suffering from PTSD have difficulty sleeping and feel detached or estranged, and these symptoms can be so severe and persistent as to significantly impair the person's daily life. A behavioral model of PTSD onset has been proposed: the traumatic event (US) triggers a strong hormonal stress response, which mediates the formation of a robust and enduring memory for the trauma. Subsequent recall of the event in response to cues and reminders (CS) releases more stress hormones (conditioned response) and even further consolidates the memory leading to PTSD symptoms, such as flashbacks, nightmares, and anxiety (Pitman and Delahanty, 2005). The persistence of PTSD can be explained in terms of a trauma-induced strengthening of the memory trace. More specifically, it is hypothesized that noradrenergic hyperactivity and stress hormones facilitate the encoding and consolidation of the memory (Pitman, 1989; O'Donnell et al., 2004; Yehuda, 2006).

Although it is not possible to precisely reproduce PTSD in an animal model, fear conditioning in rodents can be used to mimic and elucidate some aspects of PTSD, including the processing of fearful stimuli and the encoding of emotional memory. As described above, fear conditioning is readily induced in laboratory animals by pairing a CS, such as contextual cues, with a fear-inducing US, such as a foot shock. Presentation of the neutral CS at some later time evokes a stereotypic fear response in the animal, including the stress response and activation of the autonomic nervous system. This is similar to the scenario in which contextual cues associated with a traumatic event can precipitate onset of PTSD symptoms in patients. Thus, it is possible to closely approximate some of the PTSD symptoms in an animal model that can be used for preclinical research. In principle, all pharmacological compounds thus far shown to have the ability to disrupt fear memory reconsolidation could potentially be useful for designing new drugs that can be used in clinical trials. Some of these compounds, including antagonists of beta-adrenergic or glucocorticoid receptors, which target the stress pathways, are already employed in clinical pharmacology for treating other diseases. Hence, they represent the most readily available potential therapies.

Targeting memory reconsolidation and the noradrenergic system in an attempt to treat PTSD has already been explored at the preclinical level and is currently being used in clinical trials. One method involves administration of the beta-adrenergic blocker propranolol, commonly used to treat hypertension, following recall of the traumatic memory. Several years ago, researchers first tested the effect of propranolol on memory reconsolidation using inhibitory avoidance in rats (Przybyslawski et al., 1999). Systemic administration of propranolol given after the reactivation of the inhibitory avoidance memory disrupted the memory at subsequent tests. More recently, using another paradigm known as auditory fear conditioning, other researchers have shown that propranolol injected either systemically or into the lateral nucleus of the amygdala (LA) after reactivation of a 2-month-old memory weakened the fear response when tested 48 h later (Debiec and LeDoux, 2004, 2006).

Another pharmacologically targeted pathway for the potential treatment of PTSD is the glucocorticoid pathway. The endogenous stress hormone corticosterone bidirectionally modulates memory retention (McGaugh and Roozendaal, 2002; Roozendaal, 2002). Low doses increase memory retention, while high doses disrupt it. Recent studies have reported that glucocorticoids, when administered after the reactivation of a contextual fear memory, have an amnesic effect on the original memory and provide evidence that a possible mechanism for this effect is an enhancement of extinction of the expression of the original memory (Cai et al., 2006). Another study, however, revealed that intra-amygdala blockade of glucocorticoid receptors with the antagonist mifepristone after reactivation of inhibitory avoidance memory significantly disrupts the original memory, probably interfering with its reconsolidation process (Tronel and Alberini, 2007). In light of these results, the role of the glucocorticoid pathway following memory reactivation has clearly been established and promises to be an additional site of pharmacologic intervention for PTSD.

Substance abuse generally leads to a chronic condition believed to result from an addict's inability to permanently abstain from drug use. Drug addicts repeatedly relapse to drug seeking even after years of abstinence, and this pathologic behavior is frequently induced by the recall of memories and environmental

stimuli intimately connected to the rewarding effects of the drug. Therefore, disruption of memory reconsolidation provides an unprecedented potential strategy to disrupt memories that facilitate drug addiction. Promising results have recently been reported in animals dependent on morphine or cocaine by injecting, after memory reactivation, inhibitors of protein synthesis or ERK (extracellular signal-regulated kinase), or by disrupting the expression of the immediate-early gene *zif268* both peripherally and within specific brain regions, such as the amygdala, hippocampus, or nucleus accumbens (Lee et al., 2005; Miller and Marshall, 2005; Milekic et al., 2006; Valjent et al., 2006). In some of these studies, inhibitors were administered to animals that had previously acquired a place preference in response to the drug of abuse, a learning known as conditioned place preference. Animals learned to associate the euphoria of the drug with a specific location, choosing to spend more time there. Administration of several of these inhibitors after reactivation of the drug-related memory interfered with its reconsolidation and abolished the place preference. Other studies investigated a different type of task in which animals form a CS–drug association during drug self-administration training, a model of drug seeking (Lee et al., 2005, 2006). These studies showed that infusion of zif268 antisense oligodeoxynucleotides into the basolateral amygdala, prior to the reactivation of a CS–cocaine association, abolishes its impact on the learning of a new cocaine-seeking response or maintenance of cocaine seeking as well as relapse to a previously established drug-seeking behavior. Furthermore, the same group later demonstrated that conditioned withdrawal could be disrupted following the reactivation of a CS–withdrawal association (Hellemans et al., 2006).

How might a clinical strategy for disruption of reconsolidation of a pathogenic memory be designed? An example of methodology involves pairing pharmacotherapy with memory retrieval within a carefully controlled clinical setting. For example, a patient's memory could be evoked through reexposure to key sensory components of the memory, or reminder cues, immediately followed by treatment with an antagonist or inhibitor that interferes with the reconsolidation of that particular memory. Another strategy might involve patient self-administration during a spontaneous memory flashback, presumably when the memory becomes pliable. Better understanding the mechanism of memory reconsolidation and the consequences of its disruption on human behavior will ultimately help clinicians to target mental illnesses based on pathogenic memories.

4.15 Molecular Aspects of Memory Dysfunction in Alzheimer's Disease

J. Chin, E. D. Roberson, and L. Mucke, Gladstone Institute of Neurological Disease and University of California, San Francisco, San Francisco, CA, USA

4.15.1 Introduction

Alzheimer's disease (AD) is the foremost human disease of memory. Independent streams of research on the molecular mechanisms of AD and the molecular basis of memory, which historically were quite distinct, are now converging in exciting ways. The study of AD may provide novel insights into basic mechanisms of memory, and even more importantly for the over 24 million patients with AD worldwide (Ferri et al., 2005), discoveries about the molecular basis of memory are advancing our understanding of the disease and yielding new treatment targets.

AD typically begins with mild forgetfulness in the elderly. Early on, before memory problems interfere with day-to-day functioning, a diagnosis of mild cognitive impairment (MCI) is often made. As years go by, deficits become more severe and patients are forced to curtail their usual activities. Deficits in other cognitive domains become increasingly apparent, including executive dysfunction, anomia and other language problems, visuospatial dysfunction, and ultimately, global cognitive impairment. Median survival is about 12 years after first symptom onset (Roberson et al., 2005).

Although the diagnosis of probable AD is made during life, definite diagnosis is made only at autopsy. The hallmark pathological features of AD are extracellular amyloid plaques and intracellular neurofibrillary tangles (NFTs) (**Figure 1**), combined with neuronal and synaptic loss, vascular amyloidosis, astrocytosis, and microgliosis. Most of these changes occur in a stereotypical regional distribution, with medial temporal structures involved in memory affected earliest and most severely.

Biochemical and genetic studies of AD have identified several molecules that may play a causal role in its pathogenesis (**Figure 2**). For the most part, these molecules have been studied primarily in the context of AD. In the first half of this chapter, we consider the impact of these AD-related molecules on memory. In addition, many molecules that have been studied primarily in the context of synaptic plasticity and memory, including a variety of receptors, channels, second messengers, kinases, and transcription factors, are also involved in AD. In the second half of the chapter, we consider AD-related memory impairment in relation to these molecules.

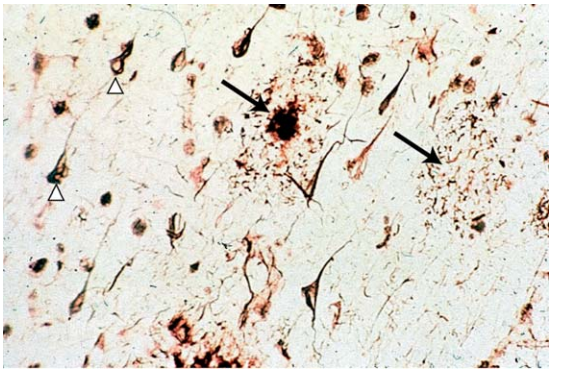

Figure 1 Plaques and tangles. This silver-stained section of cerebral cortex from a patient with Alzheimer's disease shows extracellular amyloid plaques (black arrows) and intracellular neurofibrillary tangles (white arrowheads). (Courtesy of Dr. Nitya R Ghatak, Virginia Commonwealth University Health System.)

4.15.2 Memory Impairment by AD-Related Molecules

In this section, we examine several molecules that likely contribute to the pathogenesis of AD, including the amyloid precursor protein (APP), amyloid-β peptide (Aβ), the β- and γ-secretases that release Aβ from APP by proteolytic cleavage, the microtubule-associated protein tau, the lipid carrier apolipoprotein E (apoE), and α-synuclein, which also plays an important role in Parkinson's disease. For each molecule, we briefly review its normal function and the evidence for its involvement in AD and then examine studies of its relationship to memory deficits in both humans and animal models.

4.15.2.1 APP and Aβ

APP is a ubiquitously expressed, multifunctional type I membrane protein with potential roles in signaling (Turner et al., 2003), axonal transport (Kamal et al., 2000; Satpute-Krishnan et al., 2006),

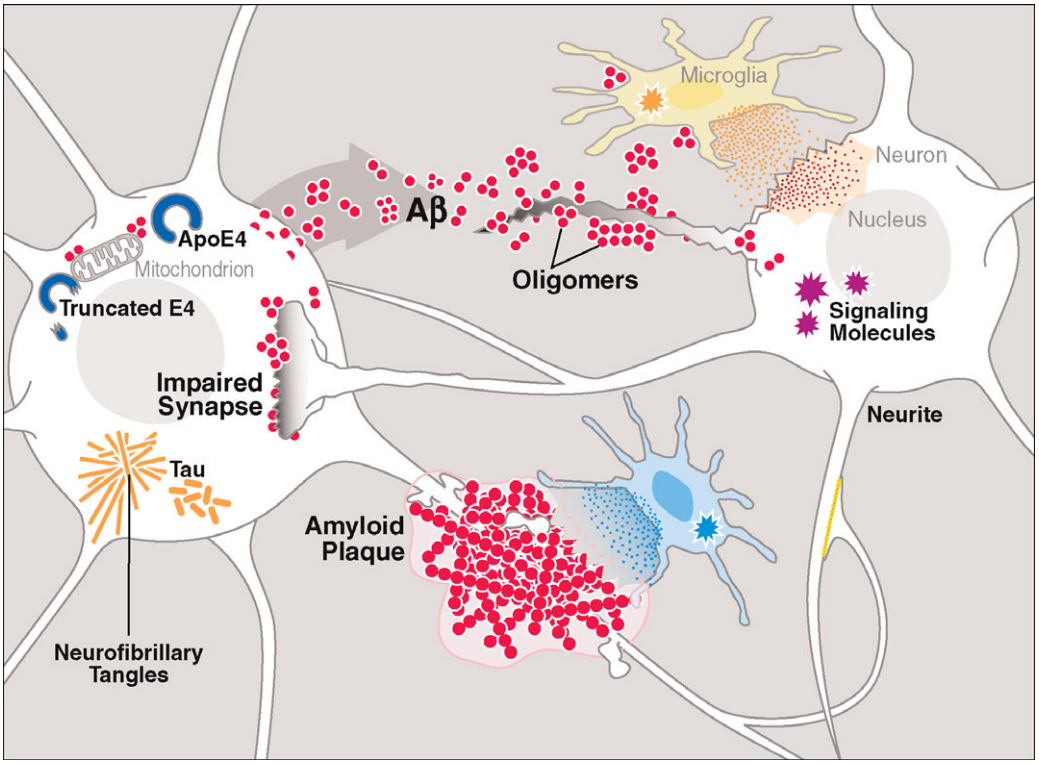

Figure 2 Key molecules involved in Alzheimer's disease pathogenesis. Aβ peptides produced by neurons and other brain cells aggregate into a variety of assemblies, including amyloid plaques containing Aβ fibrils and soluble nonfibrillar oligomers. Some of these Aβ assemblies impair synapses and neuronal dendrites, either directly or through the engagement of pathogenic glial loops. However, other glial activities protect neurons against dysfunction and degeneration. ApoE4 and tau promote Aβ-induced neuronal injury and also have independent adverse effects. (From Roberson ED and Mucke L [2006] 100 years and counting: Prospects for defeating Alzheimer's disease. *Science* 314: 781–784.)

transcriptional regulation (Cao and Südhof, 2001), neurite outgrowth (Leyssen et al., 2005), synaptogenesis (Mucke et al., 1994; Morimoto et al., 1998), and regulation of glutamate uptake (Masliah et al., 1998). APP-null mice have deficits in learning and memory, abnormal long-term potentiation (LTP), and loss of synapses (Dawson et al., 1999; Seabrook et al., 1999).

Proteolytic cleavage of APP produces several biologically active fragments. Among them are Aβ peptides, produced by the sequential action of two proteases, β- and γ-secretase, on APP (**Figure 3**). Aβ peptides of 40 (Aβ40) or 42 (Aβ42) amino acids in length are the primary species produced. Aβ42 is believed to be more pathogenic, since it is more prone to aggregation and more toxic when applied to cells than Aβ40 (Jarrett et al., 1993; Seilheimer et al., 1997). Aβ has been shown to decrease synaptic transmission (Hsia et al., 1999; Kamenetz et al., 2003; Priller et al., 2006) or LTP (Lambert et al., 1998; Walsh et al., 2002), which may represent physiological functions, pathogenic mechanisms, or both. Neuronal activity stimulates the production and release of Aβ, which in turn depresses excitatory synaptic transmission, at least at certain synapses (Kamenetz et al., 2003). Under normal circumstances, this feedback loop could help regulate synaptic activity. In AD, aberrant neuronal activity might turn this feedback loop into a vicious cycle that increases Aβ production and impairs neurotransmission (Palop et al., 2006, 2007).

A great deal of additional biochemical and genetic evidence suggests an involvement of Aβ in AD, which forms the basis of the 'amyloid hypothesis' of AD pathogenesis (Hardy and Higgins, 1992; Tanzi and Bertram, 2005). Aβ is the major constituent of amyloid plaques, one of the pathological hallmarks of AD (Glenner and Wong, 1984). Mutations in APP cause autosomal dominant AD (Goate et al., 1991); AD-causing APP mutations are concentrated around the Aβ domain, and most increase the Aβ42/Aβ40 ratio or total Aβ production (Theuns et al., 2006). Presenilin mutations, the other major known cause of autosomal dominant AD, also increase the relative

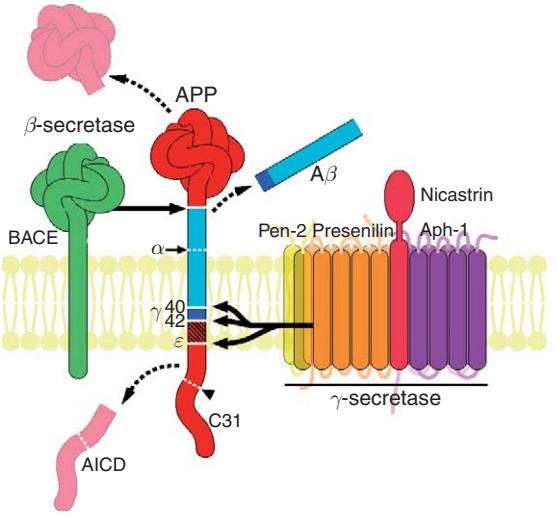

Figure 3 APP, Aβ, and the secretases. Aβ production depends on sequential proteolytic cleavage of APP by β-secretase, also known as β-site APP-cleaving enzyme 1 (BACE1), and the γ-secretase complex, composed of presenilin and other proteins. γ-Secretase can cleave APP at different locations to generate Aβ40, Aβ42, or the APP intracellular domain (AICD). Caspase cleavage at the carboxy-terminus yields the C31 fragment. (Modified from Roberson ED and Mucke L [2006] 100 years and counting: Prospects for defeating Alzheimer's disease. Science 314: 781–784.)

abundance of Aβ42 (see the section titled 'γ-Secretase') (Levy-Lahad et al., 1995; Rogaev et al., 1995; Sherrington et al., 1995). In addition, polymorphisms in the gene for insulin-degrading enzyme, which degrades Aβ, may contribute to AD risk (Ertekin-Taner et al., 2004).

The first animals with prominent AD-like pathology, and still the most widely studied, were transgenic mice with neuronal expression of human APP (hAPP) carrying familial AD mutations (Games et al., 1995; McGowan et al., 2006). These mice have high levels of Aβ and several, but not all, of the neuropathological hallmarks of AD. For example, age-dependent plaque deposition is a universal feature, whereas tangles do not develop. Because hAPP mice develop age-dependent learning and memory abnormalities (Kobayashi and Chen, 2005; McGowan et al., 2006), these models provide an opportunity to test hypotheses about how Aβ contributes to cognitive impairment in AD.

At a molecular level, there are a variety of hypotheses for how Aβ might interfere with normal neuronal function and survival. For example, Aβ can bind directly to lipid bilayers, altering membrane fluidity (Müller et al., 2001). It also forms pores or otherwise permeabilizes membranes, increasing their conductance to ion flow (Pollard et al., 1995; Kayed et al., 2004). In addition, Aβ binds to and influences the function of a variety of cellular proteins (Verdier et al., 2004), including the α7 nicotinic acetylcholine receptor (Oddo and LaFerla, 2006), integrins (Sabo et al., 1995), the receptor for advanced glycation end-products (RAGE; Yan et al., 1996), mitochondrial enzymes (Lustbader et al., 2004), and the APP holoprotein (Shaked et al., 2006). Several of these interactions are discussed in more detail in the section titled 'Memory-related molecules in AD.'

4.15.2.1.1 Aβ and plaques

The deposition of Aβ into amyloid plaques has been the focus of much AD research, given the prominence of plaques in AD patients and related animal models and their relative ease of detection. Plaque deposition in AD brains has historically been studied with neuropathological methods, including histochemical staining with amyloid-binding dyes and immunostaining with Aβ antibodies. It can now be imaged *in vivo* in living human subjects by positron emission tomography with a plaque-binding agent termed Pittsburgh compound B (PIB) (Klunk et al., 2004) (**Figure 4**).

The leading hypothesis for how plaques might disrupt neuronal function is by inducing changes in surrounding neurites. A subset of amyloid plaques in both AD patients and mouse models, termed neuritic plaques, are surrounded by swollen and tortuous neuronal processes (Knowles et al., 1999; Tsai et al., 2004). Plaque-associated neuritic dystrophy may alter the electrophysiological properties of the circuits involved (Knowles et al., 1999; Stern et al., 2004).

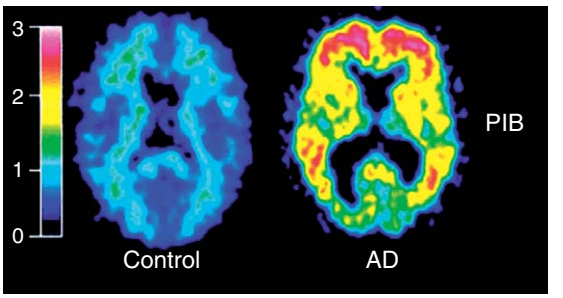

Figure 4 *In vivo* imaging of amyloid plaques with Pittsburgh compound B (PIB). PIB–positron emission tomography scan of a 79-year-old patient with AD shows a robust signal attributable to amyloid plaque binding, compared with a 67-year-old control subject. (From Klunk WE, Engler H, Nordberg A, et al. [2004] Imaging brain amyloid in Alzheimer's disease with Pittsburgh Compound-B. *Ann. Neurol.* 55: 306–319.)

However, plaque deposition does not correlate well with memory deficits in AD. Amyloid deposition tends to be an early event in AD pathogenesis that plateaus and does not worsen as cognition deteriorates throughout the disease course (Arriagada et al., 1992; Ingelsson et al., 2004; Giannakopoulos et al., 2007). Also, plaques do not have the preferential distribution in medial temporal structures involved in memory that is seen with NFTs (see the section titled 'NFTs, neuronal death, and memory loss'). Rather, plaques are seen first in the neocortex, particularly in prefrontal and posterior parietal regions (Price et al., 1991; Buckner et al., 2005; Kemppainen et al., 2006). Data from animal models also support a mechanistic dissociation between plaques and cognitive deficits (Holcomb et al., 1998; Westerman et al., 2002; Palop et al., 2003; Kobayashi and Chen, 2005; Lesné et al., 2006; Cheng et al., 2007). While neuritic dystrophy correlates with cognitive deficits better than plaque load (McKee et al., 1991), many dystrophic neurites in AD brains are not associated with plaques (Wang and Munoz, 1995). Recent findings in hAPP transgenic mice suggest that vascular amyloidosis and oxidative stress may contribute to the pathogenesis of plaque-independent neuritic dystrophy (Esposito et al., 2006).

4.15.2.1.2 Soluble Aβ oligomers

Because deposition of fibrillar Aβ in plaques does not correlate well with cognitive deficits, interest has grown in nonfibrillar forms of Aβ. Increasing evidence points to a pathogenic role for oligomeric Aβ assemblies that are soluble in aqueous solutions. Multiple types of Aβ oligomers have been described, including low-molecular-weight species (dimers and trimers) and larger globular species (including dodecamers and Aβ-derived diffusible ligands) (Podlisny et al., 1995; Lambert et al., 1998; Lesné et al., 2006). Putative Aβ oligomers have been detected in the cerebrospinal fluid (CSF) and brain tissue of AD patients (Podlisny et al., 1995; Kuo et al., 1996; Pitschke et al., 1998; Kayed et al., 2003; Lacor et al., 2004) and hAPP transgenic mice (Podlisny et al., 1995; Lambert et al., 1998; Lesné et al., 2006; Cheng et al., 2007). Extracellularly, oligomers seem to bind preferentially to dendritic and synaptic regions (Lacor et al., 2004; Barghorn et al., 2005). Aβ42 is more prone to oligomer formation than Aβ40 (Dahlgren et al., 2002; Bitan et al., 2003), which may relate to their relative pathogenicity (Aβ42 > Aβ40).

In mixed neuronal/glial cultures and brain slices, oligomeric Aβ is a potent neurotoxin, inducing neuronal death within 24 h (Roher et al., 1996; Lambert et al., 1998; Chen et al., 2005a). Direct experimental comparisons suggest that oligomeric Aβ is more toxic than fibrillar or monomeric Aβ (Klein et al., 2001; Dahlgren et al., 2002).

At physiological concentrations, Aβ oligomers interfere with synaptic plasticity, and memory. Both low-molecular-weight and larger globular oligomers interfered with LTP when acutely applied to hippocampal slices, whereas monomers did not (Lambert et al., 1998; Wang et al., 2004; Barghorn et al., 2005; Walsh et al., 2005). Injection of oligomeric Aβ into the cerebral ventricles blocked LTP *in vivo* and impaired learning and memory (Walsh et al., 2002; Cleary et al., 2005; Lesné et al., 2006). The effects of Aβ on LTP are acute and independent of neuronal death (Chen et al., 2000). Although oligomer-induced blockade of LTP in hippocampal slices could not be reversed by washing out Aβ (Townsend et al., 2006), *in vivo* impairment of LTP by oligomers could be blocked when Aβ antibodies were injected after the Aβ (Klyubin et al., 2005).

4.15.2.1.3 Neuronal dysfunction versus neuronal death

The ability of Aβ to induce both neuronal dysfunction and neuronal death raises the question of which effect is primarily responsible for the memory deficits in AD. Evidence from animal models points toward an important role for neuronal dysfunction. First, although hAPP mice have memory deficits, most lines do not have prominent neuron loss in the areas most affected in AD, including entorhinal cortex and hippocampal area CA1 (Irizarry et al., 1997a,b; Takeuchi et al., 2000). Also, memory impairment in hAPP mice can be rapidly reversed by treatments that lower Aβ levels but are not likely to change neuron numbers (Dodart et al., 2002; Kotilinek et al., 2002). Rather than frank neuronal loss, hAPP mice have synaptodendritic changes, including reduction of presynaptic terminals, loss of postsynaptic spines, and simplification of dendritic arborization, that may contribute to cognitive impairment (Mucke et al., 2000; Buttini et al., 2002; Lanz et al., 2003; Chin et al., 2004; Moolman et al., 2004; Wu et al., 2004; Spires et al., 2005). Whether these alterations would ultimately lead to neuronal loss if mice had a longer lifespan is unknown. It is also unknown how long it takes neurons to die in the brains of humans with AD.

Differentiating the relative contributions of neuronal dysfunction and neuronal loss to cognitive deficits in AD patients has been difficult, because

neuron loss is commonly found early in the disease (Price et al., 2001). However, several observations suggest that dysfunction may at least add to the impairments that are likely to result from progressive neuronal loss. Synaptodendritic alterations similar to those observed in hAPP mice are also observed in AD (Terry et al., 1991; Masliah et al., 2001a; Shim and Lubec, 2002; Moolman et al., 2004). Synaptic loss is an early event that correlates with cognitive impairment in AD (Terry et al., 1991; Masliah et al., 2001a). In addition, synaptic failure may precede and contribute to neuronal death (Selkoe, 2002). Finally, the frequent fluctuations in cognition seen in AD patients cannot be explained by sudden changes in neuronal numbers and are likely a manifestation of neuronal dysfunction (Palop et al., 2006).

4.15.2.1.4 Other APP fragments

Aβ is not the only biologically active APP fragment. γ-Secretase cleavage liberates a carboxy-terminal fragment known as the APP intracellular domain (AICD). The AICD activates the adapter protein Fe65, which translocates to the nucleus and regulates gene expression (Cao and Südhof, 2001, 2004). The AICD/Fe65 pathway stimulates expression of many genes, including neprilysin, a peptidase that degrades Aβ (Pardossi-Piquard et al., 2005), the P53 tumor suppressor, which controls programmed cell death (Alves da Costa et al., 2006), and components of the cytoskeleton (Müller et al., 2006). The AICD also modulates calcium stores in the endoplasmic reticulum (Leissring et al., 2002). While AICD-dependent changes in gene expression may be a factor in patients with APP mutations (Wiley et al., 2005), their importance in sporadic AD remains unclear. AICD levels and some cytoskeletal target genes are unchanged, while others are upregulated, and neprilysin expression is decreased (Wang et al., 2005; Müller et al., 2006).

The ectodomain of APP can be shed by α- or β-secretase, generating secreted APP fragments known as sAPPα and sAPPβ, respectively. Ectodomain shedding is a prerequisite for γ-secretase cleavage and, thus, Aβ and AICD production. sAPP may have independent effects, particularly neuroprotective and neurotrophic activities (Mattson, 1997; Kerr and Small, 2005; Zheng and Koo, 2006).

Finally, APP is cleaved by caspase(s) at a site 31 amino acids from the carboxy terminus; the resulting C-terminal fragment is termed C31 (Gervais et al., 1999; Lu et al., 2000). Transgenic mice expressing hAPP with a mutation that prevents this cleavage have less pronounced cognitive impairment than mice expressing caspase-sensitive hAPP (Galvan et al., 2006). The favorable effect of this mutation may be a result of reduced generation of C31, which is neurotoxic (Lu et al., 2000; Galvan et al., 2002). It may also be caused by changes in protein–protein interactions involving the APP carboxy terminus, including APP multimerization (Lu et al., 2003) and interactions with motor proteins (Satpute-Krishnan et al., 2006).

4.15.2.2 BACE

The first step in production of Aβ from APP is shedding the large APP ectodomain by β-secretase (**Figure 3**). The primary β-secretase enzyme is an aspartyl protease termed β-site APP cleaving enzyme (BACE1, also known as Asp2, memapsin 2) (Hussain et al., 1999; Sinha et al., 1999; Vassar et al., 1999; Yan et al., 1999). Genetic deletion of BACE1 dramatically reduces Aβ levels (Roberds et al., 2001) and prevents Aβ-dependent cognitive deficits in hAPP mice (Ohno et al., 2006). Thus, BACE1 inhibition is an attractive potential AD therapy.

Two aspects of BACE physiology are of particular interest in relation to synaptic transmission and neuronal function. First, BACE activity, at least its cleavage of APP, is dynamically regulated and increases with neuronal activity (Kamenetz et al., 2003). This effect contributes to a putative feedback loop whereby increased neuronal activity stimulates Aβ production, which in turn can suppress synaptic transmission (Kamenetz et al., 2003). Alterations in BACE regulation may be important in AD pathogenesis, as BACE activity is increased in AD (Holsinger et al., 2002) and after other types of neuronal injury (Blasko et al., 2004). Second, BACE1 has other substrates beyond APP, many of which affect neuronal function (**Table 1**). Among these are neuregulin 1, a

ligand in the ErbB signaling pathway (Willem et al., 2006). In the absence of BACE cleavage, lack of neuregulin/ErbB signaling results in peripheral nerve hypomyelination (Willem et al., 2006). Cleavage of substrates besides APP may also contribute to AD. Mice overexpressing human BACE1 have neurodegeneration and memory deficits (Rockenstein et al., 2005). However, these effects are not a result of increases in Aβ levels, which are actually lower in BACE-overexpressing mice than in mice with normal BACE levels (Lee et al., 2005; Rockenstein et al., 2005), presumably because BACE overexpression promotes APP processing in an earlier component of the secretory pathway (Lee et al., 2005).

4.15.2.3 Presenilins

Shortly after the discovery that mutations in the APP gene cause autosomal dominant AD, two other genes were found in other families with early-onset AD: presenilin 1 (PS1) on chromosome 14 and presenilin 2 (PS2) on chromosome 1 (Levy-Lahad et al., 1995; Rogaev et al., 1995; Sherrington et al., 1995). PS1 mutations have since proven to be the most common cause of dominantly inherited AD, responsible for more than 50% of cases. Over 150 different mutations spanning the protein have been identified. PS2 mutations are much less common and tend to produce a somewhat less severe phenotype (Bertram and Tanzi, 2004). PS1 and PS2 are 67% identical and are ubiquitously expressed in the brain and other tissues.

The normal functions of the presenilins were unknown at the time of their discovery and are still being elucidated today. Most attention has focused on presenilin's role in Aβ production as a key component of γ-secretase. However, diverse γ-secretase-independent roles of presenilins continue to emerge, and controversy remains about the degree to which these roles contribute to AD and whether the AD-linked mutations cause primarily a gain or loss of function.

4.15.2.3.1 γ-Secretase

The presenilins are membrane-embedded aspartyl proteases that form the catalytically active center of the γ-secretase complex, along with nicastrin, Aph-1, and Pen-2 (De Strooper et al., 1998; Edbauer et al., 2003). γ-Secretase cleaves type I membrane proteins within their transmembrane domains (reviewed in Wolfe, 2006). Its substrate selectivity is rather broad, with the main requirement being a short extracellular domain (Struhl and Adachi, 2000). Thus, γ-secretase has many substrates (**Table 2**).

One of these is, of course, APP. Shedding of the large extracellular domain of APP by α- or β-secretase generates carboxy-terminal fragments (CTFs) that make suitable substrates for γ-secretase (**Figure 3**). The γ-secretase complex can cleave β-CTF at different sites, generating either Aβ40 or Aβ42. PS mutations favor production of Aβ42 over Aβ40 (Borchelt et al., 1996; Scheuner et al., 1996). Given the considerable evidence that Aβ42 is more pathogenic (see the section titled 'APP and Aβ'), this effect is believed to be an important mechanism by which PS mutations lead to AD. γ-Secretase is also responsible for generation of the AICD (see the section titled 'Other APP fragments').

4.15.2.3.2 γ-Secretase-independent roles of presenilins

In addition to their role in Aβ production, presenilins have several other functions, many of which are independent of γ-secretase, as they are not blocked by γ-secretase inhibitors or by point mutations that abolish secretase activity.

Several of these functions relate to calcium regulation. Presenilin mutations increase calcium release from the endoplasmic reticulum induced by inositol-1,4,5-trisphosphate (IP_3) (reviewed in LaFerla, 2002). One mechanism for this effect seems to be overfilling endoplasmic reticulum (ER) Ca^{2+} stores (Leissring et al., 2000). Presenilins form calcium leak channels

in the ER membrane; this function is lost in AD-associated mutants, leading to overfilling of the ER with Ca^{2+} (Tu et al., 2006). Others have pointed to an upregulation of IP_3 receptors in presenilin-deficient cells as another possible cause for increased calcium release (Kasri et al., 2006). Whatever the underlying mechanism, the resulting increases in intracellular calcium release induced by presenilin mutations are likely to contribute to neuronal dysfunction.

Presenilin also regulates intracellular signaling pathways that control tau phosphorylation. Presenilin stabilizes cadherin–cadherin complexes that interact with and activate phosphatidylinositol-3 kinase, stimulating Akt activity, which, in turn, suppresses glycogen synthase kinase (GSK) activity and tau phosphorylation (Baki et al., 2004). This γ-secretase-independent effect of presenilin in preventing tau phosphorylation is lost in AD-associated mutants and, thus, may enhance tau-mediated neurotoxicity (Baki et al., 2004).

Conditional PS1/PS2 double-knockout mice have learning and memory impairments, LTP deficits, aberrant tau phosphorylation, and neurodegeneration, although their Aβ levels are not increased (Saura et al., 2004), suggesting that mutations impairing APP-independent PS functions could also contribute to AD-related deficits.

4.15.2.4 Tau

Tau is a small microtubule-associated protein (MAP) and a member of the MAP2 superfamily (Weingarten et al., 1975; Cleveland et al., 1977; Dehmelt and Halpain, 2005). It has a variety of functions, including stabilizing microtubules, enabling neurite outgrowth, regulating axonal transport and controlling neuronal susceptibility to overexcitation (Shahani and Brandt, 2002; Avila et al., 2004; Roberson et al., 2007). Tau knockout mice are surprisingly normal, with no abnormalities in general health, fertility, longevity, gross brain cytoarchitecture, or learning and memory (Harada et al., 1994; Ikegami et al., 2000; Dawson et al., 2001; Tucker et al., 2001; Roberson et al., 2007). This may be, at least in part, the result of compensation by other MAPs, since double knockouts lacking both tau and MAP1B have 80% mortality in the first few weeks postnatally (Takei et al., 2000). Microdeletions on chromosome 17q21 including the tau gene are associated with mental retardation in humans (Lupski, 2006), but these deletions also involve several other genes. The fact that tau knockout mice have a very mild phenotype suggests that the loss of other genes might underlie the deficits associated with these deletions.

Tau was first implicated in AD by the discovery that NFTs are composed of heavily phosphorylated tau forming paired helical filaments (Grundke-Iqbal et al., 1986; Kosik et al., 1986; Wood et al., 1986; Lee et al., 1991). Interestingly, mutations in tau cause frontotemporal dementia, but not AD (Rademakers et al., 2004). However, the tau gene contains several polymorphisms that are in linkage disequilibrium, creating several unique haplotypes, one of which is associated with AD (Myers et al., 2005). The high-risk haplotype, known as H1c, is associated with roughly 10% more tau expression than other haplotypes (Kwok et al., 2004). This is consistent with the observation that reducing tau expression is protective in mouse models of AD (Roberson et al., 2007). The H1c haplotype also affects splicing of tau. Transcripts of the single tau gene are alternatively spliced to generate six different isoforms in adults (**Figure 5**). The most important distinction is between those isoforms with three copies of the microtubule-binding domain (termed 3R tau) and those with four (4R). The H1c haplotype is associated with slightly higher production of 4R than 3R tau (Myers et al., 2007). The mechanism by which these differences in tau expression raise AD risk is unclear.

4.15.2.4.1 NFTs, neuronal death, and memory loss

The study of tau's contribution to memory dysfunction in AD has concentrated largely on NFTs. Interest in NFTs dates all the way back to Alzheimer's original report (1907), which focused more on tangles than on plaques. Two observations form the basis of the hypothesis that tangles produce memory deficits in AD. First, the regional distribution of NFTs, which evolves in a stereotypical manner over the course of the illness, begins in medial temporal structures involved in memory (Braak and Braak, 1991). Tangles first appear in the transentorhinal region (stage I), then the entorhinal cortex (stage II), hippocampus (stage III), temporal neocortex (stage IV), and eventually other neocortical areas (stages V–VI) (**Figure 6**). Second, NFT counts correlate with clinical dementia severity, unlike amyloid plaque deposition, which does not (Giannakopoulos et al., 2007; but see Näslund et al., 2000).

Neuron loss may be a key mechanism underlying the connection between tau aggregation into NFTs and memory deficits. NFT burden correlates with the severity of neuronal loss (Giannakopoulos et al., 2007). NFT counts also correlate with levels of CSF tau, which increase in AD, possibly as a result of tau release

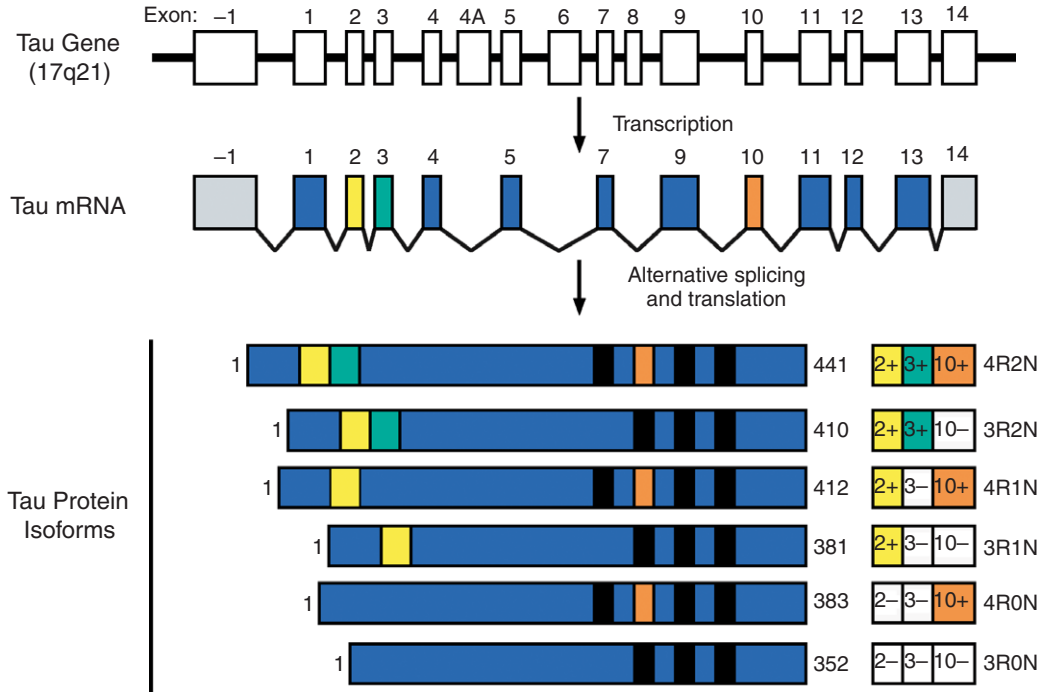

Figure 5 Alternative splicing of tau isoforms. The tau RNA can be alternatively spliced to include zero, one, or two amino-terminal inserts encoded by exons 2 and 3. Isoforms contain either three or four microtubule-binding domains, depending on whether exon 10 is included. (Modified from Buée L, Bussière T, Buée-Scherrer V, et al. [2000] Tau protein isoforms, phosphorylation and role in neurodegenerative disorders. *Brain Res. Rev.* 33: 95–130.)

from dying neurons (Arai et al., 1995; Tapiola et al., 1997; Giannakopoulos et al., 2007). Increased CSF tau is associated with poorer cognitive performance (Wallin et al., 2006) and a higher risk of progressing from MCI to AD (Blennow and Hampel, 2003).

Animal and cellular models also support a link between tau aggregation and neuron death (McGowan et al., 2006). Many transgenic mouse lines expressing human tau with mutations that favor tau aggregation display memory deficits and neuron loss (Lewis et al., 2000; Tatebayashi et al., 2002; Pennanen et al., 2004; McGowan et al., 2006). Overexpression of tau in large neurons of the lamprey leads to fibrillar tau aggregates and neuronal degeneration, an effect blocked by compounds that inhibit tau aggregation (Hall et al., 2001, 2002). Expression of aggregation-prone tau mutants in cultured neuroblastoma cells also causes toxicity that can be reversed by point mutations or small molecules that block aggregation (Khlistunova et al., 2006).

4.15.2.4.2 Tangle-independent roles for tau

There are limitations to the data suggesting a connection between NFTs and cognitive decline. Because much of the human data are correlational, they cannot establish causal relationships. Notably, animal model data indicate that aggregation is not the only means by which tau can impair neuronal and cognitive functions. Tau overexpression induced neurodegeneration in *Drosophila* in the absence of NFTs (Wittmann et al., 2001). Even in tau transgenic mice that have NFTs, neurodegeneration affects cells that do not have tau aggregates (Andorfer et al., 2005; Spires et al., 2006). Nonfibrillar tau might induce neuronal death by stimulating cell cycle reentry in normally postmitotic neurons (Andorfer et al., 2005; Khurana et al., 2006), although other mechanisms are possible also. The rTg4510 model has an inducible mutant tau transgene that, when turned on, causes NFT formation, severe neuronal loss, and spatial memory impairment (Ramsden et al., 2005; SantaCruz et al., 2005). However, suppressing transgene expression reverses the memory deficits, even though NFT formation continues, dissociating these processes (SantaCruz et al., 2005).

The mechanisms underlying these effects of tau on neuronal function have not yet been determined, although some leads exist. Abnormal tau can interfere with axonal transport (Ebneth et al., 1998; Ishihara et al., 1999), which seems consistent with its role as a

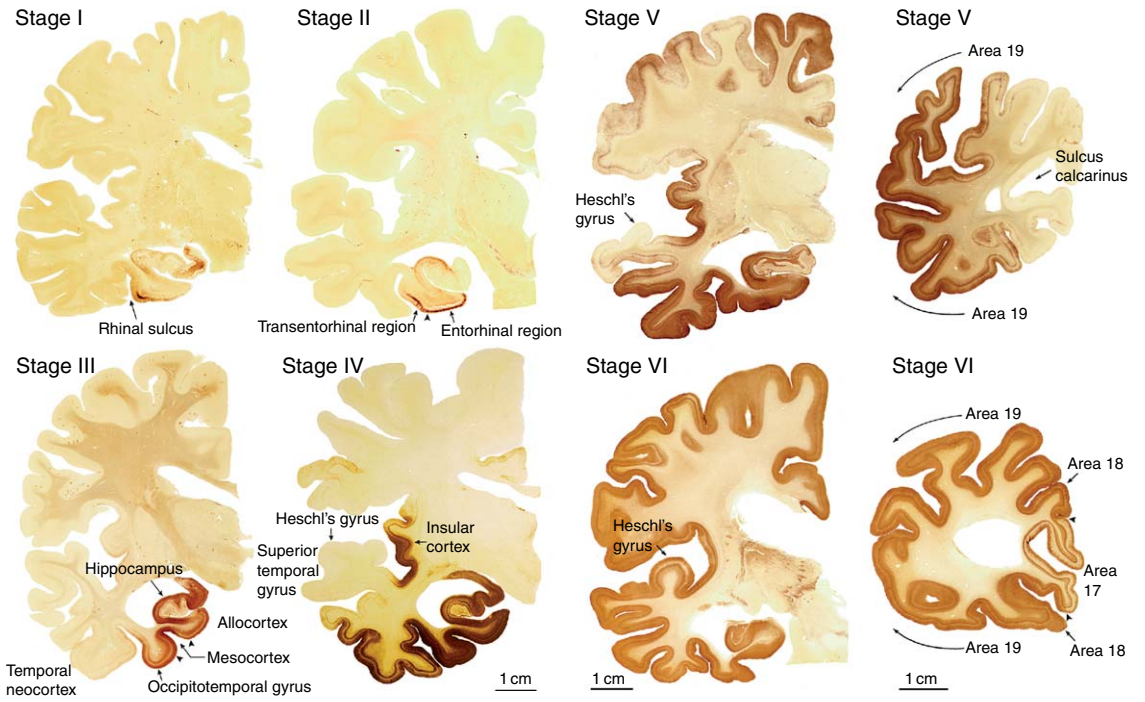

Figure 6 Stages of neurofibrillary pathology in Alzheimer's disease. Whole-brain sections were immunostained with antibody to phosphorylated tau. In stage I, involvement is limited to the transentorhinal region. Neurofibrillary pathology spreads to the entorhinal cortex in stage II. Stage III involves the hippocampus. Stage IV involves spread to the insula and inferior temporal neocortex. Finally, in stages V–VI even more neocortical areas are affected. (From Braak H, Rüb U, Schultz C, et al. [2006]. Vulnerability of cortical neurons to Alzheimer's and Parkinson's diseases. *J Alzheimers Dis* 9:35–44, with permission from IOS Press.)

microtubule-binding protein. Tau's influence on microtubule stability could also affect plasticity-related structural rearrangements, and some of these effects may relate to normal tau functions. Reversible synaptic regression during hibernation in certain rodents is associated with changes in tau, especially changes in its phosphorylation (Arendt et al., 2003). At young ages, before formation of aggregates or NFTs, tau transgenic mice have better-than-normal LTP in the dentate gyrus and longer-lasting memory than nontransgenic littermates (Boekhoorn et al., 2006), suggesting a role of soluble tau in cognitive function.

4.15.2.4.3 Tau phosphorylation and other posttranslational modifications

Aberrant tau phosphorylation is a hallmark of AD and seems to be carried out by many of the kinases involved in learning and memory (see the section titled 'Kinases'). Fully 19% of the amino acids in tau are potential phosphorylation sites (Ser, Thr, and Tyr), and many are in fact phosphorylated in AD brains (Stoothoff and Johnson, 2005). The vast majority of the phosphorylation sites are highly conserved across species and surround tau's microtubule-binding domains (**Figure 7**). Much effort has been devoted to

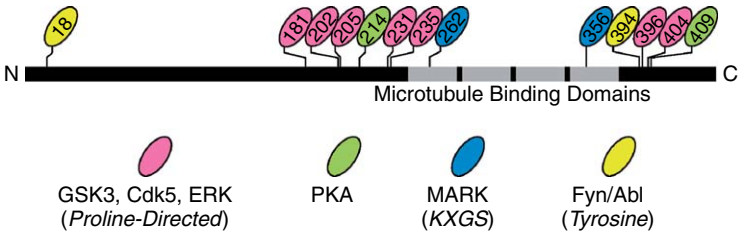

Figure 7 Tau phosphorylation sites. The four microtubule-binding domains are indicated by shading in a schematic line drawing of tau protein. Most tau phosphorylation sites surround the microtubule-binding regions.

sorting out which sites and kinases are most important in the pathogenesis of AD.

- Proline-directed kinase sites. Many tau phosphorylation sites are substrates for proline-directed kinases, which target Ser/Thr residues directly adjacent to a proline. These sites are substrates for glycogen synthase kinase 3 (GSK3), cyclin-dependent kinase 5 (Cdk5), and extracellular-signal regulated kinase (ERK), among others. Phosphorylation at these sites seems to be involved in the tau aggregation/cell death pathways mentioned above (Lucas et al., 2001; Augustinack et al., 2002; Cruz et al., 2003; Noble et al., 2003). For example, GSK3 stimulates tau aggregation (Sato et al., 2002), and GSK3 inhibition reduces tau aggregation and neurodegeneration (Noble et al., 2005).
- PKA sites. Tau is phosphorylated by cyclic AMP-dependent protein kinase (PKA), preferentially at Ser214 (Scott et al., 1993). Phosphorylation of Ser214 inhibits tau's microtubule binding and stabilizing activity (Illenberger et al., 1998). The PKA sites are near the proline-directed sites, and tau phosphorylation by PKA facilitates phosphorylation by proline-directed kinases (Singh et al., 1996; Liu et al., 2004) but may inhibit aggregation (Schneider et al., 1999).
- KXGS sites. The PKA and proline-directed sites are concentrated at both ends of the four microtubule-binding domains of tau. Within these domains are sites with a Lys-Xxx-Gly-Ser (KXGS) consensus sequence, most notably Ser262 and Ser356. These sites are phosphorylated by microtubule-affinity regulating kinase (MARK), which dramatically reduces tau's ability to stabilize microtubules (Drewes et al., 1997) and facilitates neurite outgrowth (Biernat et al., 2002). This phosphorylation may also be a prerequisite for phosphorylation at proline-directed kinase sites (Nishimura et al., 2004; but see Biernat and Mandelkow, 1999).
- Tyrosine phosphorylation. In AD brains, tau is also phosphorylated on tyrosine residues, primarily Tyr18 by Fyn and Tyr394 by Abl (Williamson et al., 2002; Lee et al., 2004; Derkinderen et al., 2005). There is considerable evidence for a role of Fyn in AD (Lambert et al., 1998; Chin et al., 2004, 2005; Lee et al., 2004), as reviewed further in the section titled 'Fyn.' Interestingly, interactions between tau and Fyn may contribute to the subcellular localization of Fyn and, thus, affect its substrate availability (Lee et al., 1998). In addition, disease-associated tau phosphorylation and mutations strongly increase Fyn binding (Bhaskar et al., 2005).
- Tau proteolysis. The carboxy terminus of tau can be cleaved by activated caspases, producing a truncated tau that aggregates more easily than full-length tau (Cotman et al., 2005). This may be an important step leading to development of tangles in AD, as tau cleavage at this site is a relatively early event in NFT formation (Rissman et al., 2004; Guillozet-Bongaarts et al., 2005). Tau is also cleaved by calpain, which produces a 17-kD tau fragment that is toxic to cultured neurons (Park and Ferreira, 2005).

4.15.2.4.4 *Tau and Aβ*

Given the prominence of Aβ and tau in AD pathology, their relationship is of considerable interest. Although expression of human Aβ does not induce NFTs in hAPP transgenic mice, it increases tangle formation in hAPP mice coexpressing mutant human tau; in contrast, expression of mutant human tau does not seem to worsen Aβ-dependent pathologies in hAPP mice (Lewis et al., 2001; Götz et al., 2001). In such multiple transgenic models, Aβ immunotherapy decreases tau pathology, further suggesting that Aβ acts upstream of tau (Oddo et al., 2004). Plausible mechanisms include Aβ-induced kinase activation and resulting tau phosphorylation (see the section titled 'Kinases'). In addition, caspase activation by Aβ may stimulate tau proteolysis that favors aggregation (Cotman et al., 2005).

Calpain-mediated tau proteolysis seems to play an important role in Aβ toxicity *in vitro*. Tau-deficient primary neurons are resistant to the rapid neurodegeneration induced by Aβ application, apparently because they lack calpain-induced tau fragments that are toxic to neurons in culture (Rapoport et al., 2002; Park and Ferreira, 2005). Reducing tau even by just 50% ameliorated Aβ-induced memory deficits in a mouse model of AD (Roberson et al., 2007). Interestingly, this effect did not seem to involve removal of a tau species with Aβ-induced posttranslational modifications. Rather, tau reduction prevented Aβ-induced epileptiform activity and compensatory inhibitory remodeling of hippocampal circuits (Palop et al., 2007; Roberson et al., 2007).

4.15.2.5 ApoE

ApoE is a multifunctional lipoprotein originally discovered for its role in intercellular transport and distribution of cholesterol throughout the body (Mahley, 1988). The brain is second only to the liver

as a producer of apoE. In addition to mediating lipid transport within the central nervous system, apoE is involved in the response to neural injury and regulation of neurite outgrowth (Mahley and Rall, 2000).

Three main apoE isoforms are produced from different alleles ($\varepsilon 2$, $\varepsilon 3$, and $\varepsilon 4$) of a single *APOE* gene on chromosome 19; apoE2 and apoE4 differ from each other and from the more frequent apoE3 by single amino acid substitutions, which have major effects on apoE structure and function (**Figure 8**) (Hatters et al., 2006; Mahley et al., 2006).

ApoE was implicated in AD by the near-simultaneous discoveries that it binds Aβ and colocalizes to amyloid plaques (Namba et al., 1991; Strittmatter et al., 1993) and that *APOE* genotype has dramatic effects on AD risk and onset (Corder et al., 1993). Individuals with one, and particularly those with two, $\varepsilon 4$ alleles are much more likely to develop AD and have an earlier age of onset compared with $\varepsilon 3$ carriers, while $\varepsilon 2$ carriers are most resistant to the disease (**Figure 9**) (Corder et al., 1993). *APOE* $\varepsilon 4$ appears to be the most important genetic risk factor for sporadic AD (Farrer et al., 1997; Raber et al., 2004; Bertram et al., 2007); 40–60% of all sporadic AD patients have at least one $\varepsilon 4$ allele (Saunders et al., 1993).

These genetic studies established that apoE4 decreases the age at which AD becomes manifest. Interestingly, even in the absence of frank AD, individuals with apoE4 have abnormalities in cognitive performance and functional neuroimaging. In apoE4 carriers, the normal age-related decline in performance on episodic memory tasks occurs at an earlier age and progresses at a faster rate than in noncarriers, while other cognitive domains do not appear to be affected (Caselli et al., 1999, 2004). ApoE4 carriers are also more likely to develop cognitive deficits following open heart surgery or head injury (Tardiff et al., 1997; Teasdale et al., 1997). Even before cognitive impairment is detectable, apoE4 carriers have hypometabolism in the same regions affected in AD, including posterior parietal, posterior cingulate, and frontal cortex (Reiman et al.,

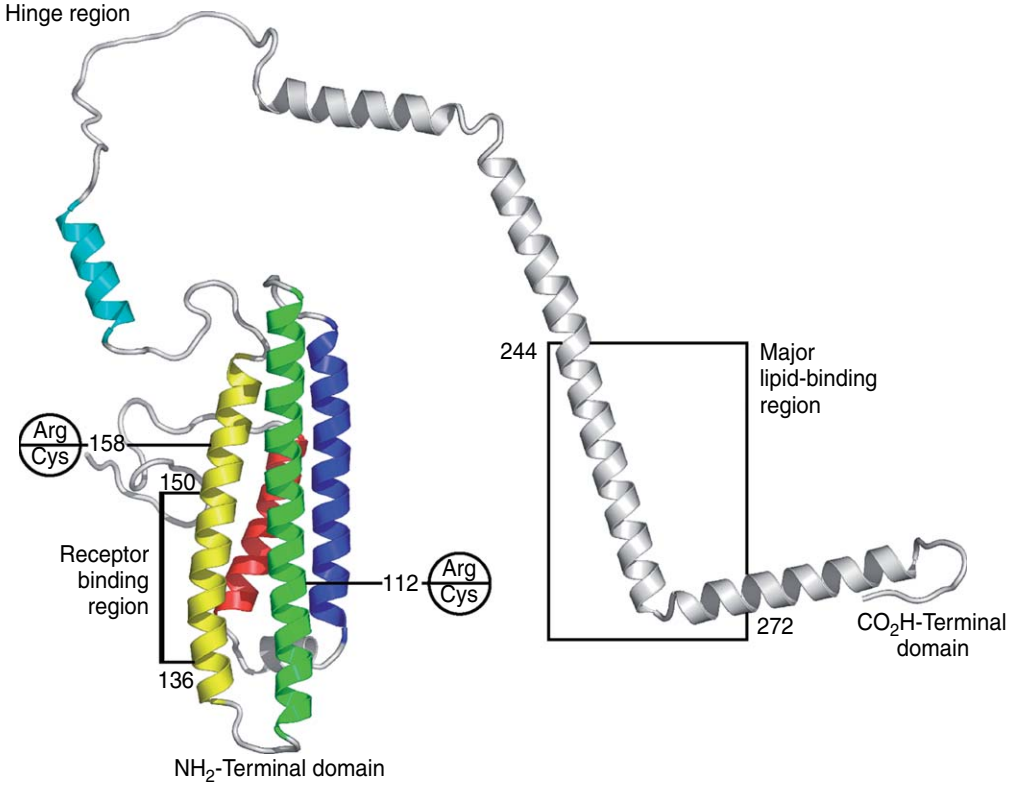

Figure 8 ApoE structure and isoforms. The apoE molecule consists of a globular amino-terminal domain that mediates receptor binding, while the lipid-binding region is in the carboxy-terminal domain. ApoE2 and apoE4 isoforms differ from the most common apoE3 by single amino acid substitutions. At amino acid positions 112 and 158, apoE3 contains Cys and Arg, whereas apoE2 contains Cys and Cys and apoE4 contains Arg and Arg. (From Hatters DM, Peters-Libeu CA, and Weisgraber KH [2006] Apolipoprotein E structure: Insights into function. *Trends Biochem. Sci.* 31: 445–454.)

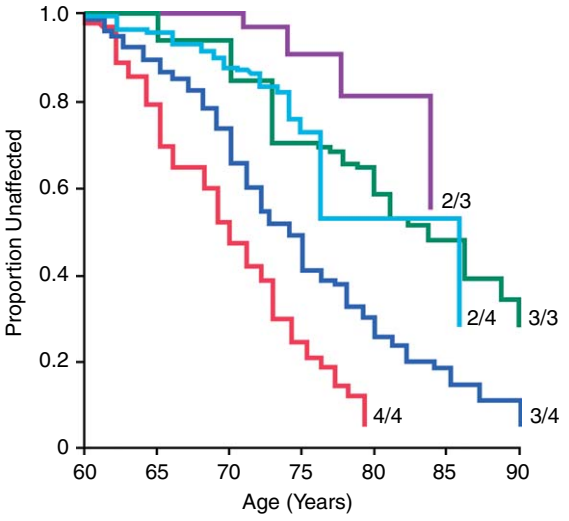

Figure 9 Effect of apoE genotype on AD risk. ApoE4 increases AD risk in a gene dose–dependent manner, while apoE2 lowers risk. (From Strittmatter WJ and Roses AD [1996] Apolipoprotein E and Alzheimer's disease. *Annu. Rev. Neurosci.* 19: 53–77.)

2004, 2005). These abnormalities are seen in apoE4 carriers as young as 20–39 years (Reiman et al., 2004).

4.15.2.5.1 Interactions between Aβ and apoE

ApoE4-related cognitive impairment is also seen in animal models, including mice expressing human apoE4 with or without hAPP/Aβ in neurons. ApoE3, but not apoE4, protects against hAPP/Aβ-induced cognitive deficits (Raber et al., 2000) and synaptic loss (Buttini et al., 2002). Remarkably, this effect is seen well before such mice form amyloid plaques. Consistent with these results, oligomeric Aβ impairs LTP more in slices from apoE4 knockin mice than apoE3 knockin mice (Trommer et al., 2005).

In addition, apoE has a prominent effect on Aβ aggregation and deposition. ApoE binds directly to Aβ and is a component of amyloid plaques (Namba et al., 1991; Strittmatter et al., 1993). ApoE4 is associated with increased deposition of amyloid plaques both in AD (Schmechel et al., 1993) and after head trauma (Nicoll et al., 1995). ApoE-deficient hAPP mice have almost no amyloid plaques (Bales et al., 1997). Compared with apoE3, apoE4 greatly increases amyloid plaque deposition in aged hAPP mice (Holtzman et al., 2000; Buttini et al., 2002). Given their effects on Aβ aggregation into fibrils and plaques, apoE isoforms may also have differential effects on Aβ aggregation into oligomers, although this has not yet been shown.

In addition to direct effects on Aβ aggregation, apoE4 increases Aβ production by stimulating endocytosis of APP-containing vesicles, which enter the endosomal pathway where much of Aβ is produced (Ye et al., 2005). ApoE also increases intracellular Aβ by enhancing its uptake from the extracellular space via the LDL receptor-related protein (LRP), although this effect is not isoform-dependent (Zerbinatti et al., 2006). Finally, once Aβ has been taken up into lysosomal vacuoles, apoE4 potentiates Aβ-induced lysosomal leakage and apoptosis (Ji et al., 2006).

4.15.2.5.2 Aβ-independent mechanisms for apoE4-induced neuronal impairments

Compared with apoE-deficient mice, female mice with neuronal expression of apoE4 develop age-dependent deficits in learning and memory even in the absence of Aβ (Raber et al., 1998, 2000), presumably because of apoE4-induced reductions in andogen receptor levels in the brain (see following). ApoE4 knockin mice also have LTP impairments not seen in apoE3 mice (Trommer et al., 2004). Neuronal expression of human apoE3, but not apoE4, protected mice lacking endogenous apoE against synaptodendritic damage elicited by excitotoxic drugs (Buttini et al., 1999). Notably, these excitoprotective effects of apoE3 were eliminated when apoE3 and apoE4 were coexpressed in the same mice, suggesting a dominant adverse effect of apoE4 (Buttini et al., 2000).

ApoE is also found in NFTs and has effects on tau (Namba et al., 1991). ApoE3 binds to tau, whereas apoE4 does not (Strittmatter et al., 1994). ε4 carriers have more NFTs than age-matched ε3 homozygotes (Ohm et al., 1999). ApoE4 also stimulates microtubule depolymerization (Nathan et al., 1995), possibly through effects on tau. Neuronal, but not astroglial, expression of apoE4 in transgenic mice increases tau phosphorylation (Tesseur et al., 2000). Neuronal expression of endogenous apoE occurs primarily after neuronal injury (Xu et al., 2006b). In neurons, apoE4 undergoes cleavage by a chymotrypsin-like protease activity, and E4 is more susceptible to cleavage than E3 (Huang et al., 2001). The resulting C-terminally truncated apoE stimulates tau phosphorylation and NFT formation (Huang et al., 2001; Brecht et al., 2004). Truncated apoE can escape the secretory pathway and enter the cytosol, where it binds to mitochondria and impairs their function (Mahley et al., 2006).

ApoE also has cerebrovascular effects that may contribute to memory dysfunction. ApoE4 carriers have higher plasma cholesterol levels (Hallman et al., 1991) and are at higher risk of carotid atherosclerosis (Terry

et al., 1996), coronary artery disease (Chen et al., 2003), and ischemic stroke (McCarron et al., 1999). The overlap between these cerebrovascular risks and AD is becoming increasingly clear (Martins et al., 2006).

There are interesting gender differences in the effects of apoE that point toward important interactions with sex hormones. Among ε4 carriers, women are more likely to develop AD than men (Payami et al., 1996), and female apoE4 mice are more susceptible to memory deficits than their male counterparts (Raber et al., 1998, 2000; Grootendorst et al., 2005). This difference may be the result of effects of apoE4 on androgen receptors. ApoE4 decreases androgen receptor levels in males and females, and females may be more susceptible to this effect because of their lower circulating androgen levels (Raber et al., 2002; Raber, 2004).

Last, apoE4 is intrinsically less stable than apoE3 (Morrow et al., 2002). As a result, brain apoE levels are lower in individuals with the ε4 allele, an isoform difference that has also been identified in apoE4 and apoE3 knockin mice (Gregg et al., 1986; Ramaswamy et al., 2005). Thus, in addition to the adverse gain-of-function effects described above, apoE4 may contribute to neurological impairments by a loss-of-function mechanism. Consistent with this notion, ApoE-deficient mice display age-dependent synaptic loss, deficient regenerative axonal sprouting after perforant pathway transection, and greater susceptibility to diverse neural injuries (Masliah et al., 1995a, b; Buttini et al., 1999, 2000; Krzywkowski et al., 1999).

4.15.2.6 α-Synuclein

α-Synuclein is a small, cytosolic protein that is enriched in presynaptic terminals; it regulates presynaptic function and neurotransmitter release (Chandra et al., 2004; Fortin et al., 2005). It is also the main component of Lewy bodies, neuronal inclusions associated with most forms of Parkinson's disease (PD) and other Lewy body diseases (Spillantini et al., 1997). Mutations in α-synuclein are linked to rare forms of autosomal dominant PD (Polymeropoulos et al., 1997). α-Synuclein also seems to play a role in the intriguing clinical and neuropathological overlap between PD and AD. Many AD patients have Lewy bodies, sometimes known as the Lewy body variant of AD, and many PD patients develop AD-like dementia (Perl et al., 1998), emphasizing the fact that AD is a polyproteinopathy combining the accumulation of abnormal assemblies or fragments of Aβ, tau, apoE, and α-synuclein.

The initial link between α-synuclein and dementia was established through the discovery of a so-called 'nonamyloid component' (NAC) of plaques in AD brains, which turned out to be a fragment of α-synuclein (Uéda et al., 1993; Iwai et al., 1995). α-Synuclein promotes Aβ aggregation *in vitro* (Yoshimoto et al., 1995), although it doesn't seem to increase amyloid plaque deposition *in vivo* (Masliah et al., 2001b). α-Synuclein does, however, worsen Aβ-induced neuronal deficits independently of plaques. Doubly transgenic mice expressing hAPP/Aβ and wild-type human α-synuclein in neurons displayed more synapse loss, greater reductions in choline acetyltransferase-positive neurons, and more severe cognitive impairments than the singly transgenic parental strains, even though α-synuclein had no effect on plaque formation *in vivo* (Masliah et al., 2001b). This study also revealed that Aβ strongly promotes α-synuclein aggregation, both *in vitro* and *in vivo*. α-Synuclein concentrations are elevated in synaptic boutons in AD brains, suggesting that α-synuclein also plays a role in synaptic pathology in the human condition (Masliah et al., 1996). Whether the underlying mechanisms relate to α-synuclein's normal functions or to its abnormal aggregation remains to be determined.

4.15.3 Memory-Related Molecules in AD

Although some of the major players in the pathobiochemistry of AD have been identified, it is just now beginning to be understood how these molecules affect neuronal function and impair learning and memory. Mouse models of AD recapitulate many aspects of the human disease, both in terms of pathology and in relation to behavioral/memory impairments. Indeed, transgenic mouse models have provided a unique opportunity for synergy between two historically separate fields of biomedical research – AD research and the basic scientific analysis of learning and memory. As reviewed below, research in the last 15 years has revealed that AD-relevant molecules such as Aβ, tau, and apoE affect several aspects of neuronal function and cellular mechanisms of plasticity that have been implicated in the formation of long-lasting memories.

4.15.3.1 Neurotransmitter Release

Reliable neurotransmission requires a steady supply of synaptic vesicles filled with neurotransmitter to be ready for release at the presynaptic terminal. Since trafficking of new synaptic vesicles from the cell body

can take several hours, nerve terminals are equipped with a special machinery that allows for local recycling and refilling of synaptic vesicles, a process that replenishes vesicle pools within seconds to minutes (Südhof, 2004; Fernandez-Alfonso and Ryan, 2006; Kavalali, 2006; Ryan, 2006). The number of recycling vesicles and the efficiency with which they fuse with (exocytosis) and are retrieved from (endocytosis) the presynaptic terminal plasma membrane set the boundaries on the duration and frequency of neurotransmission, particularly during repetitive stimulation. Thus, factors that affect vesicle cycling, particularly steps that are rate limiting, can have profound consequences on synaptic efficacy.

The fusion of synaptic vesicles with the presynaptic membrane and their recovery through endocytosis require a number of neuron-specific proteins. The levels of many proteins that coordinate the docking and fusion of synaptic vesicles are decreased in AD as well as in experimental models (Honer, 2003; Scheff and Price, 2003). Synaptophysin, one of the most abundant membrane proteins on synaptic vesicles, is integral to the vesicle fusion process for neurotransmitter release. Decreases in synaptophysin have been used extensively as a measure of synaptic impairments in both AD and transgenic mouse models of the disease (Masliah et al., 1993; Mucke et al., 2000; Honer, 2003; Scheff and Price, 2003). Decreased levels of proteins involved in vesicle release, such as synaptophysin, may represent decreased expression at intact synapses, synaptic degeneration, or both.

In addition, several proteins involved in the local endocytosis and recycling of vesicles, including synaptotagmin, AP2, AP180, and dynamin I, are altered in AD and in some mouse models of the disease, as illustrated in **Figure 10** (Honer, 2003; Yao, 2004; Nixon, 2005). Animal models in which any of these proteins are mutated or ablated exhibit abnormal synaptic vesicle size and number, synaptic transmission deficits, and even mortality in extreme cases (reviewed in Yao, 2004; Kavalali, 2006). For some factors, both protein and mRNA levels are decreased in AD, suggesting that the expression of the corresponding genes may be dysregulated. Other factors may be depleted by increased cleavage and degradation (Yao, 2004; Kelly et al., 2005; Kelly and Ferreira, 2006; but see Yao et al., 2005). Impaired vesicle recycling may also contribute to some of the

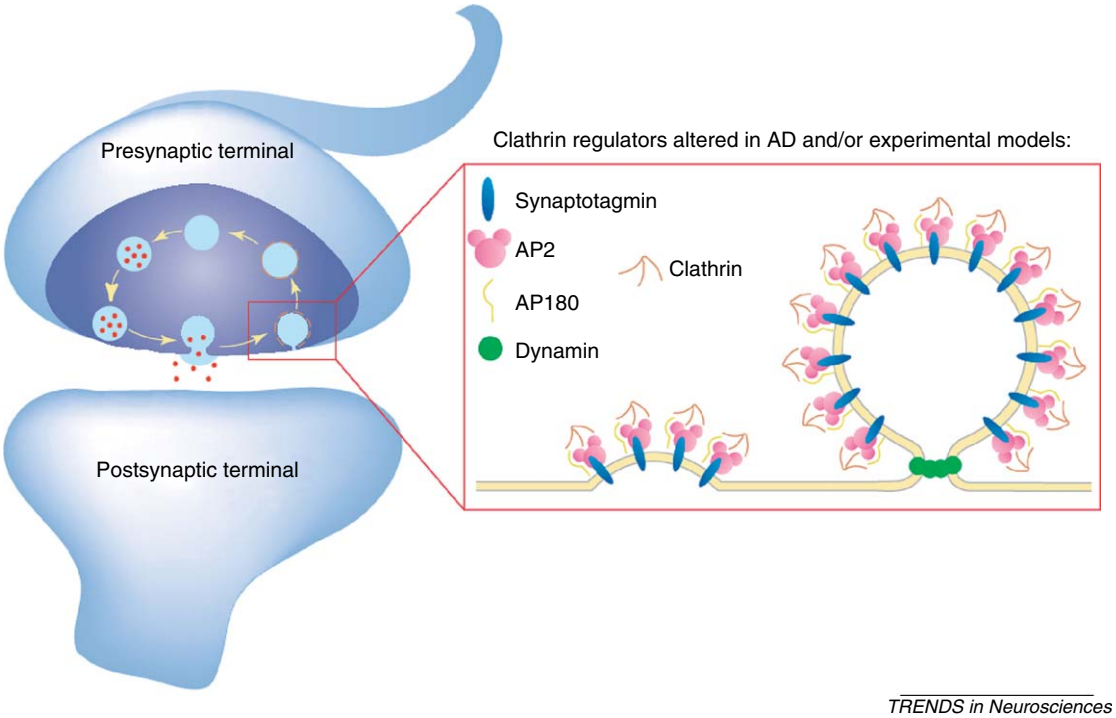

Figure 10 Alzheimer's disease (AD) affects clathrin-mediated synaptic vesicle recycling in synapses. Synaptic vesicles are recycled through clathrin-mediated endocytosis, which requires clathrin and regulatory proteins. The levels of several key regulators (see red box) of this process are decreased in AD as well as in experimental models of the disease. (From Yao P [2004] Synaptic frailty and clathrin-mediated synaptic vesicle trafficking in Alzheimer's disease. *Trends Neurosci.* 27: 24–29.)

ultrastructural changes found in AD brains and related mouse models. Decreases in synaptic density, attributed to synapse loss, are accompanied by an increase in size of the remaining synapses (reviewed in Scheff and Price, 2003). Although it has been hypothesized that such increases represent compensatory changes to maintain overall synaptic contact area, it has also been proposed that impaired endocytosis for local generation of vesicles leads to an overall accumulation of membrane and enlargement of nerve terminals (Yao, 2004).

In summary, alterations in levels of key components in synaptic vesicle trafficking may contribute to deficits in neurotransmitter release in AD.

4.15.3.2 Receptors and Channels

A large number of cell surface receptors and channels are located on the postsynaptic membrane, ready to receive and transduce input from presynaptic contacts. The strength of any given synapse can remain stable over time, increase, or decrease based on the number, localization, and activity of the neurotransmitter receptors and ion channels at the postsynaptic membrane. In this section, we review several receptors and channels that play important roles in synaptic plasticity and describe how alterations in their levels, localization, or function may contribute to AD-related cognitive dysfunction.

4.15.3.2.1 NMDA receptors

N-methyl-D-aspartate (NMDA) receptors play a critical role in the induction of LTP by acting as coincidence detectors of presynaptic glutamate release and postsynaptic depolarization (reviewed in Wang et al., 2006). Subsequent influx of calcium through the NMDA receptor triggers a series of intracellular signaling events that culminate in the induction of gene expression required for long-term changes in synaptic efficacy.

Currently approved therapies for the treatment of AD include an NMDA receptor antagonist, which is thought to protect neurons against increased calcium permeability of NMDA receptors and to increase the synaptic signal-to-noise ratio (Tariot and Federoff, 2003; Jacobsen et al., 2005). Studies in transgenic mouse models of AD and cell culture experiments are beginning to unravel the mechanisms by which AD-relevant molecules such as Aβ might alter NMDA receptor functions and impact synaptic plasticity.

As reviewed in the section titled 'Soluble Aβ oligomers,' many studies have reported that Aβ potently inhibits the induction of LTP both *in vitro* and *in vivo* (reviewed in Walsh and Selkoe, 2004). Although it is uncertain whether Aβ directly binds NMDA receptors, several lines of evidence demonstrate that at least part of Aβ's effect on LTP may be a result of alterations in the level, availability, or activity of NMDA receptors at the postsynaptic membrane.

In vitro, low concentrations of synthetic Aβ peptides acutely augment NMDA receptor–mediated calcium influx and synaptic transmission (Wu et al., 1995; Wu and Dun, 1995; Kelly and Ferreira, 2006). Furthermore, Aβ-dependent degradation of dynamin and the scaffolding protein PSD-95 can be blocked by NMDA receptor antagonists (Almeida et al., 2005; Roselli et al., 2005; Kelly and Ferreira, 2006). However, Aβ produces a delayed NMDA receptor–dependent reduction in synaptic transmission (Cullen et al., 1996). Because prolonged NMDA receptor stimulation leads to down-regulation of receptor activity through the recruitment of negative feedback loops (Oster and Schramm, 1993; Resink et al., 1995; Salter and Kalia, 2004; Braithwaite et al., 2006), it is possible that acute, Aβ facilitates glutamatergic transmission and sensitizes neurons to excitotoxic events (Mattson et al., 1993), whereas chronically, it leads to a down-regulation of NMDA receptor activity.

In vivo, hAPP transgenic mice that produce high Aβ levels have decreased levels of phosphorylation of Tyr-1472 of NR2B subunits of the NMDA receptor, particularly in the dentate gyrus (Palop et al., 2005). Phosphorylation at this residue affects the gating of the channel and is positively correlated with NMDA receptor currents (Lu et al., 1999; Alvestad et al., 2003; reviewed in Salter and Kalia, 2004), suggesting that the decreased phosphorylation found in hAPP mice may contribute to an attenuation of NMDA receptor-dependent signaling. Importantly, decreased levels of Tyr-1472 phosphorylation were associated with decreased activity of Fyn, a src-kinase family member that phosphorylates NR2B subunits at this residue, and increased expression of striatal-enriched phosphatase (STEP), a tyrosine phosphatase that negatively regulates Fyn activity (Chin et al., 2005). STEP can dampen NMDA receptor-dependent activity when engaged by high levels of stimulation (Pelkey et al., 2002; Braithwaite et al., 2006). The regulation of tyrosine kinases, such as Fyn, by Aβ is discussed in more detail in the section titled 'Kinases.'

Phosphorylation at Tyr-1472 also regulates the interaction of NMDA receptors with the scaffolding protein PSD-95 and with AP-2, an adaptor molecule that triggers clathrin-mediated endocytosis (Lavezzari

et al., 2003). *In vitro* experiments demonstrate that Aβ-dependent dephosphorylation of Tyr-1472 induces endocytosis of NMDA receptors, resulting in decreased surface expression of this key regulator of LTP induction (Snyder et al., 2005). The results of this study suggested a model in which extracellular Aβ binds α7 subunit-containing nicotinic acetylcholine receptors and thereby activates the phosphatases PP2B (calcineurin) and STEP, resulting in dephosphorylation of NR2B (**Figure 11**). Thus, Aβ may impair synaptic plasticity by inducing the dephosphorylation of Tyr-1472 and attenuating NMDA receptor activity through a variety of mechanisms.

The attenuation of glutamatergic transmission by Aβ may have different consequences depending on the brain region affected. If brain regions that control neuronal excitability on a global scale are particularly susceptible to Aβ-induced impairments of glutamatergic transmission, aberrant increases in overall brain activity may result. Such a notion is supported by findings that hAPP mice with high levels of Aβ exhibit nonconvulsive seizure activity in EEG recordings, which was associated with the induction of compensatory inhibitory mechanisms and impairments in synaptic plasticity (Palop et al., 2007).

4.15.3.2.2 AMPA receptors

α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) receptors are glutamate-gated channels that mediate most of the fast excitatory synaptic transmission in the brain and provide the primary means of postsynaptic depolarization in glutamatergic neurotransmission. AMPA receptor localization is dynamically regulated by neuronal activity, and rapid insertion and removal of these receptors into/from the postsynaptic membrane are key mechanisms by which long-term changes in

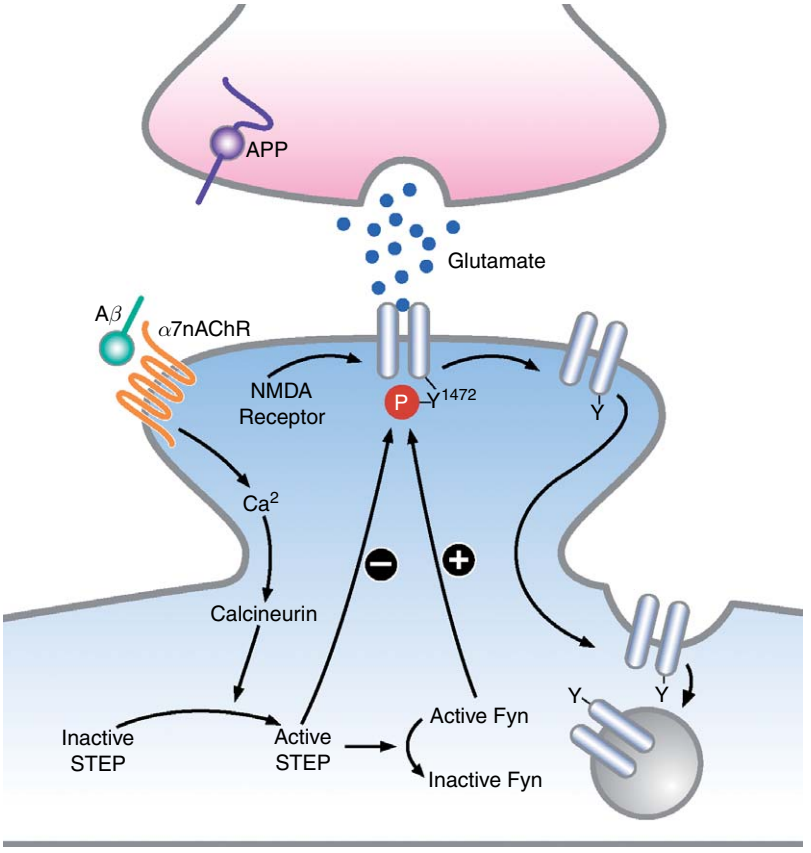

Figure 11 Aβ attenuates *N*-methyl-D-aspartate (NMDA) receptor signaling. Under normal circumstances, phosphorylation of the NMDA receptor at Tyr1472 is controlled by a balance between phosphorylation by Fyn and dephosphorylation by STEP. STEP also negatively regulates Fyn. In models of AD, Aβ activates α7 nAChRs and increases STEP activity, resulting in a net decrease in Fyn activity and Tyr1472 phosphorylation. In the absence of Fyn-mediated tyrosine phosphorylation, NMDA receptors are endocytosed.

synaptic strength (LTP and LTD) are expressed (Bredt and Nicoll, 2003; Esteban, 2003).

Such dynamic regulation of AMPA receptor density at the synapse requires that a pool of receptors be available for use at any given time. Indeed, recycling endosomes in dendritic compartments maintain a pool of AMPA receptors that can be rapidly mobilized and shuttled to the synaptic membrane in response to NMDA receptor activation to effect increases in synaptic strength (**Figure 12**) (Park et al., 2004; reviewed in Kennedy and Ehlers, 2006), whereas LTD-inducing stimuli result in endocytosis and removal of AMPA receptors from the synapse (Bredt and Nicoll, 2003).

In addition to their role in rapidly modifying synaptic strength, AMPA receptors play a critical role in another, slower form of plasticity called synaptic scaling (reviewed in Turrigiano and Nelson, 2004). In this type of homeostatic plasticity, the overall synaptic strength of a neuron is modulated to regulate its excitability depending on its history of activity. Periods of reduced activity result in increased levels of AMPA receptors at the synapse, whereas periods of increased activity lead to removal of AMPA receptors from the synapse. Moreover, regulation of AMPA receptor density at the postsynaptic membrane partly underlies distance-dependent scaling, in which synapses that lie farther from the soma are endowed with increased synaptic strength so they can transmit information with similar fidelity as synapses located closer to the soma (Andrasfalvy and Magee, 2001; Smith et al., 2003).

Several factors contribute to the ability of AMPA receptors to fulfill these critical roles in dictating synaptic strength and homeostatic control of neuronal activity, including expression levels, dendritic transport, and local synaptic trafficking within the endosomal pathway. Thus, impairments in any one of these processes may lead to deficits in synaptic plasticity and in the regulation of activity levels.

It is particularly interesting in this regard that reductions in several AMPA receptor subunits have been documented in the entorhinal cortex and hippocampus in AD and related transgenic mouse models (Yasuda et al., 1995; Chan et al., 1999; Wakabayashi et al., 1999; Carter et al., 2004; Chang et al., 2006; Palop et al., 2007). In AD, AMPA receptors also appear to be cleaved by caspases (Chan et al., 1999). In primary neurons or slices treated with Aβ or isolated from hAPP transgenic mice, surface expression of AMPA

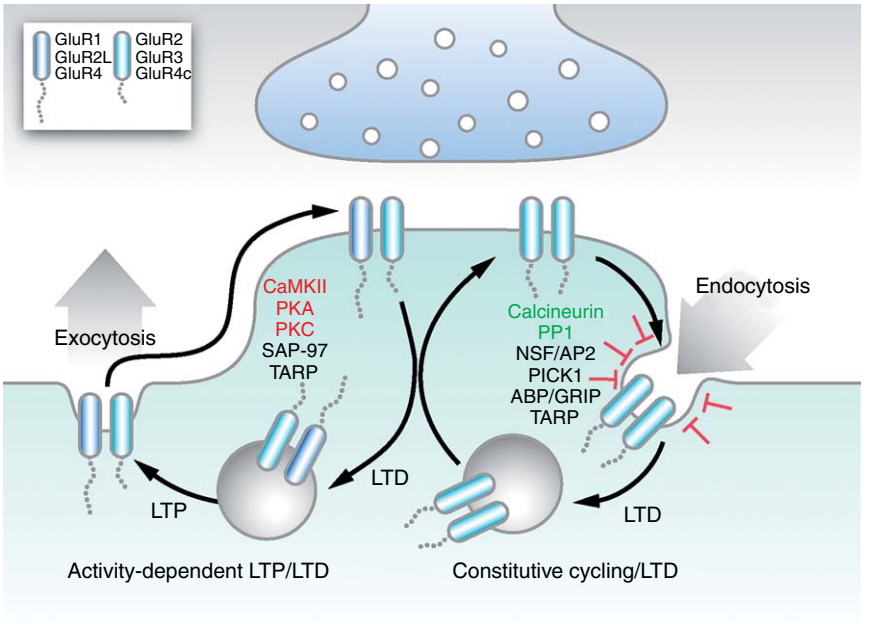

Figure 12 α-Amino-3-hydroxy-5-methyl-4-isoxazole-proprionic acid (AMPA) receptor trafficking. The trafficking of AMPA receptors between the synaptic membrane and recycling endosomes regulates synaptic strength. The insertion of AMPA receptors into the synapse (in long-term potentiation [LTP]) and the endocytosis of synaptic AMPA receptors (in long-term depression [LTD]) are governed by the activities of several kinases, phosphatases, and binding proteins. In Alzheimer's disease or related models, the activities of several kinases are decreased (red font), whereas the activities of several phosphatases are increased (green font), which may contribute to overall decreases in synaptic strength.

receptors is decreased (Almeida et al., 2005; Roselli et al., 2005; Hsieh et al., 2006). Such alterations may contribute to the decreased AMPA-mediated currents and increased NMDA/AMPA current ratios found in several *in vitro* and transgenic mouse models of AD (Hsia et al., 1999; Chang et al., 2006; Shemer et al., 2006).

Since AMPA receptors play such key roles in synaptic and homeostatic plasticity, alterations in their expression or trafficking may contribute to deficits in synaptic plasticity and learning and memory in AD and related models. As reviewed in the next section, it has been hypothesized that increased cholinergic activity in early stages of AD may be recruited to support synaptic scaling, perhaps in response to the loss of normal mechanisms underlying this homeostatic plasticity (Small, 2004).

4.15.3.2.3 Nicotinic acetylcholine receptors

Neuronal nicotinic acetylcholine receptors (nAChRs) are key modulators of neurotransmission. Presynaptically localized receptors enhance neurotransmitter release, postsynaptic receptors transduce fast excitatory transmission and calcium-regulated signaling, and perisynaptic or nonsynaptic receptors modulate neuronal excitability (Dani and Bertrand, 2006).

Although cholinergic activity is increased in early stages of AD, the loss of cholinergic neurons, particularly in the basal forebrain, is a characteristic neuropathological feature of AD that is thought to contribute to cognitive decline (Auld et al., 2002). The levels of acetylcholine receptors in AD brains, particularly the primarily presynaptically localized α7 subunit–containing nAChRs, are also decreased in postmortem tissues and by *in situ* imaging of receptor binding in live patients (Burghaus et al., 2000; Guan et al., 2000; reviewed in Auld et al., 2002; and Oddo and LaFerla, 2006). It is unclear whether this decrease simply reflects the loss of neurons expressing the receptors. Some studies report that α7nAChR mRNA levels are increased in the hippocampus of AD patients (Hellstrom-Lindahl et al., 1999; but see Mousavi et al., 2003), suggesting that decreases in protein levels and receptor binding may indeed reflect synaptic loss or neuronal degeneration. The use of acetylcholinesterase inhibitors to boost cholinergic signaling has long been a standard treatment for mild to moderate AD (reviewed in Jacobsen et al., 2005; Roberson and Mucke, 2006), but these regimens do not appear to provide long-lasting benefits.

A number of studies have shed light on how Aβ peptides may alter cholinergic signaling in AD. *In vitro* evidence demonstrated that Aβ binds α7nAChRs with high affinity, although experimental conditions and cell types can determine whether Aβ inhibits or stimulates the receptor (Wang et al., 2000; Liu et al., 2001a; Dineley et al., 2001, 2002; Pettit et al., 2001). Aβ-induced stimulation of α7nAChRs can appear to block receptor function but may simply occlude the effect of other ligands such as nicotine by potently stimulating the receptor and inducing calcium influx (Dougherty et al., 2003). Unlike the majority of membrane-bound receptors, nAChR expression is increased upon receptor stimulation (Fenster et al., 1999), which may account for several reports that Aβ increases α7nAChR levels *in vitro* and in hAPP transgenic mice (Dineley et al., 2001; Chin et al., 2005; Snyder et al., 2005).

Moreover, α7nAChRs can be targeted to somatodendritic compartments and have been found in perisynaptic regions on postsynaptic membranes, where they are in a strategic position to modulate intracellular signaling processes through their high calcium permeability (Fabian-Fine et al., 2001; Xu et al., 2006a). In primary cortical neurons, Aβ activates the calcium-dependent phosphatase PP2B (calcineurin) by engaging postsynaptic α7nAChRs (Snyder et al., 2005). One consequence of this activation is activation of the phosphatase STEP and subsequent dephosphorylation of the Tyr-1472 of the NR2B subunit of the NMDA receptor, either through direct dephosphorylation by STEP or through STEP-mediated desphosphorylation and inactivation of tyrosine kinases such as Fyn that are known to phosphorylate the NMDA receptor at this residue (see **Figure 11**).

These *in vitro* findings are in line with observations in hAPP mice, in which increased levels of α7nAChRs are concomitant with increased STEP levels, Fyn suppression, and decreased phosphorylation of Tyr-1472 of NR2B subunits (Chin et al., 2005; Palop et al., 2005). It remains to be determined whether the engagement of α7nAChRs by Aβ in AD and in experimental models of the disease represent primary pathogenic mechanisms or compensatory mechanisms to boost synaptic scaling (Small, 2004; Geerts and Grossberg, 2006) or combat excitotoxicity (Palop et al., 2007).

4.15.3.2.4 Potassium channels

The activities of potassium (K^+) channels, which efflux K^+ and hyperpolarize cells, play an important

role in neuronal survival, because they govern membrane excitability and because the intracellular potassium level is a determinant of apoptosis (Yu, 2003). New discoveries have highlighted how diverse K^+ channels in neuronal dendrites fine-tune excitability and affect neuronal information processing by regulating the induction of NMDA receptor–dependent synaptic plasticity in the hippocampus (reviewed in Yuan and Chen, 2006).

Phosphorylation-dependent modulation of K^+ channel activity, particularly of the Kv4.x family, is a major means by which synaptic plasticity is regulated and dendritic information processing is achieved (reviewed in Birnbaum et al., 2004; Yuan and Chen, 2006). Based on the kinetics of time-dependent inactivation, K^+ currents can be separated into different components. One such component, the fast-inactivating A-type K^+ current, plays a particularly important role in regulating membrane excitability, because it responds quickly to subthreshold depolarization and its activation delays the generation of action potentials (**Figure 13**). Inhibition of this current by pharmacological agents that block ion flux or stimulate phosphorylation of the channel markedly increases intracellular calcium (Hoffman et al., 1997; reviewed in Yuan and Chen, 2006).

Interestingly, Aβ inhibits A-type K^+ currents in primary hippocampal and neocortical neurons, increasing dendritic calcium influx and neuronal excitability (Good et al., 1996; Ye et al., 2003; Chen, 2005). This process may contribute to the observation that nonfibrillar Aβ assemblies increase neuronal excitability in various *in vitro* models (Hartley et al., 1999; Jhamandas et al., 2001; Turner et al., 2003; Ye et al., 2004; but see Yun et al., 2006). Aβ may inhibit K^+ currents through the aberrant engagement of tyrosine kinases, as tyrosine kinase inhibitors abrogated the ability of Aβ to increase excitability of cholinergic neurons (Jhamandas et al., 2001). Aβ treatment also induces K^+ channel abnormalities in cultured fibroblasts that are similar to K^+ channel abnormalities detected in fibroblasts isolated from AD patients (Etcheberrigaray et al., 1993, 1994). While regulated increases in intracellular calcium are important for synaptic plasticity, sustained increases in intracellular calcium through Aβ's effect on K^+ channels could impair synaptic plasticity and sensitize neurons to excitotoxic injuries (Xie, 2004).

Although A-type K^+ channel currents are generally inhibited by Aβ, the expression levels of K^+ channel subunits that contribute to the A-type current are increased in early stages of AD and in primary cerebellar neurons after treatment with Aβ (Angulo et al., 2004; Plant et al., 2006). Such increases in subunit expression may represent compensatory mechanisms aimed at restoring membrane excitability.

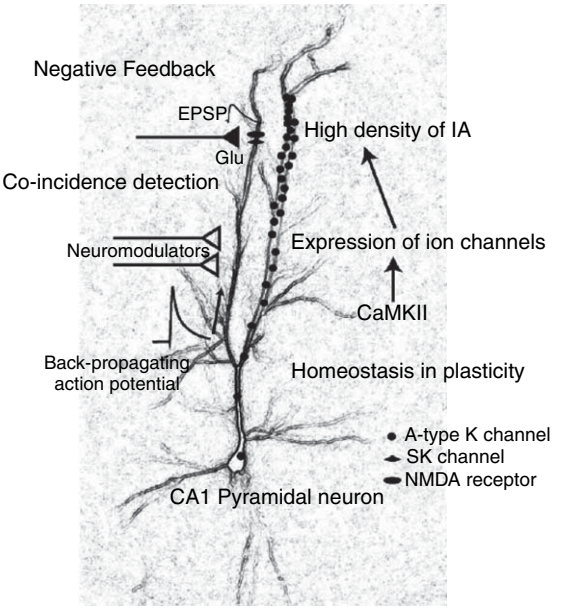

Figure 13 Dendritic K^+ channels influence neuronal information processing. SK and Kv4.2-encoded A-type K^+ channels are expressed at high levels in dendrites. Propagation of back-propagating action potentials and release of glutamate and neuromodulators within an appropriate time window ensures *N*-methyl-D-aspartate (NMDA) receptor activation through three coinciding events (as depicted in left dendrite above). Regulation of K^+ channel expression is also a homeostatic mechanism regulated by CaMKII. Activation of CaMKII promotes expression of both α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid receptors and A-type K^+ channels, resulting in antagonizing effects on neuronal responsiveness. Alzheimer's disease–related decreases in the activity of A-type K^+ channels increase neuronal excitability and intracellular calcium and may contribute to excitotoxicity. (From Yuan L and Chen X [2006] Diversity of potassium channels in neuronal dendrites. *Prog. Neurobiol.* 78: 374–389.)

4.15.3.3 Calcium Signaling

Downstream of cell surface receptors and ion channels at the postsynaptic membrane, a myriad of intracellular signaling molecules await instruction. Depending on the dynamics of receptor/channel activity, local Ca^{2+} plumes of various magnitudes are generated to direct the kinase cascades and other signaling pathways that transduce signals to the nucleus or other subcellular compartments. In

this section, we discuss several aspects of calcium homeostasis that impact the dynamics of postsynaptic signaling and describe kinase pathways that play key roles in the induction and maintenance of long-term changes in synaptic efficacy. Special emphasis is placed on those aspects that are altered in AD and related models and on how their dysregulation contributes to plasticity deficits. Finally, we review the mechanisms by which extracellular, neuromodulatory factors such as brain-derived neurotrophic factor (BDNF) and Reelin influence synaptic plasticity and how AD-related alterations in these factors exacerbate impairments in synaptic function.

Calcium (Ca^{2+}) plays fundamental roles in synaptic plasticity and neuronal survival. Calcium signals, either from the extracellular milieu or from intracellular stores, must be precisely regulated both temporally and spatially to achieve tight control over intracellular signaling pathways that transduce signals from extracellular sources (Yuste et al., 2000; Berridge et al., 2003). Disruptions in neuronal Ca^{2+} homeostasis and calcium-regulated signaling likely play important roles in normal aging and AD, impairing synaptic plasticity and cognitive function, and contributing to neuronal loss in vulnerable regions (Mattson and Chan, 2003; Xie, 2004; Smith et al., 2005a; Kelly et al., 2006). Acute treatment of primary neurons and cell lines of neuronal origin with Aβ induces rapid, transient increases in intracellular calcium levels, whereas chronic exposure to Aβ leads to slower, more progressive increases in resting calcium levels (Xie, 2004; Kelly and Ferreira, 2006). Aβ peptides, particularly oligomeric assemblies, have been suggested to insert into neuronal cell membranes and form calcium-fluxing pores (reviewed in Pollard et al., 1995; Glabe and Kayed, 2006). Alternatively, such assemblies may increase intracellular calcium levels by increasing influx through calcium channels, releasing calcium from intracellular stores, or modulating intracellular calcium dynamics through alterations in endogenous calcium binding proteins (**Figure 14**).

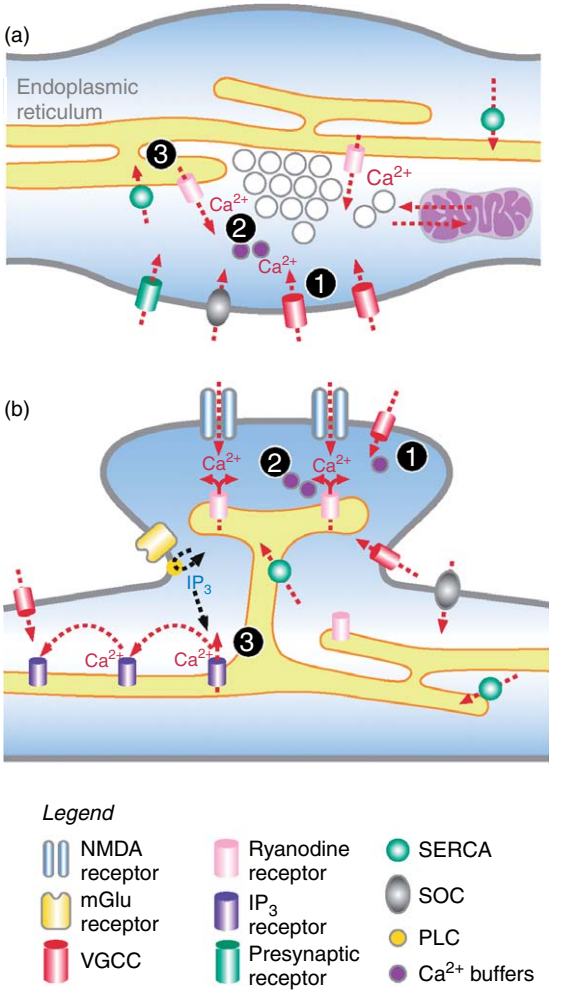

Figure 14 Ca^{2+} dysregulation in AD. Intracellular Ca^{2+} levels in the presynaptic terminal (top) and postsynaptic spine (bottom) are regulated by the influx of Ca^{2+} through Ca^{2+} channels (1), the buffering of free Ca^{2+} by Ca^{2+}-binding proteins (2), and the release of Ca^{2+} from intracellular Ca^{2+} stores (3). AD-related alterations in the levels and/or activities of Ca^{2+} channels, receptors, and Ca^{2+}-binding proteins perturb calcium homeostasis and may contribute to deficits in synaptic plasticity as well as increase susceptibility to excitotoxicity. (Modified from Bardo S, Cavazzini MG, and Emptage N [2006] The role of the endoplasmic reticulum Ca^{2+} store in the plasticity of central neurons. *Trends Pharmacol. Sci.* 27: 78–84).

4.15.3.3.1 Calcium channels

Ca^{2+} channels play diverse roles in synaptic transmission, on both the presynaptic and the postsynaptic side (Augustine et al., 2003). Presynaptic N- and P/Q-type voltage-sensitive Ca^{2+} channels are primarily involved in triggering synaptic vesicle exocytosis, whereas postsynaptic L-type voltage-sensitive Ca^{2+} channels contribute to the integration of synaptic activity and the transduction of signals that trigger a transcriptional response. Synaptic activity induces Ca^{2+} entry through NMDA receptors and L-type channels. The magnitude and temporal dynamics of the combined calcium influx determine which signaling pathways become engaged (Bradley and Finkbeiner, 2002; Deisseroth et al., 2003; Thiagarajan et al., 2006).

Aβ potentiates currents through L-type voltage-sensitive Ca^{2+} channels in primary neurons (Brorson

et al., 1995; Ueda et al., 1997; Ekinci et al., 1999; Fu et al., 2006). Although the underlying mechanisms have not been fully characterized, one possibility is Aβ-stimulated phosphorylation of L-type Ca^{2+} channels, which would increase conductance through the channel (Ekinci et al., 1999). In addition, because L-type Ca^{2+} channels are voltage sensitive, Aβ could indirectly modulate Ca^{2+} currents by blocking voltage-gated potassium channels (see earlier section), altering neuronal excitability and prolonging membrane depolarization (Good et al., 1996; Birnbaum et al., 2004). Finally, Aβ exposure leads to increased expression of particular L-type Ca^{2+} channel subunits on surface membranes in neuronal cell lines (Scragg et al., 2005; Chiou, 2006), which may contribute to long-term changes in Ca^{2+} homeostasis. Because Ca^{2+} influx through L-type channels could contribute to deranged Ca^{2+} homeostasis and signaling, L-type Ca^{2+} channel blockers are now in clinical trials for the treatment of AD (reviewed in Jacobsen et al., 2005; Roberson and Mucke, 2006).

4.15.3.3.2 Calcium-binding proteins

The level of intracellular free Ca^{2+} is governed by a balance between the entry of Ca^{2+} into the cytoplasm, either from extracellular sources or from intracellular stores, and the removal of Ca^{2+} by buffers, pumps, and exchangers (reviewed in Berridge et al., 2003). Many cell types contain particular calcium-binding proteins that act as buffers by rapidly binding and sequestering free Ca^{2+}. The primary cytosolic calcium-buffering proteins include calbindin-D_{28K}, calretinin, and parvalbumin, which are differentially expressed in various populations of neurons and play important regulatory roles in the maintenance of Ca^{2+} homeostasis (Hof et al., 1999). Parvalbumin is expressed in interneurons that modulate local circuitry in the neocortex and hippocampus, whereas calbindin and calretinin are expressed by both interneurons and pyramidal cells in the neocortex and hippocampus. Since disruption of neuronal Ca^{2+} homeostasis appears to contribute to AD pathogenesis, the levels and distribution of these types of calcium buffers in various areas of the AD brain and AD models have been the focus of a rapidly increasing number of studies.

Neuronal populations that express the calcium buffers calretinin and parvalbumin appear to be relatively preserved in AD (Hof et al., 1993; Fonseca and Soriano, 1995; Sampson et al., 1997). Losses of parvalbumin-expressing neurons have been documented in the entorhinal cortex and hippocampus of AD brains, but this loss appears to occur at late stages of the disease and may be secondary to degeneration of principal neurons in the same region (Solodkin et al., 1996; Brady and Mufson, 1997; Mikkonen et al., 1999). Such findings supported the hypothesis that neurons containing high levels of calcium-buffering proteins, and presumably a high calcium-buffering capacity, are relatively resistant to AD-related neurotoxicity (Hof et al., 1993). Late-stage loss of calcium-binding proteins was related to loss of neurons producing these proteins (Solodkin et al., 1996).

The calcium-binding protein calbindin is expressed in local circuit interneurons and pyramidal cells of the neocortex. In addition, it is very highly expressed in granule cells of the dentate gyrus and in Purkinje cells of the cerebellum (Celio, 1990). Calbindin regulates intracellular Ca^{2+} levels and is important for synaptic plasticity and learning and memory (Molinari et al., 1996). Calbindin levels in dentate granule cells are depleted in hAPP mice with high hippocampal levels of Aβ, and the magnitude of this depletion correlates tightly with cognitive deficits (Palop et al., 2003). Transgenic mice expressing the carboxy terminus of hAPP also exhibit depletions of calbindin in the dentate gyrus (Lee et al., 2006). Similar calbindin depletions occur in the dentate gyrus of AD patients, in whom the greatest depletions were seen in individuals with the most severe dementia (Palop et al., 2003). Moreover, calbindin mRNA levels in the hippocampus are also reduced in AD and in hAPP mice, supporting the hypothesis that calbindin depletions result from decreased expression of the calbindin gene rather than from loss of dentate granule cells (Iacopino and Christakos, 1990; Sutherland et al., 1993; Palop et al., 2003).

Similar calbindin depletions in the dentate gyrus have been observed after chronic neuronal overexcitation, for example, in human temporal lobe epilepsy, $GABA_B$ receptor-deficient mice, and models of kindling or kainate-induced chronic excitotoxicity (Tonder et al., 1994; Magloczky et al., 1997; Nägerl et al., 2000; Ruttimann et al., 2004; Palop et al., 2007). Calbindin reductions in the dentate gyrus of hAPP mice and in AD brains may also result from an imbalance between excitatory and inhibitory inputs (Palop et al., 2003, 2006, 2007). The ability of granule cells to downmodulate calbindin over a wide dynamic range may explain, at least in part, why these neurons are relatively resistant to degeneration in AD (West et al., 1994; Irizarry et al., 1997b; Palop et al., 2003), since calbindin reduction can lead to an

inactivation of voltage-gated calcium channels, limiting calcium entry and protecting against excitotoxicity (Nägerl et al., 2000).

4.15.3.3.3 Intracellular stores

In addition to influx from the extracellular compartment, the release of Ca^{2+} from intracellular stores in the ER is a major source of free Ca^{2+} that is available for signaling and synaptic plasticity (Rose and Konnerth, 2001; Berridge et al., 2003; Bardo et al., 2006). To maintain such a supply of Ca^{2+}, the ER faces the daunting task of sustaining an immense concentration gradient of Ca^{2+} across its membrane: The concentration of free Ca^{2+} in the ER lumen is about one thousand times greater than resting levels in the cytosol. Sarco-ER Ca^{2+} ATPases (SERCAs) actively transport Ca^{2+} into the ER to clear Ca^{2+} from the cytosol and fill ER stores. The liberation of Ca^{2+} from these internal stores is regulated by two types of channels in the ER membrane: the ryanodine receptor (RyR) and the inositol triphosphate receptor (IP_3R).

RyRs are activated by cytosolic Ca^{2+}, and their sensitivity is modulated by several factors: caffeine binding, oxidation, and high luminal Ca^{2+} levels increase sensitivity, whereas phosphorylation (by PKA) and calmodulin binding decrease activity (reviewed in Berridge et al., 2003; Bardo et al., 2006). IP_3Rs must be activated by the second messenger IP_3, which is generated upon stimulation of Gq-coupled receptors on the plasma membrane, such as metabotropic glutamate receptor types 1 and 5 ($mGluR_{1,5}$), serotonin receptors ($5\text{-}HT_2$), and muscarinic receptors (M1–3). The binding of IP_3 to IP_3Rs then sensitizes the receptors to Ca^{2+}, which increases receptor activity at low concentrations but inhibits it at high concentrations, such as those reached after release of Ca^{2+} from the ER (Berridge et al., 2003). IP_3Rs are often tethered to IP_3-producing cell surface receptors by scaffolding proteins such as Homer, linking the source of IP_3-production to its site of action (Ehrengruber et al., 2004). IP_3R activity can also be influenced by phosphorylation, which modulates the sensitivity of IP_3Rs in different directions, depending on the kinase involved. For example, phosphorylation by Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) decreases activity, whereas phosphorylation by Fyn kinase increases activity (Cui et al., 2004; Bare et al., 2005). Together, the activities of SERCAs, RyRs, and IP_3Rs monitor intracellular Ca^{2+} levels and regulate release of Ca^{2+} from the ER in a process called Ca^{2+}-induced Ca^{2+} release (CICR).

Several aspects of Ca^{2+} dysregulation in AD and AD mouse models have been linked to alterations in ER Ca^{2+} signaling. AD-related mutations in presenilin 1, presenilin 2, and APP increase cellular sensitivities to IP_3, caffeine activation of RyRs, and blockade of SERCA pumps, enhancing Ca^{2+} liberation from the ER (Smith et al., 2005a; Stutzmann, 2005). Overfilling of ER stores or excess phosphorylation of IP_3Rs or RyRs through aberrant activation of kinases by Aβ or other AD-related molecules may result in ER hypersensitivity and exaggerated Ca^{2+} release upon physiological stimulation of these receptors (discussed in the section titled 'Intracellular calcium stores'). As a result, even normal stimuli, such as synaptic activity and activation of mGluRs, could disrupt the intracellular Ca^{2+} homeostasis.

Mutations in presenilin 1 have been particularly linked to dysregulation of ER Ca^{2+} signaling by mechanisms that are unrelated to γ-secretase activity. As mentioned in Section 4.15.2.3.2, wild-type, but not AD-mutant, presenilin 1 and 2 can act as low-conductance Ca^{2+}-permeable ion channels, which may account for the majority of passive Ca^{2+} leaks from the ER (Tu et al., 2006). This Ca^{2+}-fluxing activity is important for maintaining normal steady-state intraluminal levels of Ca^{2+} and is exhibited by the unprocessed, holoprotein form of presenilin in the ER (Tu et al., 2006). In contrast, the secretase activity of presenilin emerges only in later compartments (trans-Golgi network, endosome) after assembly with other components of the γ-secretase complex (Tandon and Fraser, 2002). AD-related mutations in PS1 (PS1-M146V) or PS2 (PS2-N141I) abrogate the Ca^{2+} fluxing properties of the presenilins and abolish the passive efflux of Ca^{2+} out of the ER, overloading the ER with Ca^{2+}.

AD-related increases in levels of RyRs may also contribute to ER hypersensitivity and exaggerated Ca^{2+} release. RyR binding is increased in the entorhinal cortex and hippocampus in early stages of AD, suggesting increased levels of RyRs in these areas (Kelliher et al., 1999). Presenilin mutations are associated with increased levels of RyRs in transgenic mice and cell culture models (Chan et al., 2000; Smith et al., 2005b; Stutzmann et al., 2006). hAPP mice and primary cortical neurons treated with Aβ also show increases in RyRs (Supnet et al., 2006), suggesting that increased levels of Aβ are the unifying mechanism.

Together, these studies indicate that dysregulation of ER Ca^{2+} dynamics may contribute to impairments in synaptic plasticity and cognitive function associated with AD.

4.15.3.4 Kinases

Kinase activity is often coupled to the activity of receptors and channels at the plasma membrane and is crucial to the transduction of extracellular signals to cytosolic or nuclear targets. Signaling specificity is conferred by the type of receptor activated by synaptic activity, the dynamics and distribution of the ensuing Ca^{2+} influx, and the scaffolding of particular kinases to receptors/channels. Phosphorylation events triggered by active kinases can alter enzymatic activities or protein conformations of target molecules, setting in motion molecular cascades that culminate in cytoplasmic changes or nuclear events including gene transcription. Over the years, researchers have uncovered important roles for many kinases in synaptic plasticity and demonstrated how the orchestration of their activities leads to the induction, expression, and maintenance of long-term changes in synaptic efficacy. Notably, the levels, localization, or activities of many of these kinases are disrupted in AD, providing clues into the mechanisms by which AD impairs synaptic and cognitive function. In this section, we discuss several kinases whose roles in synaptic plasticity have been well characterized and how AD-related alterations in these kinases or associated signaling pathways may contribute to synaptic dysfunction.

4.15.3.4.1 MAPKs

The mitogen-activated protein kinase (MAPK) superfamily comprises three major subclasses of Ser/Thr kinases that are involved in the regulation of growth, differentiation, and cellular responses to stress and/or inflammatory cytokines. The extracellular signal-regulated kinases (ERKs) regulate growth, proliferation, and differentiation in many cell types and are essential for short-term increases in synaptic efficacy and for the expression and maintenance of LTP (Pearson et al., 2001; Thomas and Huganir, 2004; Davis and Laroche, 2006). The p38 branch of the MAPK family was originally characterized as key transducers of stress and inflammatory responses to cytokines but has recently been discovered to also mediate the induction and expression of LTD (Pearson et al., 2001; Thomas and Huganir, 2004). The activity or localization of ERK and p38 family members are altered in AD and related models, and their misregulation has been implicated in impairments of synaptic plasticity (Johnson and Bailey, 2003; Haddad, 2004). The third branch of the MAPK family is made up of the c-Jun N-terminal kinase/stress-activated protein kinases (JNK/SAPKs), which transduce stress signals, including oxidation and DNA damage, as well as growth and differentiation signals (Raivich and Behrens, 2006). Aβ-induced generation of reactive oxygen species activates JNK/SAPK, and such activation has been documented in AD and in AD models (reviewed in Zhu et al., 2004; Smith et al., 2006). Aβ-related engagement of JNK/SAPKs has been associated with overt cell death rather than more subtle effects on synaptic/neuronal functions. We will thus focus our discussion of MAPKs in AD-related synaptic impairments on ERK and p38.

ERK1/2 is activated rapidly after the induction of LTP. Although ERK1/2 activity is not necessary for the induction of LTP, it is critical for its maintenance and for learning and memory (English and Sweatt, 1997; reviewed in Thomas and Huganir, 2004; Davis and Laroche, 2006). In combination with other signaling pathways, LTP-induced ERK1/2 activation increases the expression of proteins necessary for long-term changes in synaptic efficacy, including the activity-regulated cytoskeletal protein (Arc/Arg3.1) (Roberson et al., 1999; Waltereit et al., 2001; Ying et al., 2002). Additional targets of ERK1/2 that are important for the expression or maintenance of LTP include cytoskeletal proteins such as MAP-2 and Tau, which modulate the structural organization of neurites; Kv4.2 potassium channels, which control dendritic depolarization and neuronal excitability; AMPA receptors, which are inserted into the membrane and increase synaptic strength; and mTOR, a component of the ribosomal machinery that controls synthesis of new proteins (reviewed in Haddad, 2004; Birnbaum et al., 2004; Kelleher et al., 2004; Sweatt, 2004). Clearly, tight regulation of ERK1/2 activity, dynamics, and localization is necessary to orchestrate its many effects on synaptic efficacy (**Figure 15**).

Increased levels of active ERK1/2 in AD brains are typically associated with neurofibrillary tangles and amyloid plaques (Trojanowski et al., 1993; Pei et al., 2002; Haddad, 2004; Webster et al., 2006). ERK1/2 phosphorylation of tau, described above in the section titled 'Tau phosphorylation and other posttranslational modifications,' has been well documented as a means by which hyperphosphorylated tau is generated in AD (reviewed in Haddad, 2004). In addition, the dysregulation of ERK1/2 activity may contribute in other ways to synaptic dysfunction, as indicated by studies in animal and *in vitro* models of AD. ERK1/2 activity has been shown to mediate the effects of Aβ on synaptic plasticity, including Aβ's effect on L-type calcium channels

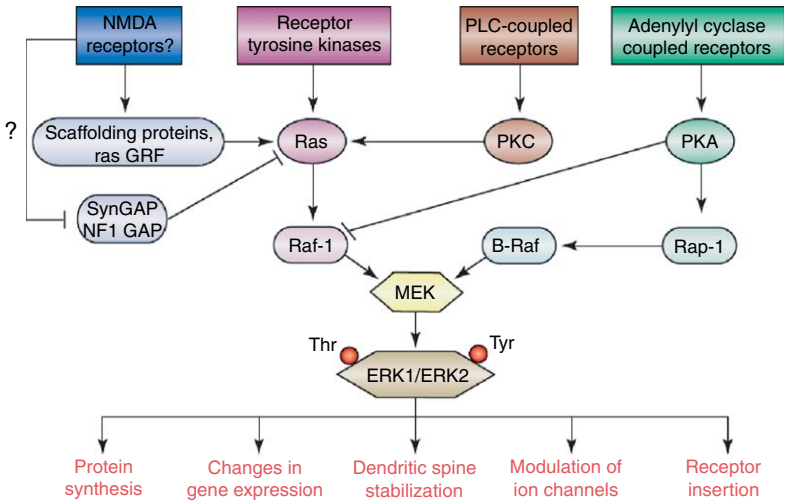

Figure 15 Regulation and targets of extracellular signal-regulated kinase (ERK)1/2 signaling in neurons. The ERK/mitogen-activated protein kinase cascade is activated by a number of receptors and pathways, and therefore plays a critical role in the integration of a wide variety of signals. The targets of ERK1/2 modulate processes that are crucial for synaptic plasticity (red font), all of which are impaired in Alzheimer's disease and experimental models. (From Sweatt JD [2004] Mitogen-activated protein kinases in synaptic plasticity and memory. *Curr. Opin. Neurobiol.* 14: 311–317.)

(reviewed in the section titled 'Calcium channels'). Interestingly, the kinetics of ERK1/2 activity depend on the duration of Aβ exposure and on Aβ's assembly state. Exposure of primary neurons or hippocampal slices to oligomeric Aβ acutely activated ERK1/2, but chronically decreased ERK1/2 activity, while exposure to fibrillar Aβ progressively increased ERK1/2 activity (Rapoport and Ferreira, 2000; Bell et al., 2004). Similarly, young hAPP transgenic mice exhibit increased ERK1/2 activity, whereas older hAPP mice exhibit decreased ERK1/2 activity, in particular in hippocampal subregions (Dineley et al., 2001; Chin et al., 2005; Palop et al., 2005). Certain brain regions may be able to downregulate ERK1/2 activity through compensatory mechanisms. For example, the phosphatase STEP dephosphorylates and inactivates ERK1/2 and is increased by Aβ *in vitro* and in the hippocampus of hAPP mice (Chin et al., 2005; Snyder et al., 2005; Braithwaite et al., 2006). Although the downregulation of aberrant ERK1/2 activity may be neuroprotective, it may also increase Aβ production (Kim et al., 2006) and decrease the expression of gene products required for the formation of long-term memories.

Although much emphasis has been placed on p38-mediated phosphorylation of tau, this process does not contribute greatly to the hyperphosphorylation of tau in AD (reviewed in Johnson and Stoothoff, 2004). p38 signaling also regulates synaptic plasticity by mediating long-term depression (LTD) of synaptic strength (reviewed in Thomas and Huganir, 2004). Inhibitors of p38 activity block LTD mediated by mGluRs or NMDARs (Bolshakov et al., 2000; Zhu et al., 2002), and inhibition of either p38 or mGluR activity prevents Aβ-induced LTP deficits in hippocampal slices (Wang et al., 2004). Furthermore, levels of phosphorylated, active p38 are increased in AD brains and related mouse models (Hensley et al., 1999; Zhu et al., 2000; Savage et al., 2002; reviewed in Johnson and Bailey, 2003; Hwang et al., 2005). Thus, Aβ-induced neuronal p38 activation may impair synaptic function in AD by promoting LTD.

4.15.3.4.2 CaMKII

Calcium/calmodulin-dependent protein kinase II is a major constituent of the postsynaptic density (PSD) that interacts with NMDA receptors and the cytoskeletal protein α-actinin (*See* Chapter 4.23). When activated by calcium influx during high-frequency stimulation, CaMKII translocates to the PSD and undergoes autophosphorylation at Thr286 of the αCaMKII subunit, resulting in prolonged calcium/calmodulin-independent CaMKII activity. This process is thought to underlie, at least in part, the conversion of a transient calcium signal to long-lasting enhancement of synaptic strength. Genetic or pharmacological manipulations that decrease levels of CamKII or prevent its autophosphorylation abolish LTP and

impair learning and memory (reviewed in Colbran and Brown, 2004).

In addition to its influence on gene transcription, CaMKII's cytoplasmic targets have also received great attention for their roles in the expression and maintenance of LTP. CaMKII promotes the insertion of alpha-amino-3-hydroxyl-5-methyl-4-isoxazolepropionate receptors (AMPARs) into the synapse, surface expression of Kv4.2 potassium channels, and activity of R-type calcium channels (reviewed in Colbran and Brown, 2004). Moreover, CaMKII-dependent modulation of cytoskeletal proteins regulates modifications of dendritic spine morphology associated with LTP (reviewed in Carlisle and Kennedy, 2005).

Although levels of CaMKII are relatively preserved in AD brains, levels of active, autophosphorylated CaMKII are significantly decreased (Mah et al., 1992; Simonian et al., 1994; Amada et al., 2005). These changes may be subregion specific, as decreases in autophorylated CaMKII were found in the hippocampus, but not in the amygdala (Amada et al., 2005). Consistent with these findings, Aβ acutely inhibits the ability of high-frequency stimuli to induce αCaMKII autophosphorylation and subsequent LTP in hippocampal slices (Zhao et al., 2004).

Autophosphorylation of αCaMKII, and thus CaMKII activity, are negatively regulated by the phosphatase PP1, which acts downstream of the calcium-dependent phosphatase calcineurin (Blitzer et al., 1998; Hedou and Mansuy, 2003). Particularly interesting in this regard are the findings by multiple groups that Aβ activates calcineurin *in vitro* and in transgenic mouse models of AD (Chen et al., 2002; reviewed in Xie, 2004; Cardoso and Oliveira, 2005; Snyder et al., 2005). Calcineurin levels and activity are also increased in AD (Hata et al., 2001; Liu et al., 2005; but see Lian et al., 2001). Together, these results suggest that enhanced negative regulation of CaMKII may diminish its activity in AD and impair synaptic plasticity.

4.15.3.4.3 PKC

Considerable evidence indicates that protein kinase C (PKC) is critical for long-term synaptic plasticity (Hvalby et al., 1994; Bortolotto and Collingridge, 2000). Indeed, ablation of PKC or inhibition of its activity impairs LTP as well as learning and memory (reviewed in Battaini and Pascale, 2005). Part of PKC's role in LTP may relate to its actions on AMPARs (Chung et al., 2000; Boehm et al., 2006). In addition, crosstalk between the PKC and PKA pathways can amplify ERK1/2 signaling (Roberson et al., 1999).

PKC is kept in a folded, inactive conformation by the binding of its pseudosubstrate domain to the substrate-binding site in the catalytic domain. Activation of the conventional, calcium-dependent isoforms of PKC, which are highly expressed in the brain, is regulated by binding to the second messengers calcium and diacylglycerol (DAG, reviewed in Battaini and Pascale, 2005). Upon binding and activation by second messengers, PKC translocates to the membrane via interactions with the scaffolding protein RACK1, which stands for receptor for activated C kinase (reviewed in Sklan et al., 2006). Interactions with RACK1 therefore aid in localizing PKC to its substrates.

Decreased activity of PKC has been implicated in the pathogenesis of AD. PKC levels are reduced in AD brains (Cole et al., 1988). In addition to deficits in PKC activation, which may result from decreased synaptic transmission and depletion of growth factors, PKC does not translocate effectively from the cytosolic to the membrane fraction in samples from AD brains, possibly because of decreased levels of RACK1 (Wang et al., 1994; Battaini et al., 1999).

Increased PKC immunoreactivity has been found in some AD cases and in hAPP transgenic mice at the beginning stages of amyloid deposition (Saitoh et al., 1993; Rossner et al., 2001), suggesting an early hyperactivation of PKC by Aβ, which may be followed by chronic suppression. Indeed, chronic activation is known to downregulate PKC activity (reviewed in Battaini and Pascale, 2005).

The consequences of reduced PKC activity are several-fold. In addition to decreasing the potential for synaptic plasticity, reduction of PKC activity may enhance the production of neurotoxic Aβ peptides. PKC increases the processing of APP by α-secretase in the nonamyloidogenic pathway, releasing the neurotrophic sAPPα fragment and precluding Aβ production (reviewed in Olariu et al., 2005). Treatment of APP/PS1 transgenic mice with small molecule activators of PKC significantly increased sAPPα, decreased Aβ levels, and reduced premature mortality (Etcheberrigaray et al., 2004). In addition, PKC regulates Aβ levels by increasing its clearance. Overexpression of the epsilon isoform of PKC activated endothelin-converting enzyme, an Aβ-degrading enzyme, and decreased Aβ levels, plaque deposition, neuritic dystrophy, and reactive astrocytosis in hAPP transgenic mice (Choi et al., 2006).

Together, these results suggest that enhancement of PKC activity may provide some benefit in AD.

4.15.3.4.4 PKA

Since the discovery in the 1980s that activation of cyclic AMP-dependent PKA increases synaptic efficacy in *Aplysia* neurons, numerous roles for PKA have been described in both short-term and long-term plasticity (reviewed in Nguyen and Woo, 2003; Waltereit and Weller, 2003). PKA is activated rapidly by calcium influx, which leads to increased synthesis of cyclic adenosine monophosphate (cAMP) by calcium/calmodulin-sensitive adenyl cyclases. Short-term actions of PKA include phosphorylation of potassium channels, to acutely increase excitability, and phosphorylation of synaptic vesicle proteins, to increase neurotransmitter release.

LTP-inducing stimuli lead to the degradation of the regulatory subunits of PKA, resulting in sustained activity of the catalytic subunits, which translocate to the nucleus and phosphorylate the transcription factor cAMP response element binding protein (CREB) to initiate gene transcription (reviewed in Kandel, 2001). Activity of PKA is necessary for long-lasting LTP in the hippocampus: it initiates gene transcription by direct phosphorylation of transcription factors and synergizes with other kinases, such as PKC, to activate ERK1/2 signaling (Roberson et al., 1999; Impey et al., 1998; reviewed in Waltereit and Weller, 2003). The combined actions of PKA and ERK1/2 are necessary for the transcription of immediate-early genes such as Arc/Arg3.1 that are critical to memory consolidation (Waltereit et al., 2001). PKA also increases current conductance and synaptic strength via phosphorylation of synaptic AMPA receptors (reviewed in Nguyen and Woo, 2003).

Alterations in PKA signaling have been implicated in several aspects of AD. PKA contributes to tau hyperphosphorylation by direct phosphorylation and by rendering tau susceptible to phosphorylation by GSK-3 (Liu et al., 2004; reviewed in Gong et al., 2005). Although PKA is responsible for a large proportion of tau hyperphosphorylation in AD, PKA activity is decreased in AD as well as in animal and cell culture models of the disease (Kim et al., 2001; Vitolo et al., 2002; Gong et al., 2006), possibly because Aβ inhibits the proteasomal degradation of PKA's regulatory subunits (**Figure 16**) (Vitolo et al., 2002). Increasing cAMP levels by inhibition of phosphodiesterases that break down cAMP ameliorates Aβ-induced deficits in synaptic plasticity and

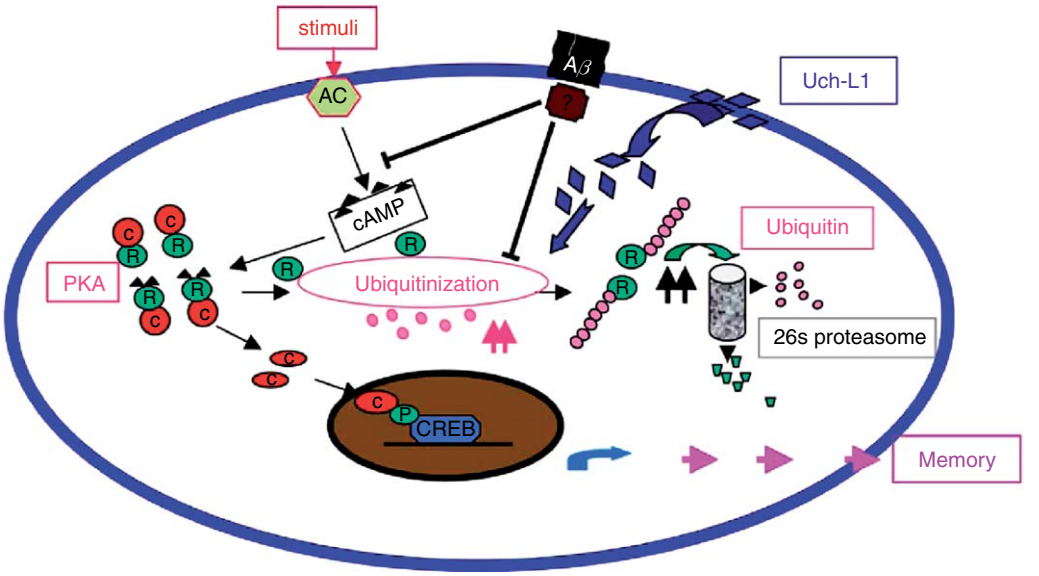

Figure 16 Aβ modulation of the ubiquitin-proteasome-protein kinase A (PKA)-cyclic adenosine monophosphate response element binding protein (CREB) pathway. Aβ inhibits adenylate cyclase activity and proteasomal degradation of the regulatory subunits of PKA, resulting in their accumulation and a shift in the PKA complex toward the inactive tetramer. Consequently, CREB phosphorylation and initiation of transcription is impaired. Transduction of Uch-L1 promotes proteasomal activity, normalizing levels of the PKA regulatory subunit and freeing the active catalytic subunit. (From Gong B, Cao Z, Zheng P, et al. [2006] Ubiquitin hydrolase Uch-L1 rescues β-amyloid-induced decreases in synaptic function and contextual memory. *Cell* 126: 775–788.)

learning and memory (Vitolo et al., 2002; Gong et al., 2004). Exogenous ubiquitin C-terminal hydrolase L1 (Uch-L1), which boosts proteasome activity, reversed Aβ-induced LTP deficits in hippocampal slices (Gong et al., 2006). Moreover, endogenous Uch-L1 activity was decreased in APP/PS1 transgenic mice, and treatment of these mice with exogenous Uch-L1 restored PKA activity and contextual memory (Gong et al., 2006).

4.15.3.4.5 Fyn

The tyrosine kinase Fyn can be activated through diverse receptors and participates in signaling pathways that control a broad spectrum of biological activities, including long-term changes in synaptic efficacy (Thomas and Brugge, 1997; Roskoski, 2004; Salter and Kalia, 2004). Ablation of Fyn abolishes LTP and impairs spatial learning and memory (Grant et al., 1992). Postnatal overexpression of Fyn can restore LTP, indicating that Fyn is a critical modulator of long-term synaptic efficacy (Kojima et al., 1997). Anchored to NMDA receptor complexes through interactions with PSD-95, Fyn phosphorylates the NR2B subunit at tyrosine residue 1472 (Tyr1472), which increases calcium conductance by altering channel gating properties and controls the internalization of the receptors by preventing AP-2 binding, a signal for endocytosis (reviewed in Salter and Kalia, 2004; Prybylowski et al., 2005). In addition, Fyn can modulate cytoskeletal dynamics by altering the phosphorylation and/or localization of cytoskeletal elements such as tau, adducin, and β-catenin (Williamson et al., 2002; Lilien and Balsamo, 2005; Gotoh et al., 2006). Moreover, phosphorylation by Fyn influences the integrity of synaptic AMPA receptors by rendering them less susceptible to proteolytic cleavage (Rong et al., 2001).

A number of findings suggest that misregulation of Fyn activity may play a role in AD. The distribution and levels of Fyn are altered in AD brains (Shirazi and Wood, 1993; Ho et al., 2005), and the toxic effects of Aβ oligomers on hippocampal slices can be blocked by the genetic ablation of Fyn (Lambert et al., 1998). Ablation of Fyn decreases – whereas overexpression of Fyn increases – Aβ-induced synaptotoxicity and premature mortality in hAPP transgenic mice (Chin et al., 2004). In addition, Fyn phosphorylates tau and binds it in a manner that is modulated both by AD-related hyperphosphorylation and by disease-related mutations in tau (Bhaskar et al., 2005; Lee, 2005). Together with *in vitro* studies demonstrating that acute application of Aβ leads to activation of Fyn signaling pathways and increased interactions with binding partners, these results suggested that Aβ may derange synaptic functions by aberrantly engaging Fyn-related pathways (Zhang et al., 1996; Williamson et al., 2002). Indeed, the overexpression of Fyn in hAPP mice with moderate levels of Aβ rendered the mice as severely impaired, with respect to biochemical and behavioral alterations, as hAPP mice with high levels of Aβ (Chin et al., 2005). These results suggest that Fyn activity sensitizes neurons to Aβ-induced neuronal impairments. Fyn also exacerbates Aβ-induced aberrant increases in neuronal activity (Palop et al., 2007).

Interestingly, aberrant engagement of Fyn activity also appears to trigger compensatory mechanisms that limit Fyn activity in the presence of elevated Aβ levels. hAPP transgenic mice exhibit significant increases in levels of the phosphatase STEP, which dephosphorylates and inactivates Fyn, and have corresponding decreases in levels of active Fyn (see **Figure 11**) (Chin et al., 2005). The increase in STEP and decrease in Fyn activity are most prominent in the dentate gyrus, a region particularly susceptible to Aβ-related synaptic dysfunction. The compensatory downregulation of Fyn activity in this region has consequences on NMDA receptor phosphorylation, calcium gating, and receptor internalization that likely further contribute to deficits in synaptic plasticity and learning and memory (Chin et al., 2005; Palop et al., 2005; Snyder et al., 2005).

4.15.3.4.6 Cdk5

Cyclin-dependent kinase 5 is an unusual Cdk that lacks a role in the cell cycle and is activated by two noncyclin activators, p35 and p39. With an extensive list of substrates, the primarily neuronal Cdk5 regulates cell death and survival, as well as a variety of specific cellular functions (reviewed in Cheung and Ip, 2004; Cruz and Tsai, 2004). Cdk5 activity is increased in AD brains and in neurons and cell lines treated with Aβ and mediates tau hyperphosphorylation (reviewed in Giese et al., 2005). It also modulates synaptic plasticity, with consequences on learning and memory (reviewed in Cruz and Tsai, 2004; Cheung et al., 2006; Angelo et al., 2006).

Presynaptic roles for Cdk5 that influence synaptic transmission include the regulation of synaptic vesicle exocytosis through phosphorylation of P/Q-type calcium channels and synapsin 1, which increases calcium influx and releases synapsin's tethering of synaptic vesicles in a reserve pool (reviewed in Angelo et al., 2006). Cdk5 also modulates endocytosis for the recycling of synaptic vesicles by phosphorylating dynamin

I and amphiphysin I, proteins necessary for clathrin-mediated endocytosis (reviewed in Angelo et al., 2006).

Postsynaptic roles for Cdk5 in synaptic plasticity include phosphorylation of PSD-95, which suppresses its multimerization and decreases PSD-95-dependent clustering of NMDA receptors and Kv1.4 potassium channels (Morabito et al., 2004). Cdk5 also phosphorylates NR2A subunits of NMDA receptors and increases calcium conductance (Li et al., 2001). Moreover, Cdk5 activity regulates dendritic spine remodeling through actions on proteins that modulate cytoskeletal dynamics, including Rho GTPases and PAK1 (Nikolic et al., 1998).

Direct evidence for a role of Cdk5 in learning and memory has come from studies of transgenic mice expressing p25, a truncated form of the Cdk5 activator p35 that results in constitutive activation of Cdk5. Transient expression of p25 led to improved synaptic plasticity and learning in hippocampus-dependent tasks (Fischer et al., 2005). These improvements were accompanied by increased spine density and synapse formation.

Thus, Cdk5 activity must be well regulated in order to maintain control over the numerous aspects of neuronal function that it modulates. p25 levels are higher in AD brains than in normal controls (Lee et al., 1999; Patrick et al., 1999; reviewed in Giese et al., 2005). Although transient expression of p25 increases synaptic plasticity, prolonged neuronal expression of p25 in transgenic mice leads to synaptic impairments, learning and memory deficits, neurofibrillary tangle formation, and neurodegeneration (Cruz and Tsai, 2004; Fischer et al., 2005). In addition, sustained Cdk5 activity increases Aβ production (Cruz et al., 2006). Thus, the generation of p25 may be initiated in early stages of AD as a compensatory mechanism to support waning plasticity and memory, but its continued presence and the resulting overactivation of Cdk5 may eventually contribute to synaptic impairments and other neuronal deficits.

4.15.3.5 Neurotrophic and Neuromodulatory Factors

During development of the nervous system, secreted neurotrophic and neuromodulatory factors regulate axonal outgrowth, dendritic maturation, synapse formation, and synaptic strength. These processes overlap widely with those necessary for synaptic plasticity and the maintenance of long-term changes in synaptic function. Therefore, it is not surprising that nature has recycled many of these same neurotrophic and neuromodulatory factors to effect synaptic plasticity in adult organisms. Two such neuromodulatory factors are brain-derived neurotrophic factor (BDNF) and Reelin. We discuss their roles in synaptic plasticity and how AD-related alterations in their levels may contribute to synaptic and cognitive dysfunction.

4.15.3.5.1 BDNF

BDNF belongs to the neurotrophin family of signaling proteins that also includes nerve growth factor (NGF), neurotrophin 3 (NT-3), and neurotrophins 4/5(NT-4/5), all of which participate in regulating the survival and differentiation of specific neuronal populations during development. However, BDNF is unique among its family members in its ability to modulate activity-dependent synaptic plasticity in the developing and the adult brain (reviewed in Lu, 2003).

The actions of BDNF have long been studied in the context of learning and memory in animal models, but the recent discovery that a Val→Met mutation in the prodomain of BDNF is linked to memory impairment and susceptibility to neuropsychiatric disorders in humans has fueled additional research (reviewed in Bath and Lee, 2006). This mutation affects the trafficking of BDNF to the secretory pathway, resulting in reduced secretion of BDNF in target regions. Moreover, BDNF mRNA and protein levels are decreased in brain regions that are vulnerable in AD, suggesting that alterations in BDNF may reflect or contribute to cognitive impairments in AD (reviewed in Murer et al., 2001; Allen and Dawbarn, 2006).

BDNF has multiple distinct functions in synaptic plasticity that can be divided into two broad categories: permissive and instructive (reviewed in Schinder and Poo, 2000; Bramham and Messaoudi, 2005). Permissive actions of BDNF prepare synapses to be LTP-competent but do not actually generate LTP. Such actions include the maintenance of the presynaptic release machinery (vesicle docking and vesicle pool dynamics), which allows neurons to follow high-frequency stimuli.

Instructive signals from BDNF are initiated in response to high-frequency stimuli that induce LTP and result in the activity-dependent expression and release of BDNF. Some of these signals modulate postsynaptic calcium influx through voltage-gated sodium channels, reducing the amount of stimulation necessary for LTP induction (gating) (reviewed in Blum and Konnerth, 2005). The majority of BDNF's

effects are mediated by TrKB receptors and subsequent signaling events that engage ERK1/2 and regulate the expression of genes, including the immediate-early gene Arc/Arg3.1 (reviewed in Blum and Konnerth, 2005; Bramham and Messaoudi, 2005). BDNF also regulates the translation of dendritically localized mRNAs associated with synapse-specific LTP (reviewed in Schuman et al., 2006). Together, BDNF's actions lead to long-lasting increases in synaptic strength.

Regulated BDNF expression also plays a central role in homeostatic synaptic scaling, through which the overall activity of a neuronal network is maintained over time (reviewed in Turrigiano and Nelson, 2004). As mentioned above, BDNF expression is activity dependent. Under situations of reduced activity, BDNF expression is reduced. GABA expression in inhibitory interneurons is then reduced, diminishing inhibition and promoting the firing rate of pyramidal neurons (Rutherford et al., 1997, 1998; reviewed in Turrigiano and Nelson, 2004).

The role of BDNF in scaling is particularly interesting in light of the decreased levels of BDNF observed in vulnerable brain regions in AD. Does the decrease in BDNF result from a primary insult and exacerbate synaptic deficits and plasticity in AD, or does it represent the attempts of an impaired network to increase neuronal activity and maintain synaptic connections? Answers to these questions are pending.

An additional complexity in considering the role of BDNF in AD is that the regulation and effects of BDNF have different outcomes depending on the state of the neuronal network on which it acts (Turrigiano and Nelson, 2004). The role of BDNF reductions in homeostatic scaling described above is evident in conditions in which normal activity has been abolished. However, in situations containing normal levels of background activity, BDNF's potentiating activity prevails. Transgenic mice overexpressing BDNF have increased seizure severity after kainic acid challenge and develop hyperexcitability in the entorhinal cortex and the CA regions of the hippocampus (Croll et al., 1999). Transgenic mice overexpressing BDNF's receptor TrKB also have a reduced threshold for kainate-induced seizures (Lahteinen et al., 2003). These studies suggest that a reduction of BDNF in AD may represent a compensatory mechanism against hyperexcitability. Consistent with this idea, removal of one BDNF allele in mice leads to increased synaptic inhibition (Olofsdotter et al., 2000).

4.15.3.5.2 Reelin

Reelin is a large glycoprotein of the extracellular matrix involved in neuronal migration and positioning during development (Tissir and Goffinet, 2003). In the mature brain, it modulates neuronal function and synaptic plasticity and regulates tau phosphorylation as well as axonal growth and dendritic spine morphology (Hiesberger et al., 1999; Liu et al., 2001b; Fatemi, 2005; Herz and Chen, 2006; Qiu et al., 2006b).

In most of the brain, Reelin is expressed by GABAergic interneurons that regulate the activity and function of neighboring glutamatergic neurons (Pesold et al., 1998; Ramos-Moreno et al., 2006). Interestingly, Reelin is also expressed highly by glutamatergic pyramidal neurons in layer II of the entorhinal cortex (Pesold et al., 1998; Perez-Garcia et al., 2001; Ramos-Moreno et al., 2006), a population of neurons that is affected early and severely by AD (Blennow et al., 2006). These neurons project primarily to the dentate gyrus and area CA1 of the hippocampus (Ramos-Moreno et al., 2006; van Groen et al., 2003), which are also vulnerable to AD (Blennow et al., 2006; Palop et al., 2003). Although Reelin does not appear to undergo calcium-dependent exocytosis (Lacor et al., 2000), its localization in secretory vesicles, axons, and dendritic spine-rich neuropils suggests that it may be released from both the cell soma and synaptic terminals (Pesold et al., 1998; Lacor et al., 2000; Pappas et al., 2001; Ramos-Moreno et al., 2006). Reelin immunoreactivity is also present in the axonal projections of glutamatergic pyramidal neurons in layer II of the entorhinal cortex (Ramos-Moreno et al., 2006), suggesting that Reelin produced by these cells is transported down axons and may impact neuronal function in target regions such as the dentate gyrus and CA1.

Two neuronal cell surface receptors that bind apoE and transport cholesterol into neurons, very low density lipoprotein receptor (VLDLR) and apolipoprotein E receptor 2 (ApoER2), bind Reelin and cooperate to transduce its signals (reviewed in Herz and Chen, 2006). The close proximity between Reelin receptors and NMDA receptors allows crosstalk between the two signaling pathways: Through a series of phosphorylation events, Reelin increases NMDA receptor function and thereby enhances the induction of LTP (**Figure 17**) (Weeber et al., 2002; Beffert et al., 2005; Chen et al., 2005b). Reelin also enhances

synaptic function by stimulating the translation of dendritically expressed mRNAs, such as Arc/Arg3.1 mRNA (Dong et al., 2003). Reelin-deficient mice have a diminished capacity for hippocampus-dependent memory, indicating that Reelin is necessary for normal plasticity and memory formation (Qiu et al., 2006a).

The localization of Reelin expression and its roles in regulating synaptic plasticity as well as tau phosphorylation suggest that decreases in Reelin might exacerbate synaptic impairments in AD. In addition to memory deficits, Reelin-deficient mice exhibit robust increases in levels of hyperphosphorylated tau (Hiesberger et al., 1999; reviewed in Herz and Chen, 2006), suggesting a role for Reelin in the generation of tau pathology in AD. Furthermore, apoE competes with Reelin for binding to VLDLR/ApoER2 receptors and decreases Reelin signaling (D'Arcangelo et al., 1999; Herz and Bock, 2002). It has been suggested that apoE4 competes more efficiently than apoE3 (reviewed in Herz and Bock, 2002), providing yet another mechanism by which apoE4 may increase the susceptibility to AD (**Figure 17**; see also the section titled 'Aβ-Independent mechanisms for apoE-induced neuronal impairments').

A few recent studies have begun to examine whether AD is associated with Reelin alterations hAPP transgenic mice with high levels of Aβ were found to have significantly fewer Reelin-expressing

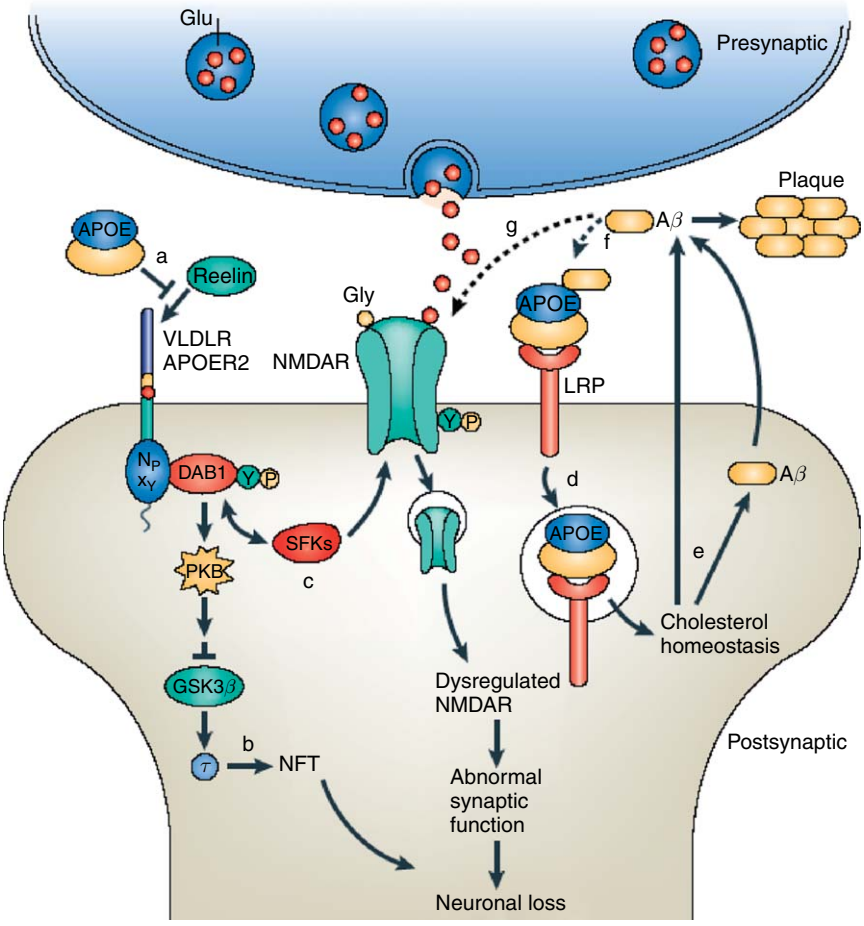

Figure 17 Reelin and ApoE signaling – implications for AD. Binding of Reelin to VLDLR and ApoER2 receptors initiates a cascade of events that leads to modulation of NMDA receptor function and enhanced long-term potentiation. ApoE can impede Reelin signaling by competing for receptor binding. Impaired Reelin signaling results in impaired synaptic plasticity as well as in elevated tau phosphorylation, which could contribute to neurofibrillary tangles associated with AD. In addition, binding of ApoE to the LRP lipoprotein receptor results in internalization of the ligand-bound receptor. Cholesterol homeostasis modulates the production and trafficking of Aβ. Secreted Aβ can bind apoE and be cleared through receptor-mediated endocytosis, promote the internalization of NMDA receptors, and deposit into plaques (From Herz J and Chen Y [2006] Reelin, lipoprotein receptors and synaptic plasticity. *Nat. Rev. Neurosci.* 7: 850–859.)

pyramidal cells in the entorhinal cortex and corresponding reductions in Reelin levels in the hippocampus relative to nontransgenic mice (Chin et al., 2007). In contrast, the number of Reelin-expressing GABAergic interneurons was not altered in either the entorhinal cortex or the hippocampus. Underscoring the relevance of these findings, qualitatively similar reductions of Reelin-expressing pyramidal neurons were found in the entorhinal cortex of AD brains (Chin et al., 2007). Increased fragments of Reelin were found in the CSF of AD patients, suggesting altered processing of Reelin (Saez-Valero et al., 2003). Increased levels of Reelin were found in the frontal cortex of AD brains (Botella-López et al., 2006). Conceivably, increases in Reelin in frontal brain regions reflect the kind of hyperactivation of frontal areas that is presumed to compensate for the failure of more vulnerable brain regions in AD (Buckner, 2004; Pariente et al., 2005; Palop et al., 2006).

4.15.3.6 Gene Expression

Short-term synaptic plasticity is effected by noncovalent modifications of existing proteins, such as ion channels, receptors, or components of the vesicle-release machinery that lead to acute modulation of synaptic strength. Long-lasting synaptic plasticity, however, requires protein synthesis and structural changes for the long-term maintenance of changes in synaptic strength (reviewed in Kandel, 2001; Carlisle and Kennedy, 2005). It is clear from the discussion in the section titled 'Kinases' that the derangement of kinase pathways in AD may disrupt the expression of pertinent genes. We consider here two proteins that play particularly important roles in gene transcription necessary for long-term plasticity (CREB) and in consolidation of long-term memories (Arc/Arg3.1), and how alterations in their expression or localization may contribute to AD-related synaptic and cognitive impairments.

4.15.3.6.1 CREB

The transcription factor CREB is essential for many forms of learning and memory (reviewed in Lonze and Ginty, 2002; and Tully et al., 2003) (*See* Chapter 4.27). CREB is a nuclear protein that modulates the transcription of genes containing cAMP-responsive elements (CREs). Phosphorylation of CREB at Ser133 leads to the recruitment of other components of the transcription machinery to CREs. Both PKA and Ca^{2+}/calmodulin kinase type IV (CaMKIV) can phosphorylate CREB at Ser133 and are responsible for rapid initial increases in CREB phosphorylation in response to neuronal activity, whereas ERK1/2-dependent phosphorylation of Ser 133 occurs with slower kinetics, involves an intermediate such as RSK or MSK family kinases, and leads to prolonged phosphorylation of CREB.

CREB target genes encompass diverse proteins, ranging from proteins involved in neurotransmission, the transcriptional machinery, or signal transduction to growth factors such as BDNF, structural proteins, channels, and transporters (reviewed in Lonze and Ginty, 2002). Consequently, disruptions in CREB activation impair numerous neurological functions.

Decreased activity of PKA and ERK1/2 in AD and related experimental models is accompanied by decreased levels of phosphorylated CREB (Dineley et al., 2001; Vitolo et al., 2002; Gong et al., 2004, 2006). Efforts are being made to determine whether promoting CREB activity is an effective means to enhance memory in normal aging and in AD (Tully et al., 2003). Indeed, treatment of transgenic mouse models of AD with agents that boost cAMP levels (and thus PKA activity) do restore PKA/CREB signaling and are associated with an amelioration of deficits in synaptic plasticity and hippocampus-dependent memory (Vitolo et al., 2002; Gong et al., 2004, 2006).

4.15.3.6.2 Arc/Arg3.1

The activity-regulated cytoskeletal protein/activity-regulated gene 3.1 is an immediate early gene (IEG) that is critical for LTP maintenance and for the consolidation of memories (Tzingounis and Nicoll, 2006). IEGs are rapidly and transiently activated at the transcriptional level after neuronal stimulation by neurotransmitters or growth factors. Some IEGs, for example, c-fos, encode transcription factors that modulate the expression of genes for proteins that affect synaptic strength, while others, such as Arc/Arg3.1, are effector IEGs whose products directly effect or maintain long-term changes in synaptic strength.

Arc/Arg3.1 was identified in 1995 by two independent groups searching for an IEG that might serve as an effector of long-term changes in synaptic strength (Link et al., 1995; Lyford et al., 1995). Both groups posited that the expression of such an effector should be (1) rapidly stimulated by neuronal activity, (2) blocked by NMDA receptor antagonists, and (3) localized to dendritic compartments. Using these criteria, both groups identified the same IEG, now known by the combined name of Arc/Arg3.1.

Arc/Arg3.1 is rapidly activated by patterned synaptic activity, including seizure activity, LTP, exploration of a novel environment, and memory-inducing behavioral paradigms (reviewed in Guzowski, 2002; Tzingounis and Nicoll, 2006). Newly synthesized Arc/Arg3.1 mRNA is rapidly transported to dendrites and accumulates in the particular synapses that were previously activated (Steward and Worley, 2001a,b). Because of these properties, the expression of Arc/Arg3.1 has been used to image behaviorally relevant activity in neuronal networks (Guzowski et al., 1999; Temple et al., 2003; Burke et al., 2005; Tagawa et al., 2005; Zou and Buck, 2006). For example, the sequential exposure of rats to two different environments results in the activation of distinct patterns of Arc/Arg3.1 expression in the hippocampus, particularly in the dentate gyrus, suggesting that Arc/Arg3.1 represents the activity of neuronal ensembles involved in the encoding of contextual information (Guzowski et al., 1999; reviewed in Guzowski et al., 2005).

Arc/Arg3.1 expression has also been used to examine the susceptibility of particular neuronal populations to Aβ-induced impairments in transgenic mouse models of AD (**Figure 18**). The induction of Arc/Arg3.1 after various stimuli is diminished in hAPP mice and hAPP/PS1 mice (Dickey et al., 2004; Chin et al., 2005; Palop et al., 2005). After exploration of a novel environment, Arc/Arg3.1 expression is reliably induced in the dentate gyrus of nontransgenic rodents (reviewed in Guzowski et al., 2005), but not in hAPP transgenic mice (Chin et al., 2005; Palop et al., 2005). Basal levels of Arc/Arg3.1 were also markedly reduced in the dentate gyrus. These alterations in Arc/Arg3.1 expression were accompanied by

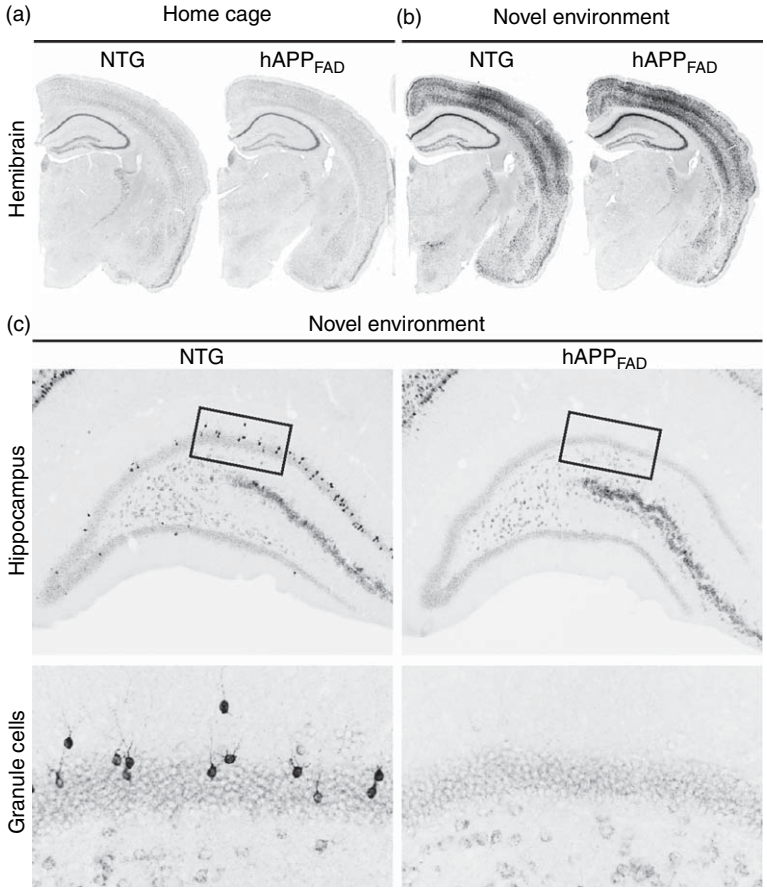

Figure 18 Imaging neuronal network activity using Arc/Arg3.1 expression. (a, b) After exploration of a novel environment, Arc/Arg3.1 expression is reliably induced in nontransgenic (NTG) mice in several brain regions including neocortex and hippocampus. hAPP transgenic mice show normal induction in the neocortex and CA1, but a striking lack of induction in the dentate granule cells of the hippocampus (a–c). (From Palop JJ, Chin J, Bien-Ly N, et al. [2005] Vulnerability of dentate granule cells to disruption of Arc/Arg3.1 expression in human amyloid precursor protein transgenic mice. *J. Neurosci.* 25: 9686–9693. Copyright 2005 by the Society for Neuroscience.)

decreased activities of NMDA receptors and ERK1/2, which regulate Arc/Arg3.1 expression. Other calcium-regulated proteins, for example, Fos and calbindin, are also depleted in the dentate gyrus of hAPP mice, and these depletions correlate well with deficits in learning and memory (Palop et al., 2003). Together, these studies indicate that the dentate gyrus is particularly vulnerable to Aβ-induced deficits in synaptic function, encoding of spatial information, and learning and memory.

Recent work by several groups has begun to shed light on Arc/Arg3.1 activities that may be particularly relevant to the synaptic and cognitive deficits observed in AD. Arc/Arg3.1 regulates AMPA receptor trafficking through interactions with endophilin and dynamin, proteins critically involved in the endocytotic recycling of synaptic vesicles (Chowdhury et al., 2006). Overexpression of Arc/Arg3.1 increases recycling rates and decreases surface expression of AMPA receptors, with corresponding decreases in AMPA receptor-mediated currents (Chowdhury et al., 2006; Rial Verde et al., 2006). In contrast, ablation of Arc/Arg3.1 increases surface expression of AMPA receptors and impairs long-term memory (Plath et al., 2006; Shepherd et al., 2006). Notably, the regulation of Arc/Arg3.1 and AMPA receptors is bidirectional, as AMPA receptor activity downregulates Arc/Arg3.1 expression (Rao et al., 2006).

The dynamic interactions between Arc/Arg3.1 and AMPA receptors may play a critical role in homeostatic scaling of synaptic strength (reviewed in Turrigiano and Nelson, 2004; Davis, 2006). Synaptic scaling is an important mode of plasticity by which neuronal networks maintain an optimal equilibrium of activity over time, and impairments of this plasticity may exacerbate synaptic and cognitive deficits in AD (Small, 2004; Palop et al., 2006).

4.15.4 Conclusions

We have surveyed here a multitude of molecules whose functions are perturbed in AD and animal models of the disease. The complexity of the pathways and interactions involved can be overwhelming, and it may be tempting to ask whether any molecule in the brain is left unaffected by the disease. Such a question has several potential answers.

Perhaps not coincidentally, this situation evokes similarities to LTP and the molecular basis of synaptic plasticity, where an equally long (and largely overlapping) list of molecules is involved (Roberson et al., 1996; Sanes and Lichtman, 1999; Malenka and Bear, 2004). This parallel highlights the fact that AD is a disease of memory not just in terms of neuropsychology but also at the molecular level, and that addressing AD may be one of the most critical applications of basic knowledge about the molecular basis of synaptic plasticity.

Second, the molecular changes in AD are not unlimited and are, in fact, bounded by multiple levels of specificity. Many are restricted to specific anatomic structures (e.g., hippocampus vs. neocortex) or even to specific subregions (e.g., CA1 vs. CA3). It is increasingly apparent that this specificity extends to the level of individual cells (e.g., principal cells vs. interneurons), an observation with important implications. Aβ-induced activation of a neurotransmitter receptor on an excitatory principal neuron might result in overexcitation of its circuit, whereas activating the same receptor on inhibitory interneurons could shut the network down, (Palop et al., 2006) (**Figure 19**). Even at the molecular level, AD-related changes can be quite specific; among the important neurotrophic factors, BDNF seems to play an important role in AD, whereas in NT3 does not appear to be involved (Hock et al., 2000).

Finally, there is at least one great boon to the long list of molecules involved in AD: a surfeit of potential targets for treating the disease. Indeed, treatments aimed at many of the molecules discussed here are now in trials for AD (Jacobsen et al., 2005; Roberson and Mucke, 2006). In terms of the AD-associated molecules in the section titled 'Memory impairment by AD-related molecules,' diverse approaches are under study, including (1) reducing the production or speeding the removal of potentially toxic proteins, for example, with β- or γ-secretase inhibitors or via immune-mediated clearance (Citron, 2004; Weiner and Frenkel, 2006); (2) preventing unwanted post-translational processing or aggregation of Aβ, tau, and apoE into particularly toxic forms (Harris et al., 2003; Khlistunova et al., 2006; McLaurin et al., 2006); (3) restoring normal functions lost by AD-related modifications, such as the microtubule-stabilizing effect of tau (Zhang et al., 2005); and (4) in the case of apoE, forcing apoE4 to adopt more apoE3-like structure and function (Mahley et al., 2006). The plasticity-related molecules highlighted in the section titled 'Memory-related molecules in AD' may provide good complementary targets. Here, the goal is to restore plasticity, boost related memory mechanisms, and protect neurons against aberrant network

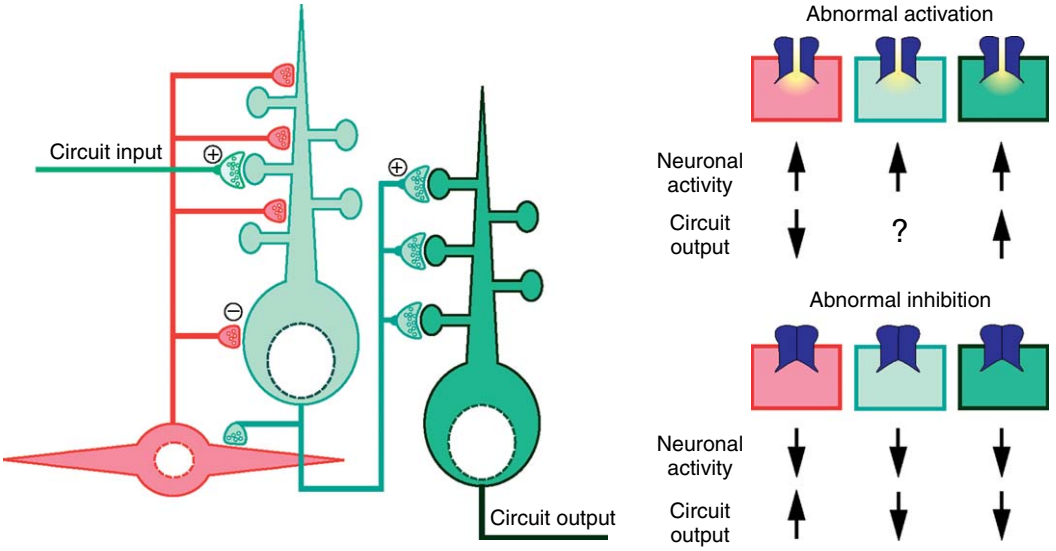

Figure 19 Consequences of the same molecular process on different cell types. The same molecular process can have a very different effect on circuit output depending on whether the cell it affects is an excitatory principal neuron (shades of green) or an inhibitory interneuron (red). Abnormal activation of an excitatory principal neuron will lead to overexcitation of the circuit, whereas abnormal activation of an inhibitory interneuron will shut the circuit down.

activities, even in the presence of pathogenic protein assemblies (Palop et al., 2006).

Thus, while complexity is certainly a feature of our current molecular understanding of AD, such issues pose exciting opportunities for neuroscientists working at the interface between AD and plasticity research, which is rapidly becoming one of the most active fronts in the battle against AD.
